Abstract

During the last 30 years, the southern European range limit of the Baltic clam *Macoma balthica* strongly shifted northward. To understand the consequences of such a retreat on populations located near the edge of its current geographic range, we developed nine microsatellite markers and tested their usefulness on 36 individuals from two populations. All loci were found to be polymorphic, with five to twenty-six alleles per locus. These results appear promising to study the fine scale genetic structure and dynamics of *Macoma balthica* populations near the range limit.

Parmesan & Yohe (2003) recently showed that more than 1500 species had experienced switches in their biotic trends coherent with the twentieth century climate warming. In the northern hemisphere, a growing number of coastal marine mollusc species are concerned by northward shifts (Wethey & Woodin 2008). However, consequences of such shifts on the function and structure of coastal ecosystems remain mostly unknown (Walther *et al.* 2002).

The Baltic clam *Macoma balthica* (Bivalvia: Tellinidae) is widely distributed in marine and estuarine soft-bottom habitats from temperate to arctic coastal waters in the North Atlantic and North Pacific oceans. Along the European coasts, its natural range is showing a strong shift toward the north-east and the species is rapidly vanishing from the Bay of Biscay (Jansen *et al.* 2007). As an important prey for migratory birds, macro-invertebrates and fish, *M. balthica* is one of the key-species along the European littoral (Philippart *et al.* 2003) and is thus of direct importance for fisheries and ecosystem conservation. Focusing on the current edge of its southern distribution, we aim to investigate the fine scale mechanisms of exchanges between unstable populations. Thus, we developed nine polymorphic

hal-00485678, version 1 - 21 May 2010

microsatellite markers and tested their usefulness by analysing two populations respectively sampled near the range limit and in the core of the species distribution.

Genomic DNA from four individuals from the Waddensee (Dutch coast) was isolated from < 15mg of muscle using a Nucleospin tissue kit (Macherey Nagel). A genomic library enriched for CA repeated microsatellites was constructed following the protocol described by Billote et al. (1999). Briefly, total DNA was digested with RsaI (Promega). After purification on a Nucleospin Column (Macherey Nagel), 3 µg of digested DNA was ligated to RsaI adapters (Rsa21F: 5'-CTCTTGCTTACGCGTGGACTA-3'and Rsa25R: 5'-TAGTCCACGCGTAAGCAAGAGCACA-3'). For the enrichment procedure, hybridization of DNA fragments was carried out using biotinylated $(AC)_{10}$ probes attached to streptavidin-coated magnetic beads (Streptavidin Magnesphere® Paramagnetic Particles; Promega). The purified enriched fraction was ligated into pGEM®-T easy (Promega) and transformed into *Escherichia coli* DH5α competent cells. Recombinants with appropriate insert sizes were determined by polymerase chain reaction (99 clones). From a total of 67 positive clones sequenced using a SequiTherm EXCEL™ II DNA Sequencing Kit (Epicentre) on a Li-Cor NEN Global IR2 DNA sequencer, 37 primer pairs were designed using OLIGO® v.6.0 (Rychlik & Rychlik 2000). Forward primers were fluorescently-labelled with infra-red fluorescent dye IRD700™ or IRD800™ for screening. The genomic DNA for genotyping was obtained using Nucleospin tissue kit (Macherey Nagel). Amplification conditions were optimized for 9 loci (Table 1) for which preliminary tests showed unambiguous patterns. Each reaction was performed in 10 µl and contained approximately 50 ng of DNA, 0.25 µM of fluorescently labelled forward primer, 0.25 µM of unlabelled reverse primer, 1.5 mM of $MgCl_2$, 0.2 mM of each dNTP, 1X PCR buffer [75 mM Tris-HCl, pH 8.8 at 25°C, 20 mM

$(NH_4)_2SO_4$ and 0.01% Tween 20] and 0.5 U of Thermoprime Plus DNA Polymerase (ABgene), using a MJ Research PTC-200 thermocycler (MJ research Inc.). Thermal cycling conditions followed a touch-down PCR procedure: 3 min of an initial denaturation step at 95°C followed by 10 cycles of denaturation at 95°C for 45s, annealing at temperature decreasing by 1°C per cycle from Ti to Ta (Table 1) for 45s and extension at 72°C for 45s, then followed by 30 cycles at 95°C for 45s, annealing at final Ta for 45s and extension at 72°C for 45s. A final extension step was carried out for 7 min at 72°C. PCR products were screened on a 6.5% polyacrylamide gel using a Li-Cor NEN Global IR2 DNA sequencer system. Allele sizes were determined using a known DNA sequence.

Polymorphism at the nine loci was tested in two populations of *M. balthica* [Fouras, N= 15 and Waddensee, N=21]. No linkage disequilibria across loci were detected using GENEPOP version 4.0.7 (Raymond & Rousset 1995). This software was also used to estimate the expected heterozygosities and adequacy of genotypic proportions to Hardy-Weinberg expectations (Table 1). Over the 36 individuals analysed, the number of alleles ranged from 5 to 26 and expected heterozygosis from 0.13 to 0.91. At the population level, deviations from Hardy-Weinberg equilibrium were variable across loci and populations. The loci Mb-mac 10 showed a significant heterozygote deficiency for both populations, which might be due to null alleles. This hypothesis was tested using MICRO-CHECKER v.2.2.3 (Van Oosterhout 2004). It was confirmed for these loci that the heterozygote deficiency were not related to deviation from panmixia or genotyping errors but possibly to the presence of null alleles. Furthermore, all populations were found to be polymorphic [e.g. mean number of alleles: 8.00 and 7.22 in Fouras and Waddensee respectively].

Although care should be taken to accommodate null alleles, these microsatellites should prove useful for analyzing fine scale genetic structures, population dynamics, and relationships within and between local populations of *Macoma balthica.*
