Abstract. The shallow mixing depth and vertical stratification of the lowest levels of the atmosphere at night has implications for the chemistry of nitrogen oxides emitted from the surface. Here we report vertical profiles of NO_3 , N_2O_5 and O_3 measured from in-situ instruments on a movable carriage on a 300 m tower. The study offers high-resolution (<1 m) vertical distributions of both NO_3 and N_2O_5 and shows that the nocturnal mixing ratios of these compounds vary widely over short vertical distance scales (10 m or less). Furthermore, there are systematic differences in the steady state lifetimes of NO_3 and N_2O_5 and in the partitioning among nitrogen oxides between different near-surface layers. These differences imply that NO_3 and N_2O_5 occupy distinct chemical regimes as a function of altitude, potentially serving as sinks for nitrogen oxides and O_3 near the surface but as reservoirs of NO_x and O_3 aloft.

1 Introduction

Atmospheric nitrogen oxide chemistry near the Earth's surface is strongly linked to the dynamics of the planetary boundary layer. During the day, the typical depth of a summertime convective boundary layer is on the order of 1.5 km, although the depth and the efficiency of mixing may vary (Stull, 1988). Daytime surface emission of NO_x (= the sum of NO and NO_2 , but emitted mainly as NO) are mixed to the boundary layer depth and enter into the well-known catalytic cycle that generates photochemical ozone pollution (Chameides, 1978). By contrast, the nocturnal boundary layer has a depth of order 0.1 km and is less efficiently mixed. As a result, nocturnal NO_x emissions tend to be more concentrated and vertically stratified than daytime emissions. The stratification is coupled to a shift in nitrogen oxide chemistry; at

night, NO_x is oxidized in the presence of excess ozone to the nocturnal nitrogen oxides, NO_3 (the nitrate radical) and N_2O_5 (dinitrogen pentoxide), which may serve either as reactive intermediates that convert NO_x to nitric acid and other products (Richards, 1983) or as nocturnal reservoirs of NO_x and O_3 (Perner et al., 1985; Brown et al., 2006). Because both the sources and the sinks for NO_3 and N_2O_5 can be spatially stratified, their mixing ratios, and their influence on nitrogen oxide and ozone transport and loss at night, can show large variability as a function of height above the surface.

Because of this nocturnal atmospheric chemical – dynamical coupling, the vertical distribution of nitrogen oxide species at night, particularly NO_3 , has been a topic of considerable recent interest. Modeling studies have consistently suggested strong vertical gradients of NO_3 and N_2O_5 within the nocturnal boundary layer (Fish et al., 1999; Galmarini et al., 1997; Geyer and Stutz, 2004a, b; Riemer et al., 2003). Experimental studies with sufficient resolution to confirm these predictions have been sparse, however. Vertical profiles of NO_3 in the troposphere have been retrieved from the time dependence of the NO_3 absorption spectrum in a slant column of scattered sunlight at sunrise, as solar photolysis removes NO_3 radicals to progressively lower altitudes (Aliwell and Jones, 1998; Allan et al., 2002; Coe et al., 2002; Saiz-Lopez et al., 2006; Smith and Solomon, 1990; Smith et al., 1993; von Friedeburg et al., 2002; Weaver et al., 1996). Aside from the work of von Friedeburg et al. (2002) this method has typically had insufficient resolution to determine profiles within the boundary layer, although it has commonly been used to determine total boundary layer column absorptions. Broadband lidar measurements have also been used to measure the total column abundance of NO_3 within the boundary layer (Povey et al., 1998). Both of these approaches have shown average boundary layer concentrations of several hundred pptv of NO_3 , well in excess of typical surface-level NO_3 mixing ratios. Stutz and coworkers (Stutz et al., 2004; Wang et al., 2006) have more recently achieved

a resolution of several tens of meters within the boundary layer for continuous measurements of NO₃, NO₂, O₃ and other trace gases throughout the night via multiple long path differential optical absorption spectrometers (DOAS) aligned over several fixed slant paths between 0–140 m. These measurements have shown significant gradients in NO₃ within the nocturnal boundary layer.

This paper presents results from a study of the vertical distribution of the nocturnal nitrogen oxides, NO₃ and N₂O₅, at high spatial resolution (<1 m) within and above the nocturnal boundary layer. Mixing ratios of both NO₃ and N₂O₅ were measured in-situ from an instrument mounted on a movable carriage on a 300 m tower. Although this study is rather limited in scope, encompassing only a single night in October 2004 with a limited set of ancillary data, it is unique both because of its high vertical resolution and because of the direct measurement of N₂O₅ vertical profiles. The ability to independently measure N₂O₅ can be important, not only because of its much larger mixing ratio relative to NO₃ in high NO_x and/or cold environments, but also because of its non-linear dependence on NO₂, which can make its calculation from column measurements of NO₃ and NO₂ under conditions of high spatial variability potentially problematic. The study shows that NO₃, N₂O₅, NO₂ and O₃ are quite variable over short distance scales within the nocturnal boundary layer and that there are systematic and often sharp changes at the interface between the nocturnal boundary layer and the residual, daytime boundary layer above it. The results are broadly consistent with the expected behavior of NO₃ and N₂O₅ from previous experimental and theoretical studies, but

show that the detailed vertical profiles of these compounds, at least at this measurement site, can be quite complex.

2 Experimental

The measurements took place at the Boulder Atmospheric Observatory (BAO) (Hahn, 1981; Kaimal and Gaynor, 1983; Vanvalin and Ganor, 1987) located in Erie, CO, USA on the night of 4–5 October 2004. Figure 1 is a map of the Boulder/Denver area showing the location of the observatory in relation to these cities (Boulder 25 km to the West, Denver 35 km to the South). The site is in an area of mixed rural/suburban development and is impacted by anthropogenic emissions from the broad urban and suburban area of Colorado's front range cities. The area immediately surrounding the observatory is grassland, and the closest large local emission sources include a landfill 3 km to the Southwest and a major highway (Interstate 25) 2 km to the East. The city of Erie, with its accompanying recent suburban development, is 3.5 km to the West.

The tower itself is 300 m in height, with its base at 1584 m above sea level. It has a motorized external carriage that can ascend or descend the tower at a rate of $\sim 0.6 \text{ m s}^{-1}$. The carriage can also be positioned indefinitely at an arbitrary height. The drive on the carriage is electric and does not produce emissions that we are aware of or that were detectable by the instruments during this study. There are meteorological stations at fixed heights of 10, 50, 100, 200 and 300 m, although not all of them were working properly at the time of this study.

In-situ measurements of NO₃ and N₂O₅ were carried out using an instrument based on cavity ring-down spectroscopy that had been designed for deployment on the NOAA P-3 aircraft (Dubé et al., 2006). This instrument had a time resolution of 1 s (vertical resolution of 0.6 m for this study), detection sensitivity of 0.4–2 pptv, and an accuracy of 25%, limited mainly by uncertainties in the inlet transmission efficiency of the two compounds. The instrument measures NO₃ by direct absorption at 662 nm (pulsed dye laser) in an ambient channel and the sum of NO₃ and N₂O₅ simultaneously in a second, heated channel using the same light source. The instrument was mounted directly to the carriage, with the air sample introduced through a 40 cm length of PFA Teflon tubing. Mixing ratios of O₃ were measured at lower time resolution (18 s) from the same inlet using a commercial O₃ monitor (total uncertainty = $2\% \pm 2$ ppbv). A thermocouple probe located at the tip of the inlet provided a continuous ambient temperature measurement. The mixing ratio of NO₂ was not measured, but may be calculated from the ratio of N₂O₅ to NO₃ and the ambient temperature.

$$[\text{NO}_2]_{\text{calc}} = \frac{[\text{N}_2\text{O}_5]}{K_{\text{eq}}(T) \times [\text{NO}_3]} \quad (1)$$

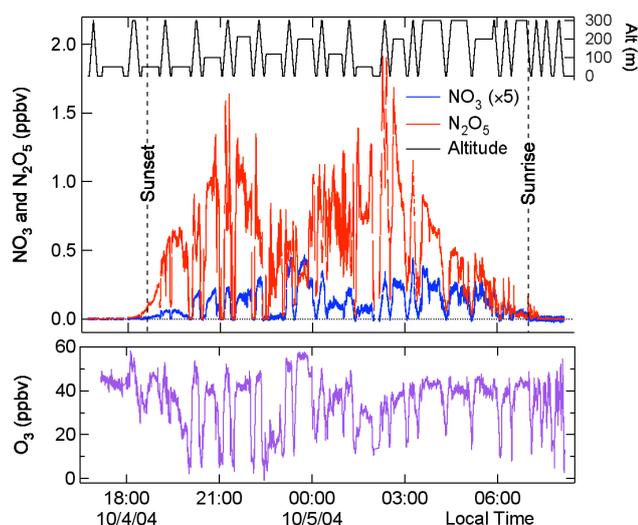

Fig. 2. Time series of the measured mixing ratios of NO₃ ($\times 5$), N₂O₅ (top graph) and ozone (bottom graph). The altitude derived from the pressure measurements appears above the top graph against the right axis. Approximate times of local sunrise and sunset (i.e., solar zenith angle = 90° at the surface) are marked.

Here $K_{\text{eq}}(T)$ is the temperature-dependent equilibrium constant for the reversible association of NO₂ with NO₃ to form N₂O₅, taken from the NASA/JPL recommendation (Sander et al., 2003). Previous field studies of this equilibrium in which all three components (i.e., NO₂, NO₃ and N₂O₅) were measured showed it to be in agreement with the calculated equilibrium to within 30% (Brown et al., 2003b); therefore, this is a reasonable estimate for the uncertainty of the calculated NO₂, with the exception of data for which the mixing ratio of NO₃ was small; no calculated NO₂ data are reported for an arbitrary threshold of NO₃ smaller than 3 pptv.

3 Results

The measurement period was from 16:40 on 4 October, or approximately 2 h prior to local sunset, to 08:10 on 5 October, approximately 1 h after local sunrise. Figure 2 shows a time series of the measured mixing ratios of NO₃, N₂O₅ and O₃, as well as the sample altitude. Peak mixing ratios of NO₃ and N₂O₅ were 90 pptv and 2 ppbv, respectively, but were uniformly smaller during periods when the carriage was at the bottom of the tower. Mixing ratios were larger earlier in the night under southerly flow than early in the morning, when the flow shifted to westerly. The available meteorological data at different, fixed heights appears in Fig. 3. There were a total of 37 individual vertical profiles (8–9 min each) that spanned the entire 300 m range of the tower and multiple shorter profiles spanning smaller ranges. Of the 37, 300 m profiles, 27 were during darkness (between sunrise and sunset). Figure 4 shows 30 of the profiles taken from just prior to

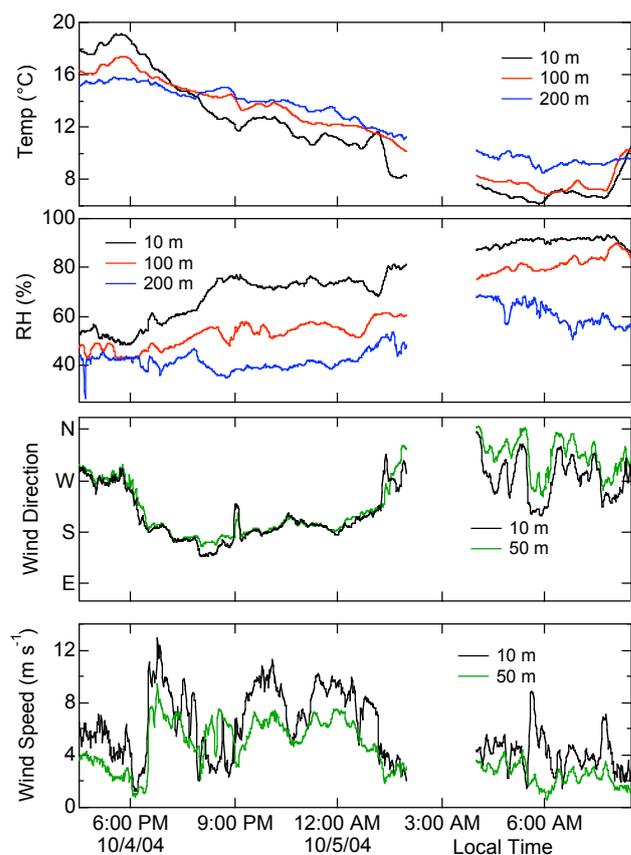

Fig. 3. Time series of meteorological data at fixed heights on the tower. Temperature and relative humidity were available from 10, 100 and 200 m, while wind direction and speed were available from 10 and 50 m only.

sunset until just after sunrise. There was considerable variability in both the overall concentrations of NO₃ and N₂O₅ between different profiles and in their distribution within individual profiles as a function of altitude. Variations between profiles were in some cases clearly evident even on vertical profiles taken only a few minutes apart. Nevertheless, many of the profiles fell into reasonably distinct categories with similar characteristics. The primary criterion for categorizing profiles was the vertical variation in potential temperature, Θ , which is an indicator of static stability and which was taken as a measure of the small-scale stratification and layering.

The observations frequently showed a three-layer structure, as shown in more detail Fig. 5. For purposes of this paper, we will use the following terms: the strongly stable layer extending from the surface to ~ 20 m will be called the “surface layer”. The statically stable layer above this, up to 100–150 m, is the “nocturnal boundary layer” (NBL). Atop this layer, we commonly observed an increase of stability over 10–20 m, which we will refer to as the “top of the nocturnal boundary layer”. Although this could be considered

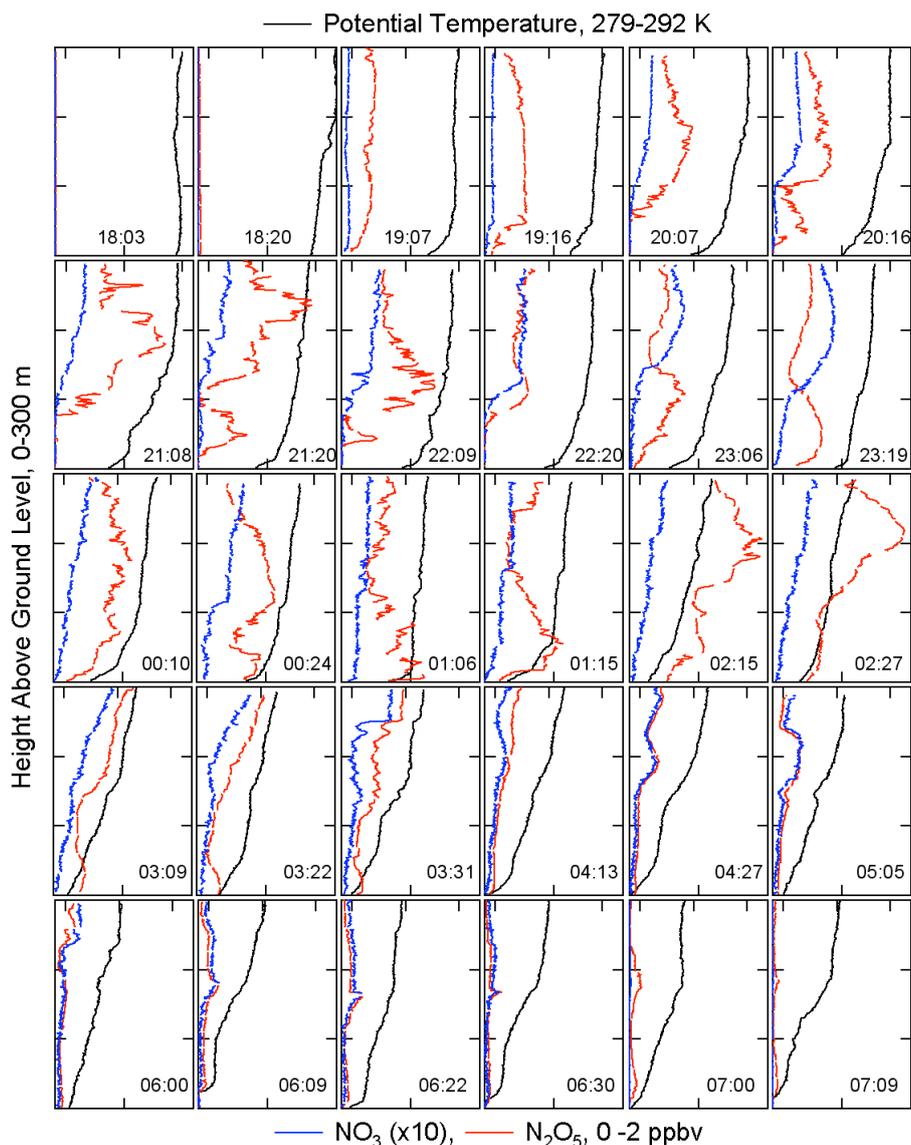

Fig. 4. Overview of 30 profiles from just prior to sunset to just after sunrise on 4–5 October. NO_3 (blue, multiplied by 10) and N_2O_5 (red) are shown against the bottom axis of each plot against a uniform scale from 0–2 ppbv. Potential temperature (black) is shown against the top axis of each plot on a uniform scale from 279–292 K. The left axes are altitude from 0–300 m. The time on each plot corresponds to the approximate midpoint of the profile.

a separate layer, the chemical observations (see below) indicated that this structure functioned as an interface. The uppermost layer, above ~ 150 m, is called the “residual layer” (i.e., the remnant of the deeper, well-mixed daytime boundary layer). In using this term, we presume that this layer had not been strongly affected by the surface since the previous afternoon.

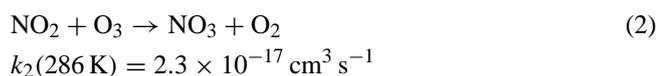

Each of the sections below contains a discussion of an example profile, and the last section discusses a composite profile made up of several individual profiles. The discussion here is largely qualitative; the limited set of measurements available for this pilot study does not allow for detailed anal-

ysis or modeling of the chemical sinks for NO_3 and N_2O_5 or their variation with altitude.

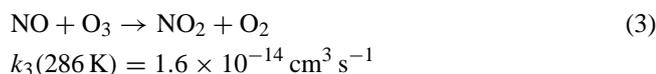

3.1 Example 1: three layer profile

An example of a three layer profile, taken during SSW flow, is shown in Fig. 6. The chemical measurements within this particular profile exhibited a smooth variation within each layer that correlated with the temperature variation in a well-defined manner. The left hand graph shows the vertical profile of the NO_3 and N_2O_5 mixing ratios and the potential temperature, Θ (top axis). The potential temperature profile and

layering is the same as that shown in Fig. 5, with a stable surface layer extending to 10–20 m and an NBL extending to 120 m. The mixing ratio of N₂O₅ decreased rapidly toward the ground within the surface layer, consistent with a sink for NO₃ and N₂O₅ at the ground surface (see discussion below). Within the NBL, N₂O₅ concentrations peaked and then declined with increasing height, while NO₃ was relatively constant or slightly increasing. These changes imply a vertical gradient of decreasing NO₂, whose calculated values are shown in the center graph of Fig. 6. The vertical profiles in NO₃, N₂O₅ and calculated NO₂ were also consistent with the observed increase in O₃ with height within this layer, also shown in the center graph of Fig. 6. A decrease in NO₂ shifts the equilibrium between NO₃ and N₂O₅ in favor of NO₃ while at the same time decreasing the production rate for NO₃ from the reaction of NO₂ with O₃ (i.e., $k_2[\text{O}_3][\text{NO}_2]$ from Reaction 2, below). By contrast, the increasing O₃ concentration increases the source strength with height.

The rate coefficient (Sander et al., 2003) is given for the average temperature during darkness on 4–5 October. The inverse relationship between O₃ and NO₂ through the NBL is consistent with emission of NO_x near the surface and consequent titration of O₃ by reaction with NO.

The net increase in NO₂ toward the surface was approximately equal to the net decrease in O₃, implying that the mixing through the NBL is slow enough relative to the rate of NO_x emission to maintain a vertical gradient. Wang et al. (2006) have noted similar behavior in NO₂ and O₃ within the NBL.

The vertical gradients in the reactivity of NO₃ and N₂O₅ and the partitioning between the nitrogen oxide species can be seen in the right hand panel of Fig. 6. The steady state lifetimes of NO₃ and N₂O₅ are the ratios of their observed concentrations to their source strength (Platt et al., 1984; Heintz et al., 1996; Brown et al., 2003a).

$$\tau(\text{NO}_3) = \frac{[\text{NO}_3]}{k_2[\text{NO}_2][\text{O}_3]}; \quad \tau(\text{N}_2\text{O}_5) = \frac{[\text{N}_2\text{O}_5]}{k_2[\text{NO}_2][\text{O}_3]} \quad (4)$$

Under conditions where NO₃ and N₂O₅ achieve an approximate steady state between their source and their loss due to reactions of NO₃ with NO or VOC and/or heterogeneous hydrolysis of N₂O₅, these lifetimes are a measure of the reactivity of the sum of the two compounds. (Note that the lifetimes are not separable; sinks for NO₃ influence the lifetime of N₂O₅ and vice versa.) On this night, the time required for the NO₂-NO₃-N₂O₅ system to achieve steady state would have been slow (several hours or more) because of the relatively cool temperatures and the large amount of NO₂ near

the surface (Brown et al., 2003a). Furthermore, Geyer and Stutz (2004a) have argued that vertical transport and mixing of N₂O₅ in the presence of strong vertical gradients can also limit the applicability of steady-state lifetimes. The observed steady state lifetimes were therefore only approximate measures of NO₃ and N₂O₅ sinks, and were most likely a lower limit to the values that would have been achieved at longer times.

Qualitatively at least, the relative changes in lifetime with height in Fig. 6 are an indication that there was a distinct shift between two regimes in NO₃ and N₂O₅ reactivity occurring at the top of the NBL, with much shorter steady state lifetimes within the NBL than in the residual layer. The change occurred over a distance scale of only a few tens of meters. Lifetimes above the boundary layer were as long as 3 h for N₂O₅, and even this was likely a lower limit (see above). The much smaller lifetimes within the boundary layer were consistent with the co-emission of NO₃ and N₂O₅ sinks with the NO_x that was their source. For example, reactive VOC and aerosol emitted from surface sources are likely to be trapped below the nocturnal inversion. Based on the NO₃ and N₂O₅ lifetimes alone, it is not possible to determine which of the two possible loss pathways contributes more to the reactivity of the pair within the boundary layer. Potential loss processes for both are discussed further in Sect. 4.

The partitioning, F(NO_x), among the nitrogen oxides is a measure of the proportion of nitrogen oxide stored in the nocturnal reservoir of NO₃ and N₂O₅ (Brown et al., 2003b).

$$F(\text{NO}_x) = \frac{\text{NO}_3 + 2 \times \text{N}_2\text{O}_5}{\text{NO}_2 + \text{NO}_3 + 2 \times \text{N}_2\text{O}_5} \quad (5)$$

The variation of F(NO_x) with height in Fig. 6 (right hand graph, top axis) is consistent with the trends in lifetime in the same graph. Within the NBL, where the lifetimes suggest rapid sinks for NO₃ and N₂O₅, the partitioning was less than 10%, but increased steadily with height. Similar to the observed trend in lifetimes, a step increase occurred at the top of the NBL, with partitioning levels above reaching 35%. Under the assumption that there was no mixing of NO_x emission from the surface to the residual layer after sunset, numerical integration of NO₃ and N₂O₅ formation at 50 ppbv of O₃ indicates a maximum value for F(NO_x) (i.e., no loss of NO₃ or N₂O₅) of approximately 55%. The observed value of 35% shows that NO₃ and N₂O₅ aloft acted primarily as a reservoir for NO_x, and could be expected to store or transport a large fraction of the available NO_x until sunrise. Because of the lack of ancillary measurements, determination of the fate of the NO_x that was lost aloft is not possible (see discussion). For example, HNO₃ formed via N₂O₅ hydrolysis would most likely be lost to deposition after the breakup of the nocturnal boundary layer after sunrise, while organic nitrate formed from NO₃+VOC reactions would potentially be longer-lived. Within the boundary layer, the apparently faster reactivity of NO₃ and N₂O₅ inferred from the lifetimes, and the slower oxidation of NO₂ by the reduced O₃ level prevented storage

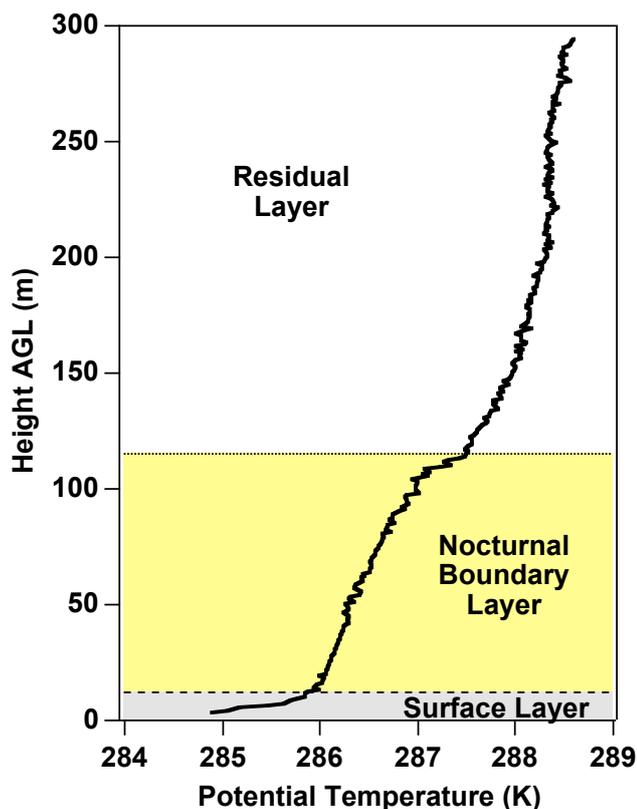

Fig. 5. Representative nocturnal potential temperature profile with labels for the most commonly observed layers, as described in the text.

of a significant fraction of NO_2 in the nocturnal nitrogen oxide reservoir. Within this layer, NO_3 and N_2O_5 appear to have served as sinks, rather than reservoirs, for NO_x .

3.2 Example 2: two layer profile

Although the surface layer was a common feature in many of the potential temperature profiles, it was absent in 6 of 12 profiles taken late in the night, between 02:30 and sunrise. In these profiles, the NBL extended continuously down to the lowest measurement height (3 m above ground). Figure 7 shows an example of one such profile. The only clear feature in the temperature profile was a layer of greater stability at 165 m, taken as the top of the NBL. Mixing ratios of NO_3 and N_2O_5 were somewhat variable within this layer, but were not clearly systematic with height. Within the residual layer, by contrast, both increased systematically with height. Profiles of calculated NO_2 and measured O_3 were similar to those seen in Fig. 6, showing increasing NO_2 and decreasing O_3 toward the surface within the NBL. The total amount of NO_x was smaller in this profile, consistent with a wind shift to the West and Northwest that took place later in the night. The trends in the steady state lifetimes and in partitioning in the right hand graph were similar to those in Fig. 6, with larger

values in the residual layer than in the boundary layer. However, the transition between the two regimes was much less abrupt. Above the boundary layer, the increase in lifetimes and partitioning was continuous, with a maximum $\tau(\text{N}_2\text{O}_5)$ of 5 h (likely a lower limit) and $F(\text{NO}_x)$ in excess of 40% at the maximum height of 300 m above ground. The partitioning value is slightly more than half of the maximum possible (see preceding section), calculated in this case to have been 70–75%. The upward trend with height suggests that above the tower these values may have continued to increase.

3.3 Example 3: multiple layer profile

The profiles in Figs. 6–7 show relatively smoothly varying changes in temperature and chemical composition with height. There were also several profiles in which this was not the case, as shown by the example in Fig. 8. This profile showed the same shallow surface layer seen in Fig. 6. In this case, however, there were at least two additional layers within the first 100 m above ground. The mixing ratio of N_2O_5 showed large spatial variability that correlated with the changes in the temperature profile. The N_2O_5 profile, and the NO_2 profile inferred from it, both indicate that there may have been additional layering correlated to some of the smaller features in the temperature profile (e.g., sharp spike near 140 m). The O_3 profile was also more variable below approximately 150 m than in the preceding examples, although the time resolution of this measurement was not sufficient to capture fine-scale structures correlated with the variations in N_2O_5 . The variable O_3 levels below 150 m and relatively constant O_3 levels above may indicate that this was the height to which surface emission had been recently mixed, even though the temperature profile did not show a clear stable layer at this point.

The lower time resolution of the O_3 measurement, and the lack of calculated NO_2 within the lowest part of the profile due to values of NO_3 below the detection limit (making the ratio of N_2O_5 to NO_3 unmeasurable), made it impossible to assess the correlation of the steady state lifetimes in the right hand graph with the temperature and chemical fluctuations seen in the other profiles. However, as with all of the preceding examples (and indeed, as with every profile for which lifetimes could be calculated), the lifetimes showed a clear increasing trend with height. Above 90 m in Fig. 8, the lifetimes appear to show a relatively smaller degree of layering and/or stratification than do the levels of NO_3 , N_2O_5 and NO_2 . This may imply that even though the NO_x occurred in relatively discrete layers, the sinks for NO_3 and N_2O_5 varied more smoothly with height above the surface.

3.4 Profile averages

The averages of the 23 individual profiles recorded between 19:00 (approximately 20 min after sunset) and 06:00 (approximately 1 h prior to sunrise) appear in Fig. 9. The two

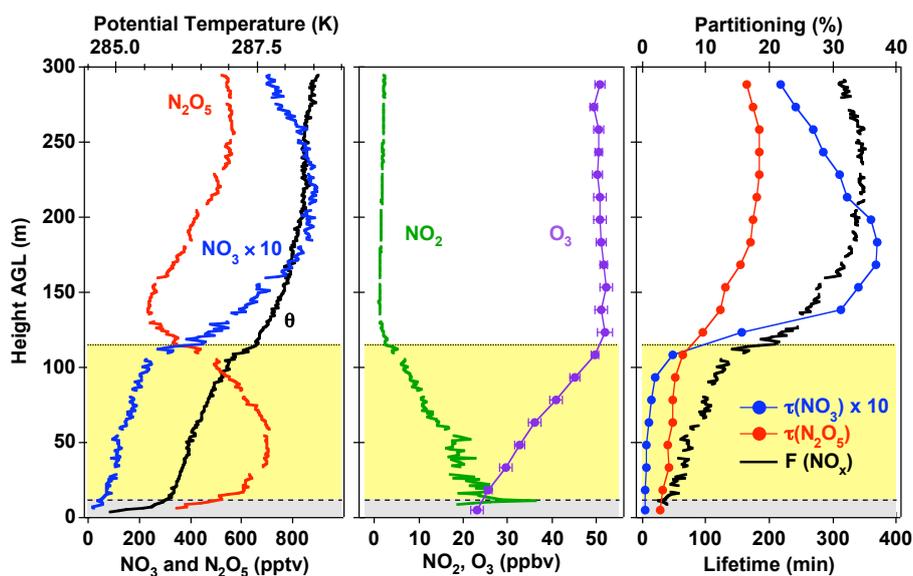

Fig. 6. Left: Profile of NO_3 and N_2O_5 (bottom axis), and potential temperature (top axis) as a function of height above ground level (AGL) from 23:15–23:23 on 4 October 2004. Note that the NO_3 mixing ratio has been multiplied by a factor of 10 to display it on the same scale with N_2O_5 . Center: Vertical profiles of O_3 (measured at 18 s time resolution) and NO_2 , calculated from the measured NO_3 , N_2O_5 and temperature according to Eq. (1). Right: Profile of NO_3 and N_2O_5 lifetimes (bottom axis) calculated according to Eq. (4) (with $\tau(\text{NO}_3)$ multiplied by 10) and partitioning, $F(\text{NO}_x)$ (top axis) from Eq. (5). The horizontal lines and color coding indicate the layer assignments according to the scheme shown in Fig. 5.

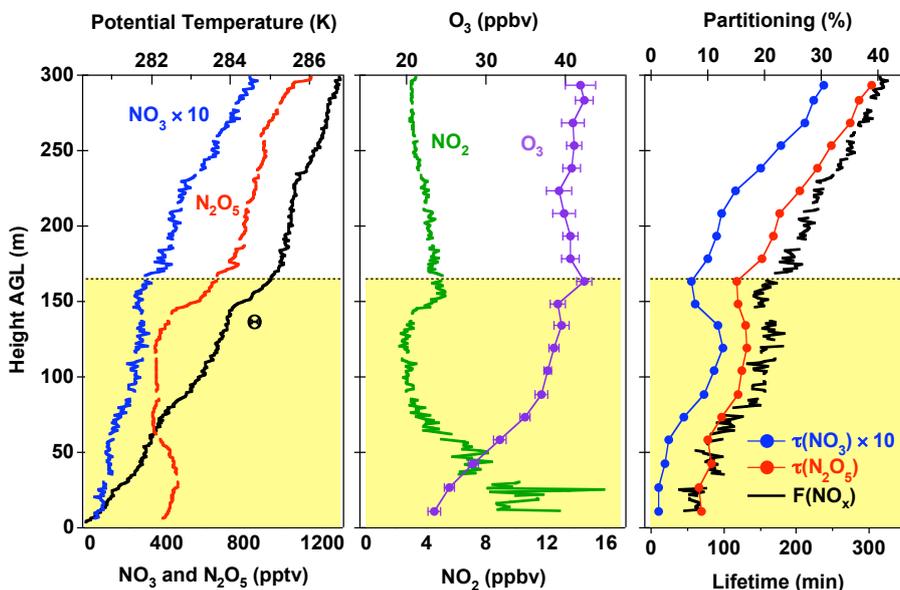

Fig. 7. Same as Fig. 6, except for a profile from 03:05–03:14. Note that O_3 is displayed against the top axis in the center graph in this figure. The layering color scheme is the same as for Fig. 5, except that the surface layer is absent.

left hand graphs show the average measured NO_3 , N_2O_5 and O_3 mixing ratios and the average potential temperature. Many of the trends discussed above for the individual profiles were also apparent in the averages. The surface layer was a consistent feature and is evident as a sharp decrease in the

average Θ in the lowest few tens of meters. The top of the NBL, on the other hand, was variable between 100–250 m in individual profiles. As a result, the averaged Θ showed a continuous increase with height above the surface layer without a characteristic discontinuity. A clearer measurement of

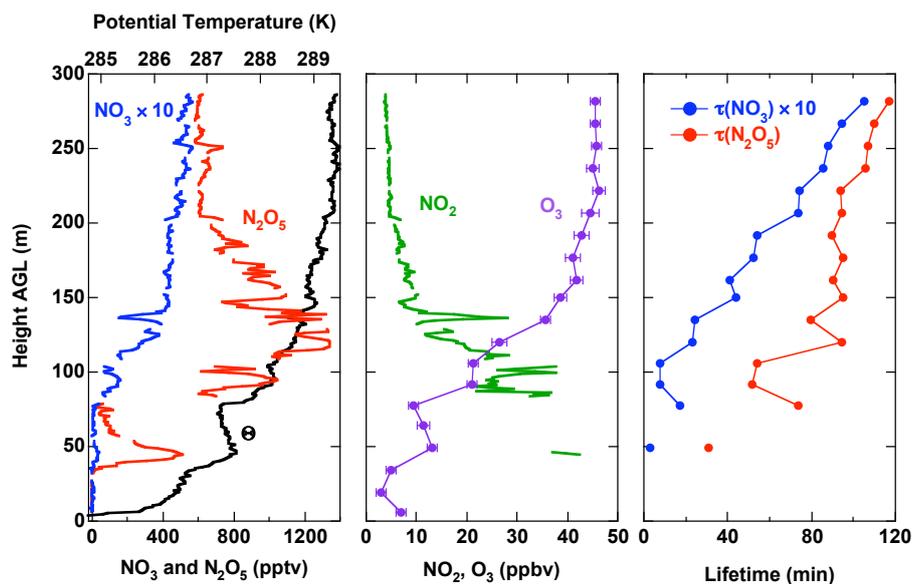

Fig. 8. Same as Fig. 6, except for a profile from 22:05–22:14.

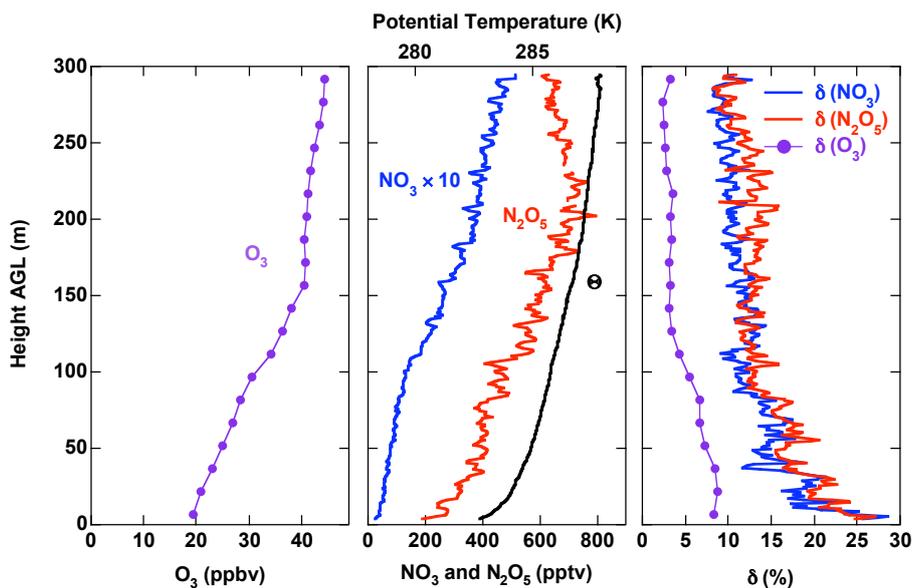

Fig. 9. Vertical profiles of averaged O_3 (left graph) NO_3 , N_2O_5 and potential temperature (Θ) (center graph) for 27 profiles between 10 April 2004 19:00–10 May 2004 06:00. The relative standard deviation of NO_3 , N_2O_5 and O_3 (see text) are shown in the right graph. The apparently systematic oscillations in the averages are an artifact of the frequency at which zero measurements were taken during vertical ascents and descents.

the average depth of the NBL was evident at 150 m from the O_3 measurement. Below this level, average O_3 decreased continuously as a result, presumably, of surface emissions of NO_x and surface deposition of O_3 . Average mixing ratios of NO_3 and N_2O_5 showed a smoothly-varying, continuous increase from the ground up with no obvious signature of the NBL.

The right hand graph of Fig. 9 shows the relative standard deviation (i.e., the quotient of the standard deviation and the average within each 1 m increment from all profiles) in NO_3 , N_2O_5 and O_3 with height. The variability in NO_3 and N_2O_5 was similar and was smaller aloft than at the surface, showing no trend with height above 150 meters but increasing steadily below 100 m. Within the surface layer, $\delta(\text{NO}_3)$ and $\delta(\text{N}_2\text{O}_5)$ increased sharply. The trend in O_3 variability was similar,

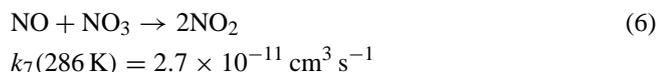

except that $\delta(\text{O}_3)$ was consistently smaller and did not show a sharp increase within the surface layer (possibly as a result of the lower time resolution of the measurement). The larger variability in O₃, NO₃ and N₂O₅ within the NBL compared to above it may have been due to variations in a number of factors, including the amount of NO_x mixed into the boundary layer, the boundary layer depth or sinks for NO₃ and N₂O₅.

4 Discussion

The temperature profiles and the chemical composition measurements are consistent with reduced mixing, stratification and layering in the lowest few hundred meters of the atmosphere at night. Although the picture was sometimes more complicated, the vertical structures could generally be grouped into the three categories shown in Fig. 5. The layers were associated not only with changes in chemical composition (i.e., NO_x and O₃), but also with reactivity of the nocturnal nitrogen oxides, NO₃ and N₂O₅ as inferred from their steady state lifetimes and nitrogen oxide partitioning. Because of the lack of ancillary measurements, it is not possible to definitively identify the nature of the sinks for NO₃ and N₂O₅ within the surface and boundary layers. There are several possibilities, including surface deposition, reaction with NO, reaction of NO₃ with surface-emitted VOC, or an increase in the rate of N₂O₅ hydrolysis near the surface.

Deposition of NO₃ and N₂O₅ would have been most important within the surface layer because of its shallow mixing depth. Assuming a moderately large deposition velocity for NO₃ and/or N₂O₅ of $v_d \sim 1 \text{ cm s}^{-1}$, their lifetime with respect to deposition, τ_d , within a surface layer of height, $h=10\text{--}20 \text{ m}$ may be estimated as $\tau_d \sim h v_d^{-1} = 15\text{--}30 \text{ min}$ (Wesely and Hicks, 2000). To our knowledge, deposition velocities for NO₃ and N₂O₅ have not been measured, and deposition losses of these compounds have typically been considered small in comparison to other losses (see, for example, Aldener et al., 2006; Stutz et al., 2004). However, the presence of a shallow surface layer could magnify the importance of deposition. Certainly, vertical gradients in O₃ arising from dry deposition (e.g., Galbally and Roy, 1980) serve to reduce the production rate for NO₃ and N₂O₅ from Reaction (2) as a function of height near the ground surface.

Reaction of NO₃ with NO is often considered to be a more important loss process than deposition near the ground at night because of the emission of NO from either soils or combustion sources and the large rate coefficient for this reaction.

In combination with Reaction (2), Reaction (6) leads only to a net increase in the rate of NO oxidation by O₃ (Reaction 3) and does not lead to a net loss of nitrogen oxides as do NO₃-VOC reactions or N₂O₅ hydrolysis. Therefore, surface NO

emissions decrease the impact of NO₃ and N₂O₅ reactions in nocturnal NO_x destruction. At the BAO site, NO may have come from either soil emission or anthropogenic sources. The flux of NO from grassland in autumn in Colorado has been measured in the range 0.2–1 ng N m⁻² s⁻¹ (Williams et al., 1987). The resulting calculated emission rate into a 20 m surface layer is 0.02–0.1 pptv NO s⁻¹, insufficient to titrate a significant amount of ozone. At a constant, 20 ppbv of O₃, the steady state NO concentration resulting from soil emission would have been 3–15 pptv, which would limit the lifetime of NO₃ to 2–10 min. Emission of NO from nearby anthropogenic sources is likely a far larger NO_x source than are soils at this site, as evident from calculated NO₂ concentrations reaching several tens of ppbv. These anthropogenic NO emissions may also have limited the lifetime of NO₃ at the BAO site if the transport time from these sources was short enough that NO was not fully oxidized to NO₂, or if the NO emission was large enough to chemically titrate all of the O₃. For example, the presence of NO may explain the zero NO₃ and N₂O₅ concentrations below 30 m in Fig. 8, where the O₃ mixing ratio was also near zero. Periodic advection of air masses containing large amounts of NO from nearby sources would be consistent with the variability in NO₃ and N₂O₅ observed below 50 m and is likely to be a large contribution to the observed gradients.

Like NO emission, surface emissions of reactive VOC that are trapped in the surface and/or nocturnal boundary layers may give rise to a rapid NO₃ loss. In contrast to reaction with NO, however, NO₃ reaction with VOC can lead to a net loss of ozone and/or NO_x depending on the VOC (Atkinson and Arey, 2003). In the absence of VOC measurements, however, an estimate of their contribution to NO₃ loss within the boundary layer at the BAO site is difficult. Emission of VOC from grassland consists largely of oxygenated VOC that are not reactive toward NO₃ and are likely not significant at night (Kirstine et al., 1998). Anthropogenic VOC in general are not particularly reactive with NO₃, except for specific classes of compounds such as alkenes (Wayne et al., 1991).

Hydrolysis of N₂O₅ is a key reaction in the conversion of NO_x to nitric acid or aerosol nitrate at night.

The reaction is efficient as a heterogeneous process on aerosol particles. As with NO and VOC, aerosol particle loading (and thus available surface area) is conceivably larger in the NBL than aloft due to trapping of aerosol or aerosol precursor (e.g. ammonia) emissions. Gradients in relative humidity with height above ground may also play a role. Relative humidity at 200 m on 4–5 October ranged between 35–65%, while at 10 m it varied from 60–90%, with an average difference in relative humidity of 29% between these heights during darkness (see Fig. 3). Therefore, hygroscopic particle growth and/or variation in the uptake coefficient for N₂O₅ with relative humidity could plausibly increase its loss

rate to heterogeneous hydrolysis at lower elevations within the NBL.

The preceding discussion demonstrates that the observed variability in NO₃ and N₂O₅ over short distance scales may result from the interaction between the nocturnal stratification of the atmosphere and the distributions of an array of potential NO₃ and N₂O₅ sinks. Furthermore, the reactivity of a compound should be directly related to its variability on both spatial and temporal scales (Junge, 1974). Previous measurements of NO₃ and N₂O₅ at a nearby measurement site (Brown et al., 2003b) showed rapid temporal variation that may have been related to the kind of spatial variability seen in this study. Such small scale variability in sinks is interesting not only from a measurement perspective; it also presents a modeling challenge. The large variability in nitrogen oxide chemistry over small scales means that an accurate representation requires calculation on extremely fine spatial scale or an accurate parameterization of the integration of small scale variations into larger scale models (Jones et al., 2005; Ravishankara, 2005).

The contrast between nitrogen oxide chemistry in the NBL and residual layers underlines the need for more complete vertical profiling studies involving a larger array of chemical and meteorological measurements. This study has primarily illustrated the potential for in-situ chemical measurements from a movable carriage on a tall tower to address this problem. Further measurements at the BAO site that include a larger array of chemical, aerosol and meteorological instrumentation, carried out over longer periods in different seasons, will be of considerable interest.

Acknowledgements. The authors thank W. C. Kuster for the loan of an O₃ monitor. This work was funded by NOAA's Air Quality and Climate Forcing Programs.
