12 **Capsule:** Grass-covered soils reduce the amount of pesticide leaching, due mainly to their
13 higher organic matter contents, thereby reducing the risk of groundwater contamination.

14
15 **ABSTRACT**

16 The purpose of this work is to assess the effectiveness of two grass covers (buffer zone and
17 grass-covered inter-row), to reduce pesticide leaching, and subsequently to preserve groundwater
18 quality. Lower amounts of pesticides leached through grass-cover soil columns (2.7 - 24.3% of
19 the initial amount) than the bare soil column (8.0 - 55.1%), in correspondence with their
20 sorption coefficients. Diuron was recovered in higher amounts in leachates (8.9 - 32.2%) than
21 tebuconazole (2.7 - 12.9%), in agreement with their sorption coefficients. However, despite
22 having a sorption coefficient similar to that of diuron, more procymidone was recovered in
23 the leachates (10.2 - 55.1%), probably due to its facilitated transport by dissolved organic
24 matter. Thus even in this very permeable soil, higher organic matter contents associated with
25 grass-cover reduce the amount of pesticide leaching and limit the risk of groundwater

1 contamination by the pesticides. The results of diuron and tebuconazole transfer through
2 undisturbed buffer zone soil columns are in agreement with field observations on the buffer
3 zone.

1

2 **1. Introduction**

3

4 As a result of numerous sources of pollution, including the use of agricultural pesticides,
5 drinking waters resources are becoming increasingly scarce and a crucial issue for developed
6 countries. It is critical that solutions are proposed to better protect water quality, in particular
7 that of surface waters, which are generally the most contaminated and also the most sensitive
8 to contamination (IFEN, 2006). Viticulture is an important agricultural sector in France, and a
9 great consumer of pesticides to control disease, insect damage and weed competition in the
10 vineyards. Consequently, many recent studies have reported the presence of pesticide residues
11 in surface- or ground waters near several vineyards at concentrations higher than the
12 European regulatory limit of $0.1 \mu\text{g L}^{-1}$ for drinking water (ECC, 1998), and the European
13 Quality Standards defined for some pesticides in the European Water Framework Directive
14 as, for example, in France (Lennartz et al., 1997; Louchart et al., 2004) and in Spain
15 (Bermudez-Couso et al. 2007). Consequently, agricultural institutions advise wine producers
16 to use alternative practices to chemical weeding and to reduce pesticide transfer by adopting
17 management practices such as grass covered inter-rows or buffer zones.

18 Numerous studies have shown that the grass cover reduces erosion and runoff due to
19 sediment deposition and increases water infiltration within the vegetated zone (Dillaha et al.
20 1989; VanDijk et al., 1996). More recent works have been concerned with the use of these
21 buffer zones to limit surface water contamination by pesticides. A number of authors have
22 reported that the amount of pesticide in the runoff from vegetated buffer zones is lower than
23 the amount entering the zone (Patty et al., 1997; Schmitt et al., 1999; Watanabe et al., 2001).
24 The effectiveness of the vegetated buffer zones at reducing the amounts of pesticide in the
25 runoff may be explained by the processes of retention and/or infiltration within the zone

1 (Kloppel et al., 1997; Mersie et al., 1999; Seybold et al., 2001; Delphin and Chapot, 2001;
2 Souiller et al., 2002; Benoit et al., 2003; Mersie et al., 2003). Lacas et al., (2005) and Krutz et
3 al (2005) reviewed the various parameters affecting pesticide infiltration and/or retention in
4 vegetative filter strips. The respective proportion of the two processes in the reduction of
5 pesticide runoff depends on the affinity of the molecules for the soil (sorption) (Arora et al.,
6 2003; Boyd et al., 2003). For example, a reduction of relatively water soluble herbicides, such
7 as atrazine and metolachlor, in the runoff from a vegetated zone could be explained by
8 increased infiltration; whereas, reduction in chlopyrifos runoff would be due to sorption onto
9 the sediments retained by the buffer zone vegetation (Arora et al., 2003). Similar conclusions
10 were reached by Boyd et al. (2003) who showed that chlorpyrifos was retained on sediments
11 deposited in vegetated buffer zones; whereas, atrazine and acetochlor infiltrated the soil and
12 were detected in the drains.

13 However, reducing the quantities of pesticides found in surface waters by promoting
14 their infiltration in buffer strips may threaten shallow water tables or even groundwater with
15 pesticide contamination. On the one hand, various studies have shown that the sorption and
16 degradation of pesticides is higher in vegetated zones than in cultivated soils (Benoit et al.,
17 1999; Madrigal et al., 2002; Krutz et al., 2003; Krutz et al., 2004) or fallow soils (Staddon et
18 al., 2001). On the other hand, these were laboratory batch studies somewhat removed from the
19 reality of field conditions. It is likely that the more infiltration rates through a vegetated soil
20 increase, the less physico-chemical equilibrium is reached. In particular the degree of non-
21 equilibrium of sorption increases with water flow as showed by Pot et al. (2005) and Vincent
22 et al. (2007); potential sorption and degradation of the compounds would decrease relative to
23 the results of the batch studies in which steady-state conditions are attained. Nevertheless,
24 very few studies have been conducted on the quantities of pesticides leached from vegetated
25 soils and the results of these studies are contradictory. In some cases, the use of grass covers

1 on soil reduces the amounts of pesticides leached compared with the amounts leached from
2 cultivated or fallow soils (Liaghat and Prasher, 1996 ; Benoit et al., 2000), in other cases,
3 there was no difference (Belden and Coats, 2004). Thus, our work contributes to a better
4 understanding of pesticide leaching through grass-covered soil, in particular structured soils
5 sensitive to leaching (loamy sand) that are representative of a widespread vineyard areas in
6 France.

7 The Cemagref of Lyon established an experimental site in St Joseph (Beaujolais,
8 France) in 2004, in order to assess the efficiency of vegetated buffer zones to reduce pesticide
9 runoff and the subsequent pesticide infiltration through the buffer zone (Boivin et al., 2007).
10 It consisted of an experimental plot laid out on an old meadow vegetated buffer zone (6 x 4.2
11 m²) interposed between the vineyard uphill and the Morcille stream downhill. An
12 homogeneous distribution of water inflow was ensure at the upper end of the buffer zone. Soil
13 water content was monitored during the water inflows using tensiometers and humidimeters
14 located at different position in the experimental plot. In addition, lysimeters implemented at
15 different locations were designed for collecting soil water at 50 cm depth when runoffs were
16 simulated. They clearly demonstrated a global reduction in pesticide concentrations (diuron
17 and tebuconazole) leached to a 50 cm soil depth relative to the initial concentration of the
18 incoming runoff. Their attempts to quantify the reduction, however, were hampered by the
19 difficulty in obtaining reliable mass balances in the field from pesticide concentration
20 measured in lysimeters which collected a limited fraction of the total infiltration through the
21 buffer zone (4% of the total buffer surface). Moreover, no field data on pesticide leaching
22 through neither the cultivated bare soil nor the inter-row grassed soil were available for
23 comparison in this site. Thus, the objectives of this work were (i) to implement an experiment
24 allowing the comparison of pesticide leaching in the buffer zone soil with a bare cultivated
25 soil and a grass covered inter-row soil, that results in better mass balance control than field

1 experiment; (ii) to better assess the role of two grass cover modalities (buffer zone and grass
2 covered inter rows) on water infiltration, and leaching or sorption of one herbicide (diuron)
3 and two fungicides (tebuconazole and procymidone), through a Beaujolais vineyard soil
4 during runoff events; and (iii) to compare the possible release of pesticides from soils after
5 subsequent runoff events. The pesticide leaching was studied using undisturbed soil columns
6 (15 x 20 cm) in laboratory and outdoor conditions. These two experiments were
7 complementary: monitoring some metabolites in the leachates under laboratory conditions,
8 and the additional grass-cover modality under outdoor conditions (inter-row vineyard). The
9 loamy sand soil was sampled in a chemically-weeded plot, in an adjacent buffer zone and in a
10 grass-covered inter-row plot. Several runoff events, with and without pesticides were
11 simulated, and pesticide concentrations were monitored in the column leachates. The results
12 of our work were compared to those obtained at the experimental site in St Joseph by Boivin
13 et al. (2007). This increased our understanding of the fate of pesticides in grass covered soils
14 compared to bare soil, and showed their potential reduce the pesticide leaching through soil
15 thus preserving groundwater quality.

16

17 **2. Material and methods**

18

19 *2.1. Chemicals*

20

21 Diuron (3-(3,4 dichlorophenyl)-1,1-dimethylurea) (3-[3,4-dichlorophenyl]-1,1-
22 dimethylurea) and two of its metabolites, DCPMU (3-3,4-dichlorophenyl-N,N-methylurea)
23 and DCPU (3-3,4-dichlorophenylurea), tebuconazole ((RS)-1-p-chlorophenyl-4,4-dimethyl-3-
24 (1H-1,2,4-triazol-1-ylmethyl) = pentan-3-ol), and procymidone (N-(3,5-dichlorophenyl)-1,2-
25 dimethylcyclopropane-1,2-dicarboximide) were obtained from Cluzeau (Sainte-Foy-La-

1 Grande, France) with > 99% certified purity. The main physico-chemical properties of the
2 pesticides are listed in Table 1. Commercial pesticide formulations were used: Canyon
3 (diuron 71g L⁻¹), Folicur EW (tebuconazole 250 g L⁻¹) and Sumisclex (procymidone 500 g L⁻¹)
4 in order to obtain more realistic results.

5

6 *2.2. Soil sampling and column set-up*

7

8 The experimental site monitored by Cemagref of Lyon (69, France) is located in the
9 Beaujolais region near St Joseph (Rhône, France). It consists of an experimental plot (25.2
10 m²) on a 25% slope laid out on a vegetated buffer zone, located between a chemically-treated
11 hillside vineyard and the Morcille stream. For the field experiment, soil water content was
12 monitored through the buffer strip using humidimeters and tensiometers, and pesticide
13 concentrations and fluxes were measured in soil water collected using lysimeters (Jordan,
14 1968; Boivin et al., 2007;). These lysimeters correspond to water percolation sampler
15 consisting of two similar and joint horizontal stainless steel plates (0.25 x 0.25 cm²) making
16 the gravimetric soil water flow converging into underlying glass bottles by means of a Teflon
17 capillary tube. The plates were placed at 50 cm depth under the soil surface taking care not to
18 disturb the underlying soil owing to a lateral slice in the ground which was filled after the
19 installation. A set of two other capillary tubes permitted to set the system at the atmospheric
20 pressure and to transfer the percolated water from the buried bottles to the surface for
21 measurements (water volumes and solute concentrations). In the field experiment, pesticide
22 leaching was monitored only in the buffer zone; then the chemically-treated soil and a
23 complementary site in the same vineyard consisted of a grass-covered inter-row plot allowed
24 to collect soil columns. No runoff occurred on this buffer strips that means that all the
25 entering water flow infiltrated into the soil. The soil is a sandy loam (arenic cambisol, FAO,

1 1998). Column extraction of the soil occurred in March 2006 (outdoor conditions) and in
2 March 2007 (laboratory conditions) before pesticide treatment of the fields, and was
3 facilitated by the use of a shovel to carefully excavate the surrounding soil. Final carving of
4 the soil was carefully performed by hand resulting in 15-cm diameter cylinders of structured
5 soil. A 25-cm long polyvinyl chloride (PVC) pipe with an internal diameter of 20 cm was
6 placed around each soil cylinder. The space between the pipe and soil was filled with
7 expandable foam to prevent water from moving preferentially down the side of the pipe rather
8 than through the soil. The minimal expansion foam was allowed to cure overnight. The
9 columns were then removed from the field by digging under the PVC pipe, and placing nylon
10 mesh (105 μm openings) at the bottom of each column base to retain the soil. Preliminary
11 experiments showed that no sorption was measured on the minimal expansion foam either on
12 the nylon mesh. Six columns were brought back to the laboratory (3 columns from the bare
13 soil, B_{L1} , B_{L2} and B_{L3} and, three from the buffer zone, BZ_{L1} , BZ_{L2} and BZ_{L3}). In addition, ten
14 undisturbed soil columns were brought to the experimental site at INRA-Dijon in march 2006
15 for installation in an outdoor, in-ground lysimeter collection system (4 columns from the bare
16 soil, B_{O1} , B_{O2} , B_{O3} and B_{O4} , three from the buffer zone, BZ_{O1} , BZ_{O2} and BZ_{O3} and three from
17 the grassed-cover vineyard, GC_{O1} , GC_{O2} and GC_{O3}). This device previously used by Landry et
18 al. (2006), consisted of a perforated PVC support connecting the columns to funnels, with
19 PFTE-lined collection tubing leading to high-density polyethylene bottles in an underground
20 pit. The volume around the columns was backfilled with sand to simulate field conditions.
21 The outdoor lysimeters allowed studying the impact of the outdoor environmental conditions
22 (temperature, rainfall, and solar radiation) on the degradation of pesticides between the
23 different runoff inflows.

24

25

1 2.3. Water inflows and experimental set-up

2
3 Same artificial inflows (simulating vineyard runoff events) were replicated at three
4 different times (T_0 , T_{14} and T_{28} days, respectively) on the soil surface for laboratory and
5 outdoor columns. The first water inflow (T_0) contained a homogeneous mixture of 5 mg L^{-1}
6 bromide and $100 \text{ } \mu\text{g L}^{-1}$ diuron, procymidone or tebuconazole, simulating contaminated
7 runoff after a rainfall event. Bromide was added as a tracer of water transfer. Input
8 concentrations were selected based on previous work on contaminated runoff from vineyard
9 (Louchart et al., 2001) and local references (Lacas, 2005). A 3.6 L volume of solution was
10 applied onto the surface of each column (176.6 cm^2), which is equivalent to the 4800 L water
11 volume applied to the experimental vegetated buffer zone (25.2 m^2) in the field experiment
12 monitored by Boivin et al (2007). This simulated runoff corresponds to a < 2-yr rain event
13 frequency (Lacas, 2005). The bromide-pesticide solution was applied onto the top of each
14 laboratory or outdoor soil column at a constant flow rate of 10.2 cm h^{-1} using a peristaltic
15 pump. This rate is lower than that used in the study by Boivin et al. 2007 (28 cm h^{-1}), but it is
16 within a realistic range; indeed, Lacas (2005) reported a slightly higher field saturation
17 hydraulic conductivity of 12.5 cm h^{-1} at 15 cm depth. Two additional water inflows,
18 consisting only of 3.6 L of water, were applied to the columns fourteen (T_{14}) and twenty eight
19 days (T_{28}) after the pesticide application in order to assess potential pesticide release from the
20 soil. Each inflow lasted 3 hours in average, except for the grass-covered inter-row soil (26h).
21 During the laboratory experiment, the soil water saturation was $55\% \pm 4\%$ for the bare soil and,
22 $64\% \pm 6\%$ for the buffer zone soil. The laboratory soil columns were maintained at $20^\circ\text{C} \pm$
23 2°C , whereas the mean outdoor temperature was 12°C during the monitored period from the
24 27 of March to 23 of April 2007; rainfall was scarce, less than 15 mm (< 5% of the runoff
25 water).

1 2.4. Leachate collection and analyses

2
3 Laboratory and outdoor column effluent was collected at 6-min intervals in 250-mL
4 glass bottles. Leachate volumes were determined gravimetrically. Each leachate sample from
5 the first water inflow (T_0) was kept for analysis. When collecting effluent from the second
6 (T_{14}) and third (T_{28}) water inflow events, three consecutive samples were mixed; so that,
7 column effluent was essentially collected at 18-min intervals. Pesticide residues contained in
8 the leachates were concentrated by solid-phase extraction with a LC-18 bonded silica
9 cartridge (3 mL, Supelclean, Supelco) for water-sample volumes <100 mL or with an LC-18
10 bonded silica cartridge (12 mL, Supelclean, Supelco) for water-sample volumes >100 mL.
11 The cartridges were pre-conditioned with similar volumes of acetonitrile then distilled water,
12 2 x 1 mL for the 3 mL cartridge, and 2 x 2.5 mL for the 12 mL cartridge. The pesticide
13 residues adsorbed by the 12 mL LC-18 cartridges were eluted using 2 x 2 mL of acetonitrile
14 (2 x 1 mL for the 3 mL cartridge), and evaporated to dryness in a rotary evaporator at 30°C.
15 The residues were then dissolved in 5 mL of methanol (2 mL for the 3 mL cartridge) and
16 stored at -18°C prior to analysis. Respective mean recovery rates for 3 mL and 12 mL
17 cartridges were 99.3% and 95.8% for diuron, 98.3% and 95.1% for DCPMU, 97.5% and
18 88.8% for DCPU, and 94.6% and 82.6% for procymidone and 55.7% and 55.6% for
19 tebuconazole. All sample concentrations were corrected based on these recovery values.
20 Samples were analyzed using a Waters HPLC equipped with a Diode Array Detector and a 25
21 cm x 4.6 mm C18-column packed with Kromasil 5 μm for tebuconazole, procymidone, diuron
22 and its two metabolites DCPMU and DCPU, and a 15 cm x 4.6 mm Waters IC Pack Anion
23 HC for Br^- . The mobile phase was acetonitrile-water at 70/30 v/v for the pesticides and a
24 sodium borate-gluconate eluent with 12% of acetonitrile for bromide. The flow rate of the
25 mobile phase was 0.8 mL min^{-1} for the pesticide analyses, and 1.8 mL min^{-1} for bromide. UV

1 detection was performed at 249 nm for diuron, DCPMU and DCPU, 220 nm for tebuconazole
2 and 203 nm for procymidone and 200 nm for bromide. Minimum detectable levels of residues
3 extracted with SPE cartridges respectively were: 1 $\mu\text{g L}^{-1}$ for diuron, DCPMU, DCPU, and
4 tebuconazole 2 $\mu\text{g L}^{-1}$ for procymidone. Minimum detectable concentration was 0.25 mg L^{-1}
5 for Br⁻.

7 *2.5. Soil characterization*

9 At the end of the monitoring period, the gravimetric soil water content was measured.
10 Then the soil columns were weighed and dried at 105°C for 24 hours before reweighing. For
11 the outdoor soil columns, the mean porosities were $0.37 \pm 0.02 \text{ cm}^3 \text{ cm}^{-3}$ for the bare soil ($0.41 \pm$
12 $0.04 \text{ cm}^3 \text{ cm}^{-3}$ for laboratory columns), $0.46 \pm 0.05 \text{ cm}^3 \text{ cm}^{-3}$ for the buffer zone soil (0.37 ± 0.02
13 $\text{cm}^3 \text{ cm}^{-3}$ for laboratory columns), and $0.28 \pm 0.06 \text{ cm}^3 \text{ cm}^{-3}$ for the grass covered inter-row soil.
14 The soil columns were then divided into 5 horizontal sections (0-2.5 cm; 2.5-5 cm, 5-10 cm;
15 10-15 cm; 15-20 cm), air-dried, weighed, and sieved to < 2 mm. The > 2 mm fractions were
16 weighed as the coarse fraction. The < 2 mm fractions were characterized by determinations of
17 texture (NFX 31-107), pH (NF ISO 10390), and total organic C (NF ISO 10694) at INRA-
18 Arras, France. The main properties of the two soils studied are presented in Table 2. The
19 surface soils from the buffer zone and the grass covered inter-rows contained more organic
20 carbon (4.0 and 3.9%, respectively) than the bare vineyard soil (0.8%) (Table 2).

22 *2.6. Batch sorption coefficient measurement*

24 For each treatment (buffer zone, grass covered inter-row and bare soils), the sorption of
25 diuron, procymidone and tebuconazole (using commercial formulations: Canyon, Sumislex

1 and Folicur EW, respectively) was measured using a batch equilibrium method. Each sample
2 consisted of 2 g dried soil (0-5 cm depth) placed in a 50 mL Teflon centrifuge tube with 10
3 mL of 1, 2.5, 5 and 10 mg L⁻¹ diuron, procymidone or tebuconazole solution. The tubes were
4 agitated on a rotary shaker for 24 h at 20°C in order to reach steady-state, then centrifuged for
5 20 min at 4000g (Beckman-Avanti J-25 centrifuge maintained at 20 ± 1°C. Blanks were
6 prepared without soil to measure pesticide sorption to the centrifuge tube. The amount of
7 pesticide adsorbed by the sample at equilibrium was determined by the difference between the
8 initial and equilibrium pesticide concentrations in solution corrected by the blank sorption
9 measurement. The experiment was performed in triplicate. Distribution coefficients K_d (L kg⁻¹)
10 ¹) for diuron, procymidone and tebuconazole were calculated for each soil sample.

$$x/m = K_d \times C_{eq}$$

11
12 Where x/m is the amount of herbicide (mg) adsorbed per kg of soil and C_{eq} is the diuron
13 equilibrium concentration (mg L⁻¹).

15 3. Results and discussion

17 3.1. Sorption isotherms of diuron, tebuconazole and procymidone

18
19 For all three pesticides, the sorption coefficients are higher in the soil from the buffer
20 zone (K_d = 12.0-42.2 L kg⁻¹) than in the grass-covered inter-row soil (K_d = 4.9-19.1 L kg⁻¹)
21 and the bare soil (K_d = 2.2-10.5 L kg⁻¹) (Fig.1, table 3). These results may be explained by the
22 higher organic carbon contents in the 0-5 cm depth soil of the buffer zone and grass-covered
23 inter-rows (3.8% and 2.7%, respectively) than in the same depth of the bare soil (0.8%)
24 (Table 2). However, based on their organic carbon sorption coefficients and, considering that
25 interaction with mineral fraction may be neglected, the organic matter in the bare and the

1 buffer zone soils seems to be more reactive (K_{oc} from 275 to 1314 L kg⁻¹) than that of the
2 grass covered soil (K_{oc} from 183 to 709 L kg⁻¹).

3 In the buffer zone, grass cover and bare soils, tebuconazole (folicur) is adsorbed in
4 greater amounts ($K_d = 10.5-42.2$ L kg⁻¹) than procymidone (sumisclex) ($K_d = 4.2-14.1$ L kg⁻¹)
5 and diuron (canyon) ($K_d = 2.2-12.0$ L kg⁻¹). These sorption coefficients are of the same
6 magnitude as those reported in the literature (Table 1; Gonzales-Pradas et al. 2002; Close et
7 al. 2005). In particular, similar diuron sorption values were obtained by Lacas (2005) with
8 bare soil from the 0-20 cm depth ($K_d = 4.6$ L kg⁻¹) and buffer zone soil from the 0-5 cm depth
9 ($K_d = 14.2$ L kg⁻¹).

10

11 3.2. Water infiltration and bromide elution under laboratory conditions

12

13 Water flow was relatively homogeneous between the triplicates of each soil treatment,
14 and the eluted water flow rates were quite similar and constant for both the bare (83.0 ± 3.0
15 mm h⁻¹) and the buffer zone (80.0 ± 0.3 mm h⁻¹) soils throughout the three flow events.
16 However, the buffer zone flow was slightly lower than the saturation hydraulic conductivity
17 of 125 mm h⁻¹ at 15 cm depth reported by Lacas (2005). After the three water inflow events,
18 we found that bromide was eluted in greater amounts in the leachates of the bare soil ($74.0 \pm$
19 1.0%) than in those of the buffer zone soil (59.9 ± 1.2 %; Table 4) despite of similar
20 recovered leachate volume. This result could be due to the absorption of bromide by the grass
21 cover vegetation as demonstrated by Xu et al. (2004) with two wetland plants, *Typha latifolia*
22 and *Phragmites australis* and more recently by Papiernik et al. (2009).

23

24

25

1 3.3. Pesticides elution under laboratory conditions

2

3 The quantities of pesticide leached at the end of the three simulations were greater in the
4 bare soil leachates (8.0% to 55.1% of applied) than in those of the buffer zone soil (6.7% to
5 24.3%) (Table 4), in correspondence with their sorption coefficients, which were lower in the
6 bare soil ($K_d = 2.2-10.5 \text{ L kg}^{-1}$) compared to those in the buffer zone soil ($K_d = 12.0-42.2 \text{ L}$
7 kg^{-1}) (Table 3). Our results are in contradiction with those of Belden and Coats (2004) that
8 showed that the presence of grass did not modify the total amount of herbicide that leached
9 through soil columns. For both soils, the amounts of pesticides recovered in the leachates
10 varied somewhat between triplicates of a given soil despite having similar pore volumes,
11 coarse fraction contents and bromide recoveries (Table 2, 4).

12 Diuron metabolites (DCPMU and DCPU) were recovered in greater amounts in the bare
13 soil leachates (7.6 and 1.0% of the initial amount of parent molecules, respectively) than in
14 those of the buffer zone (0.2 and 0.1%). This result might be explained by the faster
15 degradation of diuron in the bare soil (chemically-weeded) by a microbial population adapted
16 to the herbicide due to repeated agricultural diuron treatments on the vineyard plot as seen by
17 Rouchaud et al. (2000). Similar results were found by Belden and Coats (2004) with atrazine
18 where more deethyl-atrazine was recovered in leachates of non-vegetated soils than the
19 leachates of vegetated soil. Our hypothesis of enhanced biodegradation in the bare soil could
20 not be verified for tebuconazole and procymidone because metabolites were not monitored;
21 nevertheless, Potter et al. (2005) showed that repeated application of tebuconazole increases
22 its dissipation rate in soil.

23 Of the total amounts of pesticide leached in the three simulations (Table 4), greater
24 amounts of diuron were recovered in the percolates of bare and buffer zone soils (32.2% and
25 14.6% of the applied amount, respectively) than tebuconazole (8.0% and 6.7%, respectively)

1 in correspondence with their respective sorption coefficients ($K_d = 2.2-12.0 \text{ L kg}^{-1}$ and 10.5-
2 42.2 L kg^{-1}). However, procymidone was measured in greater amounts in the leachates (24.3
3 to 55.1%) than either diuron or tebuconazole, contrary to what would be expected based on its
4 sorption coefficient ($K_d = 4.2-14.1 \text{ L kg}^{-1}$) (Tables 3, 5). This may be due to the facilitated
5 transport of procymidone bound to dissolved organic matter as suggested by Gonzales-Pradas
6 et al. (2002).

7 After the second and third runoff events (14 and 28 days after the first inflow event)
8 when only water was applied to the soils, low to significant amounts of pesticides were
9 released to the soil solution (11.3-50.4% of the total leached amounts, or, 1.5 to 26.4% of the
10 applied pesticide). These values are of the same order of magnitude as those reported by
11 Belden and Coats (2004) who recovered from 10 to 20% of the applied atrazine or
12 metolachlor in soil leachates. The buffer zone soil released less pesticide to the soil solution
13 (0.9 to 12% of the applied amounts) than the bare soil (1.5 to 26.4%) (Table 5) in agreement
14 with its higher sorption coefficients ($K_d = 12.0-42.2 \text{ L kg}^{-1}$ relative to $K_d = 2.2-10.5 \text{ L kg}^{-1}$ for
15 the bare soil). Additional processes such as long-term non-equilibrium sorption and formation
16 of non-reversible residues may be involved; indeed, Benoit et al. (2000) showed a greater
17 formation of non-extractable residues in the grassed strip soil compared to a cultivated soil.
18 Furthermore, diuron was detected in greater amounts (4.4 to 11.5% of applied) than
19 tebuconazole (0.9 to 1.5%) in the leachates, also in agreement with their respective sorption
20 coefficients (Table 3) and with their relatively similar half-life (Table 1). Again, procymidone
21 was released in greater amounts (12.0 to 26.4%) than either diuron or tebuconazole (Table 5),
22 which may be explained by its very high persistence, particularly in acidic soils (Footprint,
23 2007-2008), and suspected facilitated transport with dissolved organic matter.

24

25

1 *3.4. Water infiltration and bromide elution under outdoor conditions*

2
3 Water flow was relatively homogeneous between the soil treatment replicates. However,
4 the eluted water flow rates were higher in both the bare ($47.6 \pm 19.8 \text{ mm h}^{-1}$) and buffer zone
5 ($66.4 \pm 3.0 \text{ mm h}^{-1}$) soils than the grass-covered inter-row soil ($7.7 \pm 3.0 \text{ mm h}^{-1}$). The lower
6 flow rate could be due to water ponding on the soil surface of the all grass-covered inter-row
7 soil columns. Consequently 3 hours after percolation began, bromide was recovered in greater
8 amounts in the leachates of the bare ($55.4 \pm 5.8\%$) and the buffer zone ($45.5 \pm 26.6\%$) soils
9 than in the leachates of the vegetated soil ($6.6 \pm 7.4\%$). This result may be related to greater
10 porosity in the buffer zone ($0.46 \text{ cm}^3 \text{ cm}^{-3}$) and the bare ($0.37 \text{ cm}^3 \text{ cm}^{-3}$) soils relative to that
11 of the tractor compacted grass-covered inter-row soil ($0.28 \text{ cm}^3 \text{ cm}^{-3}$). Then the reduced
12 infiltration through the grass-covered inter-row could be a limitation to potential benefits of
13 this management practice, in particular in case of initially compacted soil. Nevertheless, as
14 with the experiments conducted under laboratory conditions, bromide was eluted in greater
15 amounts in the percolates of the bare soils ($81.2 \pm 19.6\%$) and the grass cover soils ($83.3 \pm$
16 12.4%) than in those of the buffer zone soils ($63.4 \pm 3.3 \%$) at the end of all the three runoff
17 events (Table 6). At the St Joseph experimental site, Boivin et al (2007) estimated a bromide
18 leaching rate of 90% of the total amount added in the inflow, at the 50 cm soil depth, which
19 compares well with our results, especially when considering the uncertainty linked to this
20 result (extrapolation of the results from 4 x 2 lysimeters (0.125 m^2 each) to the total buffer
21 strip (25 m^2).

22

23

24

25

1 3.5. Pesticides elution under outdoor conditions

2

3 The amounts of the three pesticides leached through the soils after applying simulated

4 runoff were in the same order of magnitude under both laboratory and outdoor conditions

5 (Table 6). Under outdoor conditions, the pesticides were recovered in greater amounts in

6 percolates of the bare soil (from 12.9 to 45.4 %) than in those of the buffer zone (from 2.7 to

7 11.9%) and grass-covered inter-row (from 4.4 to 11.0%) soils (Table 6). The results obtained

8 for the bare and the buffer zone soils corresponded to the same value than those measured

9 under laboratory conditions which means the outdoor environmental conditions (temperature,

10 rainfall, and solar radiation) did not induce a significant differentiation of the pesticide release

11 after the 28 days of the experiment for each modality. This could be explained by the scarce

12 rainfall measured during the monitoring period, and permitted to compare all the soil cover

13 modalities under laboratory or outdoor conditions. It appeared that leaching of pesticides

14 through grass-covered inter-row soil was similar to that through the buffer zone soil. The

15 difference between the bare soil and the buffer zone and grass-covered inter-row soils might

16 be explained by both the greater amount of bromide eluted and the lower sorption coefficient

17 of the three pesticides on the bare soil relative to the two other soils. Although the amounts of

18 the three pesticides leached through the buffer zone and the grass-covered inter-row soils

19 were relatively similar, more bromide eluted through the grass covered soil (83.3% compared

20 to 63.4% for the buffer zone) and lower quantities of the pesticides adsorbed to the grass

21 covered soil ($K_d = 4.9-19.1 \text{ L kg}^{-1}$) than the buffer zone soil ($K_d = 12.0-42.2 \text{ L kg}^{-1}$).

22 However, one must remember that the water flow rates were far lower (eight times) in the

23 grass-covered inter-row soil columns than the buffer zone soil columns. One hypothesis is

24 that the longer contact times between the pesticides and soil in the grass-covered inter-row

25 columns (due to ponding conditions) favours sorption, as it has been observed for the sorption

1 of four pesticides on an organic substrate in an experimental flume (Boutron et al. 2009). A
2 lower water flow also decreases the degree of non-equilibrium sorption (Pot et al., 2005). As
3 in the experiment conducted under laboratory conditions, procymidone (from 10.2 to 45.4%)
4 was eluted in higher amounts than diuron (from 8.9 to 27.8%) and tebuconazole (from 2.7 to
5 12.9%) through the three soils. Again, these results might be explained by the higher sorption
6 coefficients of tebuconazole ($K_d = 10.5-42.2 \text{ L kg}^{-1}$) relative to those of procymidone ($K_d =$
7 $4.2-14.1 \text{ L kg}^{-1}$) and diuron ($K_d = 2.2-12.0 \text{ L kg}^{-1}$) (Table 3) and possible facilitated transport
8 of procymidone by dissolved organic matter as previously suggested by Gonzales-Pradas et
9 al. (2002).

10 As with the experiment conducted under laboratory conditions, significant quantities of
11 the three pesticides were released to the soil solutions after the second and third runoff events
12 (from 23.7 to 69.0% of the total leached amounts). The buffer zone and grass-covered inter-
13 row soils released less pesticide to the soil solution (from 1.9 to 3.8% and from 3.1 to 5.6% of
14 the applied amounts, respectively) than the bare soil (7.2 to 15.0%) (Table 7), in relation with
15 their sorption coefficients ($K_d = 12.0-42.2 \text{ L kg}^{-1}$ and $K_d = 4.9-19.1 \text{ L kg}^{-1}$ for the buffer zone
16 and grass cover soils, respectively, and $K_d = 2.2-10.5 \text{ L kg}^{-1}$ for the bare soil) (Table 7). In
17 addition, these results could be explained by a long-term non-equilibrium sorption.
18 Furthermore, the formation of non-extractable residues could be greater in the buffer zone and
19 the grass-covered soils than in the bare soil. As in the laboratory experiment, and probably for
20 the same reasons previously given, procymidone was released in greater amounts (3.8 to
21 15.0%) than tebuconazole (1.9 to 7.6%) and diuron (3.4 to 7.2%) (Table 7).

22 Boivin et al. (2007) also found that more diuron (34%) than tebuconazole (31%) leached
23 through the buffer zone at the St Joseph experimental site. Although their values are far
24 higher than ours (8.5% for diuron and 0.8% for tebuconazole), the uncertainty associated with
25 their results must be considered. Indeed, they estimated the amounts of pesticides leached

1 through the buffer strip from the measured water volumes and pesticide concentrations
2 reaching the four lysimeters, which only collected 1 m² (4%) of the buffer surface, and
3 extrapolated the results to the whole surface.

4 5 **4. Conclusions**

6
7 Results on pesticide transfer through the undisturbed soil columns according to the
8 different soil cover modalities (bare soil or buffer zone) were in good agreement whatever
9 they were obtained under laboratory or outdoor conditions which could be explained by the
10 low rainfall amount during the outdoor experiment; considering all the soil cover modalities
11 (bare soil or buffer zone and grass inter-rows), it systematically appears that more diuron than
12 tebuconazole was recovered in the leachates, in agreement with their sorption coefficients.
13 However, more procymidone than diuron was recovered in the leachates, despite their similar
14 sorption coefficients. This may be due to the facilitated transport of procymidone by dissolved
15 organic matter. All three pesticides used in this study were eluted in lower amounts through
16 the grass-covered soils (buffer zone and inter-rows) than through the bare soil, in relation with
17 their sorption coefficients, which were from 2 to 4 times higher in the grass-cover soils
18 (buffer zone and inter rows) than in the bare soil. Thus it appears that grass-covered soils
19 (buffer zone and inter-rows) reduce the amounts of pesticide leached; consequently, buffer
20 zones decrease the risk of surface water contamination without increasing the risk of
21 groundwater contamination by pesticides. Nevertheless, the reduction of the water infiltration
22 capacity in the wheeled compacted grass-covered inter-row may limit its effectiveness in
23 pesticide surface transfer reduction by increasing runoff. Consequently, it is not enough to
24 establish a grass cover in the inter-row, one also has to check its good infiltration capacity
25 especially avoiding soil compaction by tractors. However, significant quantities of pesticides

1 were released from the soil after runoff events occurring 2 to 4 weeks after the initial runoff
2 event containing the pesticides and were systematically higher from the bare soil than from
3 the grassed soils.

4 Comparison with field studies on pesticide transfer through a buffer zone which were
5 conducted in the same area from which the soil columns were collected, suggests that higher
6 pesticide leaching rates occur in the field. However, in the latter, a higher spatial
7 heterogeneity of runoff and subsequent infiltration through the surface of the grassed plot,
8 coupled with the higher runoff water flow rates may explain this difference. Indeed, both
9 phenomena are suspected to lead to a higher participation of macroporous pathways
10 contributing to the total leachate volume, increasing the risk of rapid transport without
11 equilibrium sorption. Consequently, in complement of the undisturbed soil columns study
12 reported here, which permitted to compare the influence of the different soil cover modalities
13 on pesticide transfer with a reasonable experimental effort, further field monitoring is
14 necessary to assess the real infiltration capacity of a buffer zone taking into account the spatial
15 heterogeneity of this parameter onto the plot and the influence of macropore flow on pesticide
16 leaching through the grass cover soil. In addition, the long-term behaviour of pesticides
17 accumulated in the buffer zone should be also monitored.

18 19 **Acknowledgements**

20 We thank M. Ducroux and M. Guignier (viticulturists in Villié-Morgon) who so graciously
21 granted us access to their vineyards. The authors would like to thank A. Jacobson (Utah State
22 University, Logan, USA) for her valuable comments on the manuscript. This work was
23 financially supported in part by the 'PAPIER' ECOGER Program.
