(Dated: 24 juin 2007)

We study experimentally the slow growth of a single crack in polycarbonate films submitted to uniaxial and constant imposed stress. For this visco-plastic material, we uncover a dynamical law that describes the dependence of the instantaneous crack velocity with experimental parameters. The law involves a Dugdale-Barenblatt static description of crack tip plastic zones associated to an Eyring's law and an empirical dependence with the crack length that may come from a residual elastic field.

PACS numbers: 62.20.Mk, 62.20.Fe, 46.35.+z

Stressed solids commonly break apart once a critical stress threshold is reached. However, many experiments [1, 2, 3, 4, 5] show that a given solid submitted to a subcritical stress breaks after a certain amount of time. Therefore, understanding the mechanisms of subcritical rupture of solids has become an important goal of fracture physics in order to improve the resistance of structures to delayed failure that may have catastrophic consequences. According to reported experimental works [1, 2], the dependence of the rupture time with applied stress σ can be described in many kinds of materials (polymers, metal alloys, semi-conductors, rocks...) by an Arrhenius law with an energy barrier decreasing linearly with σ . This proposed universality is disturbing since these materials have micro-structures and rheological properties very different from one another, and the rupture dynamics is certainly expected to be dependent on those properties. To lift this paradox, one must go beyond characterization of global properties such as rupture time and instead study experimentally the full time-resolved rupture dynamics, from the stress application to the final breakdown of the sample. A convenient system to start with is a two-dimensional solid with a single macroscopic initial crack submitted to a uniaxial constant load.

In this context, recent experimental studies [5] have shown that subcritical crack growth in paper sheets can be successfully described by a thermally activated mechanism inspired from previous theoretical works in elastic brittle media [6, 7]. Experimental study of slow crack growth in a visco-plastic material under stress is a very active topic [8]. General theoretical frameworks [9, 10, 11] have been proposed to predict the dependence of the crack growth velocity with experimental parameters using characteristic material time-response functions such as its compliance. However, these models involve complex integro-differential equations which are hardly tractable in practical situations where visco-plastic effects are strong. Consequently, the experimental time evolution of the *instantaneous* crack growth dynamics can not be captured easily by current models.

In order to provide more experimental insight in our

FIG. 1 – Image of a crack in a polycarbonate film with its macroscopic plastic zone at each tip.

understanding of visco-plastic effects during slow crack growth, we have performed an experimental study of the slow growth of a single crack in amorphous polymer films made of polycarbonate which is a highly non-brittle visco-plastic material. The experiments consist in the growth of a single linear crack in a polycarbonate film submitted to uniaxial and constant imposed force. The polycarbonate films used are Bayer Makrofol[®] DE and have the properties of bulk material. Before each experiment, a crack of length ℓ_i (from 0.5 to 3cm) is initiated at the center of the polycarbonate sample (height 21cm, length 24cm). Then, a constant force F is applied to the film perpendicularly to the crack direction, so that we get a mode I crack opening configuration. Using a camera, we follow the growth of the crack length ℓ under constant applied stress $\sigma = F/eH$ (e is the film thickness and H the sample height) until the total rupture of the sample. The applied stress σ is chosen such that crack growth is slow, i.e. smaller than a critical one σ_c , above which crack propagation occurs in a few seconds. More details about the experimental set-up can be found in [12].

In each crack growth experiment, during the loading phase of the film, a macroscopic flame-shaped plastic zone appears at each tip of the crack [13] and grows with the applied stress (cf. Fig. 1 where is defined the plastic zone length from tip to tip ℓ_{pz}). In the late loading stage, the crack may also start to grow at a time that appears to be statistical. It is probably a consequence of the dispersion in the local toughness of the material or in the initial crack tip shape. Consequently, the real experimental initial condition, obtained when the constant stress σ

is reached, is not exactly $\ell = \ell_i$. Depending on the moment when the crack starts to grow during the loading phase, the true initial condition of the creep experiment will be a couple of value for the crack and plastic zone length (Fig. 1) : (ℓ^*, ℓ_{pz}^*) . Finally, during the imposed stress stage, the plastic zones and the crack are both growing until the final breakdown of the sample in a way that the crack never catches up the plastic zone tip. Inside the plastic zone, the film is subjected to a thinning which brings its thickness from $125\mu\text{m}$ to about $75\pm 5\mu\text{m}$.

FIG. 2 – Time as a function of both the crack and process zone lengths for an imposed stress experiment ($\ell_i = 1.5\text{cm}$, $F = 900\text{N}$). We indicate the position of the inflexion point t_x , ℓ_x of the crack growth curve.

Typical growth curves of the fracture and plastic zone are shown in Fig. 2. Both curves show a quite similar smooth shape. This regular shape lets us think that the crack growth in polycarbonate films is a deterministic phenomenon. However, for identical experimental conditions, we notice a large dispersion of the rupture times and more generally of the crack growth dynamics. There is actually up to a factor five between the rupture time of the fastest and slowest experiments. We suggest that the explanation for this statistics in the crack growth dynamics does not come from the growth mechanism itself, but is a consequence of the dispersion in the effective initial conditions at the beginning of the constant stress phase of the experiment (ℓ^* , ℓ_{pz}^*). These initial conditions are clearly statistical and hardly controllable in our experiment. They are dependent on the moment when the crack starts growing during the loading stage of the sample and they determine all the rest of the experiment.

In Fig. 3, we show the evolution of the average rupture time $\langle T_r \rangle$ (averaged over at least ten experiments) as a function of the applied stress for a series of experiments performed at $\ell_i = 1.5\text{cm}$. We see a linear dependence of $\log\langle T_r \rangle$ with the applied stress that corresponds well to an exponential description of the rupture time as proposed by Zhurkov [1]. The linear fit of the data is of quite good quality and suggests that $\langle T_r \rangle = T_0 e^{-a\sigma}$. In Zhurkov's approach, the stress dependence of $\langle T_r \rangle$ is interpreted as an Eyring's law [14] with $a = V/k_B T$ where

FIG. 3 – Natural logarithm of the average rupture time as a function of the applied stress for a series of experiments performed for $\ell_i = 1.5\text{cm}$.

V is assumed to be a characteristic volume of the material. However, in our experiments, the parameter V can not be a constant since a different initial crack length ℓ_i gives a completely different rupture time for the same applied stress. Thus, the external applied stress σ can not be the single control parameter of the rupture dynamics. Then, it is clear that Zhurkov's description needs to be improved to take into account the specific geometry of the problem. In particular, the stress σ_y holding in the plastic zone close to the crack tips most probably participates in the dynamical processes leading to the crack growth.

The Dugdale-Barenblatt cohesive zone model [15, 16] is a good and simple mean to estimate the stress σ_y . This quantity appears intuitively as a possible control parameter for the crack dynamics just like the stress intensity factor is for brittle materials. Dugdale-Barenblatt model predicts :

$$\sigma_y = \frac{\pi}{2} \frac{\sigma}{\arcsin\left(\frac{\ell}{\ell_{pz}}\right)}. \quad (1)$$

This plastic stress σ_y can be computed at each moment using Eq. (1) with the instantaneous values of σ , ℓ and ℓ_{pz} . To account for the global dynamics during an experiment, we compute the time-averaged growth velocity on the whole experiment \bar{v} and compare it to the time-averaged plastic stress $\overline{\sigma_y}$ (see Fig. 4). Each point of this Figure represents the mean behaviour over an experiment. The data are compatible with a linear law that predicts an exponential dependence of the average growth velocity with the mean stress in the plastic zone :

$$\bar{v} = v_0 e^{a\overline{\sigma_y}} \quad (2)$$

with $a = 6.3 \cdot 10^{-7} \text{m}^2 \cdot \text{N}^{-1}$ and $v_0 = 7.8 \cdot 10^{-21} \text{m} \cdot \text{s}^{-1}$.

It is striking that the prefactor of the stress in the exponential curve (cf. Eq. (2)) is close quantitatively to the one obtained in the Eyring's law for the polycarbonate creep [12]. Both prefactors probably correspond to

FIG. 4 – Natural logarithm of the average crack growth velocity \bar{v} as a function of the average plastic stress during the growth. Each point represents the average dynamical behavior during an experiment. Experimental conditions are various ($\ell_i = 1.5, 2, 3\text{cm}$ and $2.9 < \sigma < 3.8 \cdot 10^7 \text{N.m}^{-2}$). Each experimental condition corresponds to different symbols.

a unique material constant $V/k_B T$. Thus, we can conclude that the Eyring's law plays a central role in the mechanisms of crack growth in polycarbonate films.

We now go beyond a simple analysis of the average growth dynamics by looking at the dependence of the crack velocity with the stress in the plastic zone at each time during the crack growth. We plot in Fig. 5(a) the instantaneous crack velocity $v = dl/dt$ as a function of the instantaneous value of the Dugdale-Barenblatt stress σ_y for height experiments performed with various experimental conditions. Here, the description of the instantaneous velocity by an exponential law fails, especially when the crack length becomes larger than ℓ_x at which the minimum crack velocity is reached (ℓ_x is also the inflexion point of the growth curve in Fig. 2). In fact, the Eyring's law given by Eq. (2) describes well the behaviour only when $\ell \simeq \ell_x$. We discovered that introducing a correction to σ_y linear with the crack length ℓ allows us to collapse the experimental data on a straight line (cf. Fig. 5(b)). This correction can be written as :

$$\sigma_y^{\text{corr}} = \frac{\pi}{2} \frac{\sigma}{\arcsin\left(\frac{\ell}{\ell_{pz}}\right)} + \kappa(\ell - \ell_x). \quad (3)$$

For each experiment, we determine the value $\kappa = (3.4 \pm 0.6) \cdot 10^8 \text{N.m}^{-3}$. The dispersion of κ values seems to be statistical as no systematic dependence with σ or ℓ_i could be found. This rescaling means that the crack growth velocity seems to follow :

$$\frac{d\ell}{dt} = v_0 e^{\frac{V}{k_B T} \sigma_y^{\text{corr}}}. \quad (4)$$

The collapse of the data for various experimental conditions means that v_0 can be considered as a constant.

In Eq. (3), the crack length at the inflexion point in the growth curve plays a particular role. It turns out that

FIG. 5 – Natural logarithm of the instantaneous crack growth velocity as a function of (a) the Dugdale-Barenblatt stress, (b) the corrected Dugdale-Barenblatt stress σ_y^{corr} according to Eq. (3) for height experiments performed with various experimental conditions ($\ell_i = 1.5, 2, 3\text{cm}$ and $2.9 < \sigma < 3.8 \cdot 10^7 \text{N.m}^{-2}$). In Fig. (b), the black line is the result of a linear data fit.

its value depends on the experimental conditions. This can be seen in Fig. 6(a) where the product $\kappa \ell_x$, with $\kappa = 3.4 \cdot 10^8 \text{N.m}^{-3}$, is plotted as a function of the applied stress σ . Remarkably, the dependence of $\kappa \ell_x$ with σ is well approximated by a linear relation : $\kappa \ell_x = \sigma_x - \sigma$, where $\sigma_x = 4.2 \cdot 10^7 \text{N.m}^{-2}$.

A way to clarify the meaning of this relation is to look at the dependence of the critical stress σ_c needed to break instantaneously a sample with a crack of initial length ℓ_i . In brittle materials, we would expect this critical stress to decrease in $1/\sqrt{\ell_i}$ since the rupture criterion is reached when the initial stress intensity factor equals the toughness of the material K_c [5] : $\sigma_c \sqrt{\pi \ell_i / 2} = K_c$. For an amorphous visco-plastic material such as polycarbonate, we do not get the same functional dependence. Indeed, as we can see in Fig. 6(b), the relation between σ_c and ℓ_i can be approximated by a linear equation : $\beta \ell_i = \sigma_s - \sigma_c$, where $\sigma_s = 4.07 \cdot 10^7 \text{N.m}^{-2}$ and $\beta = 3.57 \cdot 10^8 \text{N.m}^{-3}$. We note that $\kappa \simeq \beta$ and $\sigma_x \simeq \sigma_s$ and will consider these quantities to be the same material constants. So, we find that the quantity $\Sigma(\sigma_c, \ell_i) = \sigma_c + \kappa \ell_i$ may play a similar role than the initial stress intensity factor in brittle materials. Furthermore, it allows us to interpret the value

FIG. 6 – (a) $\kappa \ell_x$ for various experimental conditions ($\ell_i = 1.5, 2, 3\text{cm}$ and $2.9 < \sigma < 3.8 \cdot 10^7 \text{N.m}^{-2}$) as a function of the applied stress σ . (b) Critical rupture stress σ_c as a function of the initial crack length ℓ_i . The dotted lines are a linear fit of the data.

of the crack length at the inflexion point as defined by a characteristic value of the quantity $\Sigma(\sigma, \ell_x) = \sigma_x \simeq \sigma_s$ that corresponds to an intrinsic property of polycarbonate. Indeed, σ_s corresponds to the rupture threshold σ_c in the limit when there is no initial crack.

According to the previous analysis of the instantaneous crack velocity, crack growth in polycarbonate films appears to be ruled, during an experiment, by an Eyring's law (cf. Eq (4)) with :

$$\sigma_y^{\text{corr}} = \frac{\pi}{2} \frac{\sigma}{\arcsin\left(\frac{\ell}{\ell_{\text{pz}}}\right)} + \kappa \ell + \sigma - \sigma_s \quad (5)$$

This effective stress σ_y^{corr} is composed of the Dugdale-Barenblatt estimation of the crack tip plastic zone stress σ_y , a linear dependence with the crack length $\kappa \ell$ and the applied stress at the borders of the sample σ . Note that in Eq. (4) appears naturally a volume $V \simeq 2.8 \cdot 10^{-27} \text{m}^3$ close to the one used to describe the simple creep flow of polycarbonate ($3.1 \cdot 10^{-27} \text{N.m}^{-2}$) as well as the growth of a necking instability in polycarbonate films ($3.0 \cdot 10^{-27} \text{m}^3$). This observation reinforces the idea that the Eyring's law for crack growth is truly a consequence of the creep behavior of polycarbonate.

In Eq. (5), the viscous relaxation is taken into account by the experimentally measured evolution of the ratio ℓ/ℓ_{pz} as the crack grows. Indeed, if this ratio was con-

stant, the stress in the plastic zone would also be constant and the velocity would increase monotonously due to the linear term in crack length. In that case, the behavior would actually be qualitatively the same as the one for crack growth in brittle fracture [5]. To predict fully the *viscous* dynamics of the crack, we need a second equation that will prescribe ℓ_{pz} :

$$\frac{d\ell_{\text{pz}}}{dt} = f(\ell_{\text{pz}}, \ell, \dot{\ell}, \sigma, \dots) \quad (6)$$

An original theoretical approach recently developed by Bouchbinder [17] in extension to the Shear-Transformation-Zone Theory proposed by Falk and Langer [18] is certainly useful for deriving an equation of the plastic zone velocity (cf. Eq. (6)). Additionally, numerical simulations that can reproduce the complex visco-plastic behavior of polycarbonate may help in going further in the interpretation of our experimental results [19, 20, 21].
