<u>Résumé</u> - Une couche mince de métal est déposée sur la face la plus longue d'un prisme rectangulaire d'indice n_0 . Cette couche est recouverte par un film mince transparent de liquide du même indice n_0 , puis est prise en "sandwich" en plaçant par-dessus un autre prisme identique au premier. On détermine ainsi le rapport des amplitudes complexes transmises, en polarisation p et s, par le film qui est ainsi "suspendu" dans un milieu uniforme d'indice n_0 , ce qui permet d'évaluer les constantes optiques de ce film.

<u>Abstract</u> - The metal film is deposited on the longer face of a rectangular prism of index n_0 . The film is covered by a thin, transparent liquid film of index n_0 , and is sandwiched by placing another, identical prism on top of it. The ratio in complex amplitude transmissivity for the p- and s-polarized light of the film thus optically "suspended" in a uniform medium of index n_0 is determined, from which the optical constants of the film are evaluated.

§1. Introduction

The idea of the immersion-type transmission ellipsometry (ITE) described here was born when we were searching for an efficient method for the study of the optical properties of vacuum-deposited metal films in their earliest growth stages. The orthodox spectral adsorption measurement is hardly feasible with such films that are almost transparent: these "films" consists of separate atom clusters a few tenths to a few nanometers in diameter scattered over the substrate surface. We had found that reflection ellipsometry (RE) was a useful means for the study of such films /1/, but the uncertainties in interpreting its data drove us to the search for an independent method that compared with it. ITE was our first choice.

In ITE, the film is deposited on a transparent substrate of index n_0 , the space above the films is filled with a material of the same index, and the ratio in amplitude transmissivity of the p- and s-polarized light at an angle of incidence ϕ , \tilde{t}_p/\tilde{t}_s , is determined for the film thus optically "suspended" in a uniform medium of index n_0 . Let us write

$$\tilde{t}_{\rm p}/\tilde{t}_{\rm S}$$
 = tan $\Psi_{\rm t} \cdot \exp(i\Delta_{\rm t})$ (1)

after the usual expression $\tilde{r}_{p}/\tilde{r}_{s}$ = tan $\Psi \cdot \exp(i\Delta)$. We can easily derive that, under conditions given above,

$$\tan \Psi_{t} \exp(i\Delta_{t}) = \frac{1 - \tilde{r}_{p}^{2}}{1 - \tilde{r}_{s}^{2}} \cdot \frac{1 - \tilde{r}_{s}^{2} \exp(i2\beta)}{1 - \tilde{r}_{p}^{2} \exp(i2\beta)}$$
(2)

Here

$$\beta = -2\pi (d/\lambda) \left(\tilde{n}^2 - n_0^2 \sin^2 \phi \right)^{\frac{1}{2}} , \qquad (3)$$

C10-384

 \tilde{r}_{p} and \tilde{r}_{s} are the Fresnel coefficients at the two film surface, and d and $\tilde{n} = n$ - ik are the thickness and complex refractive index of the film respectively. Since eq.(2) is an equation of the first degree with respect of $\exp(i2\beta)$, the evaluation of n is much simpler in ITE than in conventional RE, as will be seen in §3.

To realize the situation described above experimentally, it is convenient to deposit the film on a rectangular prism of index n_0 , lay a small drop of transparent liquid of index n_0 on the film, and place another, identical prism on top of it (see S in Fig. 1). The space between the metal film and the second prism is thus filled with a very thin liquid film of index n_0 .

Some details of our experimental procedure are given in \$2. Preliminary results with Au films are given in \$3, and are discussed in \$4 together with some open questions concerning the permeation of the matched-index liquid into the granular metal film.

§2. Experimental Procedure

Figure 1 shows schematically the extinction type ellipsometer for use in ITE. Up to now, most measurements have been carried out with He-Ne laser light.

Fig.1 - Optical system for ITE. P, A: Glan-Thompson prisms. C: $\lambda/4$ -plate S: sample complex (see §1).

Fig.2 - Metal films deposited on prism face.

vacuum-deposited on the longer face of a glass rectangular prism of index $n_0 = 1.515$ (Fig. 2). In some cases, Δ and Ψ were determined for each film by a reflection ellipsometer /1/ before breaking the vacuum (stage A). After breaking the vacuum, the metal films were sandwiched between the prisms, together with the matched-index liquid, as was described in §1. The liquid was prepared by mixing silicone oils HIVAC F-4 and KF-54 (Shin-Etsu Chemical Co., Ltd.) so that its index was equal to 1.515 \pm 0.001 at 20°C (the temperature coefficient

Three pieces of film, usually of different thicknesseswere

is-5 x $10^{-4}/^\circ\text{C})$. The measurement of ${\rm \Delta}_t$ and Ψ_t was first

carried out immediately after sandwiching the film (within 30 minutes) when the

liquid did not seem to have started permeation into the metal films (Stage B). The measurement was repeated after the granular metal films had been completely permeated by the liquid (Stage C). All these ITE measurements were made keeping the sample complex S (Fig. 1) at 20°C.

The permeation started at the periphery of the film and proceeded toward the centre. The permeated region could easily be distinguished by a marked reduction in reflectivity. The boundary line between the permeated and unpermeated regions was quite distinct. It took a few weeks for the film to be completely permeated.

§3. Preliminary Results with Au Films

Figure 3 shows the changes in Δ_t and Ψ_t with the film thickness *d*. Curves B_1 and C_1 represent the observations at stages B and C respectively

Fig. 3-See text for detail.

for Au films evaporated in an oil-diffusion-pumped system (10^{-3} Pa). Curve B₂ has tentatively been drawn through points a, b and c that represent the observations at stage B for three Au films evaporated in an ion-pumped system (10^{-5} Pa). The (Δ_t , Ψ_t) values for these films at stage C are given by points a', b' and c'.

The parameters $\tilde{n} = n - ik$ and d of the *effective film*, or the hypothetical homogeneous film optically equivalent to the two-dimensional array of Au particles, can be evaluated as follows. First we substitute the observed values of Δ_t and Ψ_t into eq.(2), and solve it for exp($i2\beta$). If we raise the obtained expression for exp($i2\beta$) to the $(2\pi d/\lambda\beta)$ -th power, we obtain an equation of the form

$$\exp(i4\pi d/\lambda) = f(\tilde{n}, n_0, \Delta_t, \Psi_t) , \qquad (4)$$

from which it follows that

$$|f(\tilde{n}, n_0, \Delta_t, \Psi_t)|^2 = 1.$$
(5)

Equation (4) determines a curve on the n-k plane for each pair of observed values of Δ_t and Ψ_t . Each point on the curve corresponds to a value of d that can be calculated according to eq.(4).

Fig.4- Projected loci of the possible (n, k, d) combinations for some data points in Fig. 3.

In Fig. 4, the solid curves represent the n-k curves for points a, b and c (stage B), and the broken ones those for points a', b' and c' (stage C). The chain lines give the values of n and kfor the three films at stage A (before breaking the vacuum) that have been calculated from the values of Δ and Ψ obtained by in-situ reflection ellipsometry.

§4. Discussion

Before starting the experiment, we did not expect that the permeation of the matched-index liquid into granular metal films with thicknesses of the order of nanometers would take a few weeks. This, in itself, is an interesting problem in surface physics, but at the moment we will concentrate on the interpretation of the ellipsometric data.

points in Fig. 3. Let us suppose that at stage B there was empty space between the substrate and the liquid surface, the latter being in direct contact only with the top surfaces of the metal particles, whereas at stage C the entire space between the particles was completely filled with the liquid. If we apply the Bruggeman EMA theory /2/ to these models, we have

$$(1 - q) \frac{1 - \tilde{n}_{\rm B}^2}{1 + 2\tilde{n}_{\rm B}^2} + q \frac{\tilde{N}^2 - \tilde{n}_{\rm B}^2}{\tilde{N}^2 + 2\tilde{n}_{\rm B}^2} = 0$$
(5)

for stage B, and

$$(1 - q) \frac{1.515^2 - \tilde{n}_{\rm C}^2}{1.515^2 + 2\tilde{n}_{\rm C}^2} + q \frac{\tilde{N}^2 - \tilde{n}_{\rm C}^2}{\tilde{N}^2 + 2\tilde{n}_{\rm C}^2} = 0$$
(6)

for stage C, where $\tilde{n}_{\rm B}$ and $\tilde{n}_{\rm C}$ are the refractive indices of the effective film at respective stages, \tilde{N} is the refractive index of the metal particles, and q is the filling factor. Substituting a wide range of values of $\tilde{n}_{\rm B}$ and $\tilde{n}_{\rm C}$ (Fig. 4) that correspond to point b in Fig. 3 into eqs.(5) and (6), we searched for the solutions q and \tilde{N} that satisfy the conditions

$$I_m(q) = 0, \ 0 < q < 1; \ \text{Re}(\tilde{N}) > 0, \ I_m(\tilde{N}) \le 0$$
 (7)

No such solutions were obtainable as far as we assumed that the effective film thickness d at stage C, $d_{\rm C}$, was identical with that at stage B, $d_{\rm R}$.

It would be more natural, however, to assume that d changes with the liquid permeation. Accordingly, we chose a thickness $d_{\rm B}$ on the *n-k* curve for b in Fig. 4 which was compatible with the mass thickness $d_{\rm m}$ of this film (1.2 nm), and searched for the value of $d_{\rm C}$ on the curve for b' which, combined with the assumed value of $d_{\rm B}$, can give q and $\tilde{\mathcal{N}}$ satisfying the conditions (7). Repeating such calculations, we were able to find a range of plausible solutions. A typical set of such solutions are:

$$d_{\rm R} = 4.0 \text{ nm}, d_{\rm C} = 2.0 \text{ nm}, q = 0.33, \tilde{N} = 0.6 - 17i$$

The range of $d_{\rm B}$ that can give meaningful solutions for this particular film is 3-5 nm. Any value of $d_{\rm B}$ in this range gave $q \approx 0.33$ The value q estimated from the electron micrograph of this film (Fig. 5) on the assumption that the particles were hemicylindrical was 0.36.

Thus we conclude that (1)just after the metal film has been sandwitched with the matched-index liquid there remains empty space between the substrate and the liquid surface, and (2) when completely permeated by the liquid the effective film thickness is reduced to about one half of its original value.
