“Times” as operation that emerges from a rectangular arrangement. Until now, multiplicative reasoning and calculations are limited to situations where combining, partitioning and distributing are modelled with sequences of multiples (times tables). The following cycle of measurement activities extends stepwise multiplicative reasoning by mean of the rectangular arrangement of objects. First the multiplication of factors emerges from pacing concrete units in the length and width and using familiar products to find the number of units. This way of reasoning is then adapted to (1) calculate the number of tales of a given arrangement and to transform it by substituting the initial units in bigger or smaller ones; (2) to recognize the two rectangular arrangements of the starts of the American flag. The operative notion of commutativity ($12 \times 6 = 6 \times 12$) and distributivity emerges from these activities. This increases the power of multiplicative reasoning and extends the application of the available factual knowledge.

Endpoint: multiplicity goes together with divisibility and proportional relationship. The last inquiry is conceived to connect the conceptual, procedural and factual knowledge constructed along the reflection about the ways of reasoning and calculating in the above multiplicative setting. The challenging question is why hours do have 60 minutes. Students are engaged to “unroll” the time line of a clock segmented in units of 5 and 15 minutes and to symbolize the accumulation of time with the underlying numbers’ pattern and the corresponding product to identify how one hour is divided in equal parts (5, 10, 15, ... $\rightarrow 12 \times 5$; 10, 20, 30 $\rightarrow 6 \times 10$; etc.). The inverted number relation met before comes back by the connection of $4 \times 15$ and $2 \times 30$ with respectively 15 minutes as “a quarter of an hour” and 30 minutes as “half an hour”. Finally, by identifying all the possible ways of grouping 60 chairs in a rectangle, children discover the hide equivalents of the ‘products of the clock’. 60 then appears as ‘an object’ that can be composed and decomposed in “many ways” (e.g. $4 \times 15 = 15 \times 4$ related to $60 \div 4$ and $60 \div 15$).

**Key principles of designing task with focus on flexibility**

The chosen approach prompts the systematic extension of the numerical relationships, arithmetic operations and factual knowledge using multiplication and division to model situations. We foster that students come to act and reason in a “mathematical reality” (e.g. Freudenthal, 2003; Tall, 2013; Gravemeijer, Bruin-Muurling, Kraemer & van Stiphout, 2013), manipulating flexibly mathematical
objects and relationships at hand through symbolic representation as professional mathematicians do (e.g. Gray & Tall, 1994).

We use the framework above to develop three kinds of tasks with a specific function and to articulate them transversally and vertically in cycles of inquiries (Bell, 1993). Open tasks as “Prawn skewers” (Figure 1) prompt the exploration of a key idea (e.g. envisioning multiplicities of identical things thinking in some numbers of some amount) and the development of a symbolism to express it (e.g. \( __ \times __ \)) to express it (e.g. Bell, 1993; Back, 2011). Numerical tasks (without context) promote the organization of numbers as ties in a web of number relations (Van Hiele, 1985) which extend the personal factual knowledge (Threlfall, 2002) and the development of specific skills such as analyzing numbers multiplicatively and using the process-object symbolic to explore unfamiliar forms of operating with numbers as mental objects (Gray and Tall, 1994). Conventional tasks focus on understanding how a particular relationship (theorem-in-action) of a scheme works and can be adapted in a limited class of situations.

The constructed webs of number relations connected to the schemes of reasoning and the classes of situations form the horizontal junctions between the tasks. The same tasks are articulated vertically, considering the transitions from a lower (informal) to a higher (formal) level of reasoning, symbolizing and computing.

The task ‘Prawn skewers’ (Figure 1) exemplifies this approach. The task provides an opportunity to explore “partitioning” as a process of structuring quantities on the own level of understanding the relationships involved in equal group situations (see draft of conjectural theory above) and using the number patterns in the available tables of multiplication. We conjectured that the majority of the children would notice that 61 is an odd number (ending by 1), near 60 (60+1 and/or 62-1). Focusing by turn on number 60, they would in first instance notice it can be reached counting by two and/or ten which suggests partitioning the pile of prawns by way of repeated addition (2+2+2+2…; 10+10+10+10+10+10). Students that operate on a higher level of understanding two-digit numbers would associate 60 with 6x10 seen as “six tens”. Then, one can explore other grouping possibilities, varying additively or multiplicatively the number of prawns of each stick or transforming a founded partition in a new one, substituting smaller composite units by bigger ones and vice versa.

Considering the current phase of development of grade 2 students, we expect difficulties with the symbolization of founded structures with products (e.g. difference between “6 times 10” written as 6 \( \times \) 10 and “10 times 6” written as 10\( \times \)6) and related misunderstanding in the communication about the transformation of one possible structure into another one (e.g. 6 times 10 into 12 times 5; 6\( \times \)10=12\( \times \)5). Finally, we expect that some students could first approach the task by describing the process of exhausting the pile of 61 prawns with an arithmetical sequence of repeated subtraction and then (quickly) invert their modeling to avoid the (arising) computing difficulties.

**Methodology**

The project plan is based on a qualitative and interpretative methodology (Denzin & Lincoln, 2005) with a design research approach (Gravemeijer & Cobb, 2006). The preparation of teaching experiences is a crucial aspect of the project plan.

To prepare teaching experiences we design and reformulate mathematical tasks using a three-step cyclic process: (1) design tasks, (2) analyze what children noticed in the numbers and how they use
their knowledge about numbers and operations to solve the task presented along clinical interviews and (3) reformulate the previous task.

This text refers to one teaching experiment that involved 24 grade 2 students (age 7-8) and focuses on the students reasoning to solve the task ‘Prawn Skewer’ (Figure 1). Students knew how to add and subtract numbers until 1000 and had some experience in solving word problems. They hadn’t yet learned the multiplication tables. Data was collected through video and audio recordings of the classroom work, researchers’ notes, audio recordings of the preparation and reflection meetings with the school teacher involved.

The proposed task was designed and reformulated according to the data analysis of four clinical interviews, where students (4 students, 8-year-old) solved a first version of the task (Figure 2) analyzed in Brocardo, Kraemer, Mendes and Delgado (2015).

Since the given alternatives in the first version (groups of 3 or groups of 5) seemed to hinder the envisioning of other ways of grouping, we decided to give students the freedom to experiment and evaluate different ways of grouping, taking into account two conditions: the given quantity of prawns and the freedom to invite more or less friends. We also ‘opened’ the illustration of the task, to stimulate the students’ own constructions. Finally, by giving only the number of prawns, and by continuing to choose the ‘ugly’ number 61 (in the sense of Thompson & Saldanha, 2003), we created a problem that these students surely never encountered before.

Under these conditions, we expected that students would envision different possibilities of sticking a pile of 61 prawns, modeling from two ways of understanding “division”. This is to say, reasoning in terms of exhausting the pile by a sequence of repetitive subtraction (ratio/measurement division), and/or reasoning from the converse idea of accumulating 61 by counting on n by n (division as converse of multiplication) (Freudenthal, 1982). In second instance, we expected that the choice condition of the task should stimulate students to compare envisioned ways of grouping, considering the relation between the multiplier (number of sticks) and the multiplicand (number of prawns in each stick). Exhausting, taking away a smaller set of prawns go together with making more sticks and subtracting a bigger set with obtaining less sticks. And, increasing the number of sticks by accumulating goes together with decreasing the number of prawns in each stick, as putting a bigger set of prawns goes together with obtaining less sticks, while sticking less prawns provides more sticks. Finally, we expect a great variety of modeling, verbal explanation, and calculations, according to

---

**Figure 1: The tasks ‘Prawn skewer’ (reformulated)**

*For Vasco’s birthday lunch he prepares prawn skewers. He hesitates between using three or five prawns in each skewer.*

1. Can you explain what Vasco is thinking? How would you explain it to one of your colleagues? Which type of skewers would you prepare? Why?

2. Vasco is counting the prawns that his mother bought: 52, 54, 56, 58, 60, 61!

Think about your choice. Imagine the number of skewers you can do with this number of prawns. How many, more or less? More than 5? More than 10? More than 20? How would you find the exact number of skewers?

**Figure 2: The tasks ‘Prawn skewer’ (first version)**

*If you were Vasco how would you prepare the skewers? How many would you prepare? Why? ... 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61!*

It's Vasco’s birthday. To his birthday party he wants to prepare skewers with the same number of prawns. His mother bought a sac with 61 prawns.
levels of memorizing the products/multiples of the tables, and understanding ‘multiplicity’ and ‘proportionality’ in the experienced contexts of multiplicative thinking.

Results

The analyses of the working sheets of the students and of some dialogues occurred in the classroom gave us a global idea of the patterns of reasoning that students used to solve this task. Globally, we identified the following patterns of reasoning: trying with 18 sticks (they counted the sticks represented in the illustration); drawing the prawns’ skewers one by one (with 18 sticks); putting 2 by 2 we will arrive to 60; putting 10 by 10 gives 60; adaptation of grouping by 10 making one skewer with 11 prawn (Figure 3); adaptation by “grouping by one”; putting 5 by 5 and/or 15 by 15 gives 60 (Figure 4); intuitive notion/feeling that putting by n would give 61.

![Figure 3: Adaptation of grouping by tens, making one skewer with 11 prawns](image)

![Figure 4: Putting by 15 and by 5 with verbal description of the result](image)

The most frequent way of modeling was trying to reach 60 arithmetically, by repeated addition. Some students shortcut their long addition by mean of doubling consecutively the terms (Figure 5).

![Figure 5: Shortcutting by successively doubling as way of controlling / justifying](image)

Some dialogues suggest that some pairs of students are jumping to 60 in a kind of mental sequence of multiples, without keeping track. Having arrived at 60, they must then count the numbers of “tens” to derive the multiplier from their long addition.

Some pairs of students initially understood that they could choose the number of guests but failed to connect the given 61 prawns with the 18 sticks they counted in the picture. In a short dialog with the teacher, they envisioned ways of grouping with units, leaded by a kind of intuition (feeling) that the repeated addition they had in mind would give 61. Vera was thinking about $11 + 11 + 11 \ldots$, and moved to $5 + 5 + 5 \ldots$ as response on the teacher’s question “Why 11?”. Her colleague Martin was expecting that putting prawns by 7 would give 61, “since $7 + 7 = 14$ and $14 + 7 = 21$”.
José drew the 18 sticks and then ‘sticks’ 4 prawns in each (Figure 6). He then symbolized the represented accumulation with the long addition $4+4+4\ldots$ and tried to determine the total number of prawns, by doubling 4 and 8, transforming $4+4+4+4\ldots$ (18 times four) into $8+8+8\ldots$ (9 times 8) and $16+16+16+16+8$.

Only one group used repeated subtraction (viewpoint of exhausting 61; Figure 7). They began to subtract 1 to obtain 60 but it seemed they changed their idea and begun to work with 61, subtracting 5 until they have a remainder smaller than 5.

Finally, two pairs of students associated the information of the story and the illustration of the task with the decomposition of 61 into two parts. One pair is thinking about a combination of 18 children (the number of sticks of the illustration) and 40 children (a multiple of 10). The other pair proposes “as $41 + 20 = 61$, one has 41 and the other 20” and does not adds any other justification.

**Implications for task Design**

From data analysis, we may conjecture that the formulated instruction does not scaffold the expected mathematization including: (1) finding and representing adequately different forms of sticking the prawns, (2) choosing the preferred way, and (3) justifying this choice. It seems that “Why” is interpreted as an instruction to demonstrate and/or control that the modeling with the sequence of repeated addition indeed gives 60 prawns. This interpretation explains the spontaneous short-cutting of long additions (Figure 5). A solution to avoid this is to structure the task in an exploring phase asking explicitly to look for possible ways of sticking and a reflective one including the choice and the justification of the referred form of sticking.

On relating the choice of 61 as cardinal of the set, we can argument that the complexity of taking away, could explain the high frequency of the modeling by repeated addition and the single use of repeated subtraction. Since more students associate 61 with the near even number 60, and since the table of two and 4 are memorized, it would be meaningful to replace 61 by 62 to increase the chance that more students balanced between modeling by jumping back to exhaust 62 and jumping forwards to reach 62. We might expect that, being aware that this way of grouping would give a lot of ‘small’ sticks, more students would try to subtract a bigger quantity and finally move to jumping forwards to avoid annoying calculations.
Finally, since the representation of some stick may suggest some students to fix the multiplier and model the process directly by drawing all the set of prawns, stick by stick, we have to change the illustration to avoid the observed try-and-error approaches.

**Implications for task design in the field of multiplication**

In this text, we explicit how we analyze the influence of contexts, numbers and pictures/images aiming to potentially facilitate *noticing* (Threlfall, 2002) relevant numerical relations and *envisioning* different approaches that emerge from noticing.

Another aspect of our analysis is related with the importance to propose non-conventional equal group problems to develop flexible multiplicative reasoning. In all conventional equal group problems, two values are given. Consequently, children learn to identify the ‘kind’ of problem from the story and the given numbers. Then, they solve it applying the standard scheme of reasoning. Children’s approaches and solutions of the task ‘Prawn Skewers’ show the advantage of the missing multiplayer and multiplicand as stressed by Back (2011). They have to adapt their common way of thinking to the unusual conditions of the task (Vergnaud, 2009) noticing numerical relations and envisioning different approaches. Some fixed the multiplier counting the sticks of the pictures. Others inferred that they had to fix the number of prawns on each stick and to look how many skewers can be made. The vast majority envisioned the all process of sticking, using the knowledge that counting by ten leads to 60. A crucial advantage of these non-conventional problems is that the teacher can focus the reflection on the relationship between “continually putting prawns by \( n \)” and “taking again and again \( n \) prawns” and the use of asymmetric role of the multiplier and the multiplicand to symbolize both process.

The role of design in conceptual change:  
The case of proportional reasoning

Noa Cohen- Eliyahu
The Hebrew University of Jerusalem, School of Education, Teacher Education Program, Jerusalem, Israel; noa.cohen-eliyahu@mail.huji.ac.il

Conceptual change is extremely difficult to trigger in mathematics and science education. The present study shows the special role of design – in the fact that design can afford behaviors that lead to conceptual change. We chose the domain of proportional reasoning. The design was based on collaborative and argumentative scripts, provision of a tool for checking hypotheses, and arrangement of students with different strategies. Above all we created a task, the Blocks Task, that invites students with different strategies different solutions, whereby creating (socio-)cognitive conflicts with the possibility of enhancing conceptual change. The participants were 496 ninth graders. A central result is that performing the task resulted in conceptual change. It was also shown that the provision of a tool for checking hypotheses yielded substantially larger gains. We conclude by providing design principles for fostering conceptual change in mathematics.

Keywords: Conceptual change, cognitive conflict, task design, proportional reasoning, collaborative work.

The present paper

The focus of the present paper

The present paper aims to expose whether the block task is effective in triggering conceptual change in proportional reasoning. While triggering conceptual change in mathematics and in science education is a very challenging task. We have defined conditions for task design and we showed that they can dramatically boost conceptual change and learning in the field of proportion reasoning: Collaborative scripts, the arrangement of students in small groups and the provision of a hypothesis testing device for feedback were central design decisions. Above all, we created a special task, the Blocks Task, which invites students with different strategies in proportional reasoning (that reflect different levels in proportional reasoning) to exhibit different solutions, by such creating socio-cognitive conflicts.

Theoretical framework

The process of conceptual change had been described in literature in various ways. The pioneering model of Posner, Strike, Hewson, and Gertzog (1982) had described the conceptual change of replacing the earlier premature, and somewhat naïve, conceptions (which, at times, contradicts the scientific explanations) with more up-to-date scientific conceptions. The trigger for this change had been the dissatisfactions with the earlier conceptions. Other scholars (e.g. Vosniadou, & Verschaffel, 2004) replaced Posner et al.'s model with a model they called a synthetic model which is based on the combination of a scientific concept with the student naïve preliminary concept. Cognitive conflict had been for a long time considered as a major, necessary ingredient in the development of psychological theories that explain conceptual changes. The role of cognitive conflict is important in many mathematical fields Stylianides and Stylianides (2009) related to the potential concealed in
cognitive conflict to support the development of the student knowledge. In the domain of proof, counterexamples play a great deal as a pivotal means in creating and resolving a cognitive conflict (Zazkis, & Chernoff, 2008, Stylianides, & Stylianides, 2009). However, it was also found that introducing conflicting data was generally not sufficient for triggering conceptual change (Limón, 2001). Collaborative and argumentative settings as well as the provision of feedback are among the means described in the literature which may prompt the development of conceptual change among students (Schwarz, 2009). The block task which was designed for the purpose of the present study has been a sophistication of the blocks task developed by Harel, Behr, Lesh and Post (1992). Harel and colleagues designed the original Blocks Task as a diagnostic tool to assess the level of proportional reasoning of adolescents. I modified the task as a learning task with the potential for triggering conceptual change (Cohen-Eliyahu, 2001). The modifications consisted of posing the task in a dyadic setting, providing a collaborative and argumentative script in their interactions, and providing a hypothesis testing device (a balance) for checking hypotheses. This mathematical task has the potential to create socio-cognitive conflicts based on the three aforementioned conditions. Schwarz and Lichevski (2007) showed that the design yielded conceptual change. In an additional study, Asterhan, Schwarz and Cohen-Eliyahu (2014) examined the mechanisms that govern conceptual change with the Blocks task. In the present paper, I examine the role of design in triggering conceptual change. Let us first describe succinctly the study. More information can be found in Asterhan, Schwarz and Cohen-Eliyahu (2014).

Method

Participants

The participants were 496 Israeli ninth graders from large metropolitan areas (After studying the subject proportion ratio and percentages). 16 groups were formed with different conditions for each group: individual or pair work, with or without weighing condition (the hypothesis testing device). Students were paired according to their initial solution strategies, in order to create varied social settings based on differing initial cognitive levels. Three strategies were focused on: Students with additive strategies (N=196), students with proto-proportional strategies (N=194) and students with proportional strategies (N = 106).

Tools

The Blocks tasks were designed according to three aforementioned conditions in the field of mathematics, and its aim was to facilitate learning (i.e. conceptual change) of ratio and proportion, as follows: (a) The task enables collaborative or individual work. (b) There is a tool (scales) with which one may check (or not) whether hypotheses are correct. In other words, students receive feedback on their solutions by using scales (c) The task allows the activation of a variety of strategies by which students may be differentiated according to their levels of thinking, which may facilitate teaming them up according to their levels of proportional thinking. In each task students are shown 4 three dimensional blocks constructed from bricks (A,B,C and D). They are told the bricks in A and C is identical (the same weight = the same color) and the same is true for bricks in B and D. In each trial, students are given information about the relation between the two base block constructions A and B (A is heavier than B, B is heavier than A, or they are of equal weight). They are asked to determine the relation between the weights of the two target blocks, C and D, choosing one of the following...
four options: “C is heavier than D”, “D is heavier than C”, “They are of the same weight”, or “Impossible to determine”. They are required to provide a verbal explanation for their choice.

Figure 1: Blocks Task 1

In the current study seven configuration of the Blocks tasks had been designed. The design was aimed at leading wrong reasoning strategies to wrong answers. For example, a student using Visual explanations typically would claim that “it has less bricks in it”. A student adopting an additive reasoning strategy would use an explanation such as "when B has 6 more bricks than A, A and B weigh the same. D has 13 bricks more than C so D weighs more than C." A student adopting a proto-proportional reasoning strategy would typically draw a wrong conclusion: For example, he would say "B has more bricks than A but they have the same weight so each brick in A is heavier than single brick in B. C is 13 bricks less than D but each bricks weigh more so it's impossible to decide." Students adopting a proportional reasoning strategy would typically predict the right conclusion that C weighs more than D. They would say something like, "10 bricks in A(10a) have the same weight as 16 in B(16b) i.e. one single brick in A weighs 1.6 times one single brick in B a=1.6b. so 24 bricks in C weigh 24*a=24*1.6b = 38.4b that is more than 37b bricks in D." We see then that the Blocks task was designed to lead students with inferior strategies to give wrong answers.

Procedure

The current study consisted in three stages: pre- test, intervention and post- test.

Stage 1: Assessment and selection– pre-test. Five Blocks Task Test was administered in pen-and paper format to all students in the ninth grade classes to assess their initial level of proportional reasoning. In each tasks the blacks' constructions (A, B, C and D) were presented to the class and trained research assistants called aloud the instruction. According to their initial reasoning strategy students were arranged in order to create socio-cognitive conflicts.

Stage 2: Learning stage. Students were asked to solve collaboratively two different Blocks Tasks according to the aforementioned condition. They were provided a collaborative and argumentative script: The dyads asked to solve the tasks together. they were invited to collaborate and to argue with each other. Additionally, students that work with hypothesis testing condition get a scale after they finished each task to check their answer. An experimenter helped them to put the blocks constructions (C and D) on the scale and told them the correct answer, and asked them to explain it. All students, dyads or individuals with or without hypothesis testing device, were interviewed while this stage by trained research assistants who, repeated the instruction again and asked the student to explain their answers.

Stage 3: post – test the student answered the five Blocks Task Test again individually.
All the participants completed the three stages in less than one month.

**Results**

Over the entire sample, it appears that in all conditions, conceptual learning was attained. T–test showed significant results in comparing differential from pre-test to post-test to zero.

Analyses were conducted with a mixed model (SAS PROC MIXED) with random effects of dyad within condition and of individual within dyad and condition. Differentials means and standard deviations between pretest and posttest performance per condition are reported in Table 1.

**Table 1: Differentials mean (and SD) between pretest and posttest scores on the BlocksTask (N=488)**

There is significant different between Students who worked with feedback (single or peer) (M=.25, SD=.04) and students who worked without feedback (single or peer) (M=.13, SD=.04). The results confirmed that hypothesis-testing improved learning (F (1,422)= 5.10 p= 0.024). But in general there is no advantage to work with peer over individual work.

Further analyses were made in purpose to reveal what accord in different pairing condition. Focusing on students who lacked full proportional reasoning, non-Proportional students (Proto – proportional students (ProtoS) and additive –students (AddS)). Differentials means between pretest and posttest and standard deviations performance for non-Proportional students are reported in Table 2.

There is significant different between non-Proportional Students who worked with feedback (single or peer) (M=.26, SD=.03) and students who worked without feedback (single or peer) (M=.16, SD=.03). The results confirmed that hypothesis-testing improved learning (F (1,239)= 4.13 p= 0.043). In addition, Focusing on the non-Proportional students revealed that apart from the hypothesis-testing condition, there is significant affect to the pairing condition ((F(3, 225)=10.98, p<.0001). and the Tukey-Kramer post hoc test showed that most efficient pairing was with a partner with full proportional reasoning. The interaction between the hypothesis-testing condition and the pairing condition is significant (F(3,225)= 3.22, p=0.024). The Tukey-Kramer post hoc test showed that with feedback condition students who worked with student who reached proportional reasoning gained more than student who worked with any other pairing. But, without feedback condition the result wasn't significant.

We present here the example of two students, Ido and Shira, and show how the design of the task helped them advancing their strategies in proportional reasoning. Ido and Shira both started, according to their pre-test, in a proto-proportional stage. Neither of them had a fully proportional answer to any of the tasks, but they were well aware of the importance of looking at each of the cubes separately. After the interaction, they both progressed: Shira gave one full-fledged proportional answer and Ido, two. Right from the start, elements of the proportional discourse were apparent in both Shira and Ido’s interaction. Interestingly, the additive discourse co-existed with elements of the proportional discourse all through the interaction about the first task (see figure 2). Thus, for instance, Shira first suggested an additive argument:

24 Shira: I think, I think this (C) is bigger than this (D) because here they tell us that this (A), no, sorry, because here they tell us that this (A) is smaller than this (B) although here (A) there are more, but only by one cube more, so if here (C) there is more in three cubes, so that says that this (C) is big.

Ido, on the other hand, starts referring to multiplicative routines:

25 Ido: Look, if you take- this (A) is 11, this (A) is bigger than this (B) by 1 and here (C) it’s bigger times 3 than this (A)

26 Shira: right

27 Ido: yeah, try multiplying both of them by 3 and you’ll see what happens because it’s thirty something. 10 times 3 is 30 so 10 times 3 is 30 and 11 times 3 is 33. If you multiply it by 3 it comes out 33.

28 Shira: oh, so, like I got it, I got it, so here it’s one

29-30 Ido: and thirty one, two… that means if you put this (A & B) times 3 you’d get here 33 and 30 and if you add another one to each one of them so it will be 34 and 31.
Interestingly, Ido and Shira’s solution, though not accurately proportional (Ido found a linear relationship between the block structures, not a proportional one), still leads the two students to a correct solution. In other words, it leads them to predict that $C < D$ (by preserving the linear relationship), and the scales do not contradict it. Thus, there is no resistance of material agency. During the second phase (where $10A_{\text{cubes}} = 12B_{\text{cubes}}$), it is Ido’s disciplinary agency (that is, the previous mathematical knowledge obtained by Ido) that resists the additive discourse. The pair starts out by trying to implement the successful routine that they had employed in the first task:

106 Shira: Now, OK here there are 10, can you show me the calculation again? This (A) times 3.

After some calculations, Ido realizes this solution brings them to a dead end:

115 Ido: OK, look, we multiplied both of them times two, it (A) turned out 20 and this (B) turned out 24. Now, if we add to both of them 3, you get this (B*2) plus 3 gives 27 like this (D) and this (A*2) plus 3 gives 23, it didn’t get to 24.

According to this linear relationship, Ido and Shira agree that C and D are not equal. However, they do not have a way of determining which block (C or D) is heavier. This, because the only way they know to use the linear relationship is by applying it to affirm the relationship between the C and D blocks stays the same as between A and B. Realizing that the former routine does not work (resistance from disciplinary agency), Shira goes back to the additive discourse:

120 Shira: so look here (C & D) this is by 3 more (meaning D has 3 more than C) and here (A & B) it’s only by 2 more (meaning B has 2 more than A), get it?

After quite a long discussion (24 turns), Shira convinces Ido of her additive solution. But as she writes up her argument on the paper, Ido continues calculating numbers. The experimenter turns Shira’s attention to that and Ido explains to Shira:

147 Ido: look, this (A) is 10 and here (B) it’s 12. Just saying, I’m not saying it’s true but let’s suppose each mass here (A) is 3 and here (B) each cube is 2.5 cause that’s less and they are equal cause 3 times 10 is 30 and also 2.5 times 12 is 30 and the weight between them is equal, but each cube is different like they said here. If you multiply to get to 24 you’ll get 72. If you multiply this (a cube in D) times twenty s… twenty..

148 Shira: Oh, I get it like 2.5 times 27.

149 Ido: yes if you multiply you’ll get 67½ that means that C is bigger, (the) weight is higher than D, see?
We can see that Ido changed his mind before the balance scales proved Shira’s additive solution to be wrong. We can only hypothesize why this happened. It seems the resistance that was most important here was that of disciplinary agency. Both Shira and Ido could not initially find a multiplicative routine that would satisfy them. But once such a routine was found by Ido, they happily switched to it, being aware all along of the appropriateness of the multiplicative discourse for the problem at hand. Ido and Shira were actively engaged in convincing each other and questioning each other’s solutions. Especially impressive was Shira’s attempt, once she was convinced by Ido’s new multiplicative solution, to critically examine her previous solution:

181 Shira: so how could it be (true) if like this (covers one cube from the D structure with her hand so that there is a difference of only 2 between D and C) it’s equal and like this (raises her hand to expose the whole structure) it (C) is bigger?

182 Ido: because the weight of the cubes is not the same.

Shira is not convinced. She repeats her argument that D minus 1 cube equals C, but now Ido challenges this assumption: “who said it’s equal?” He then goes on to explain

188 Ido: you told me that there are two points (probably means cubes) less so you add two here and another one but you don’t know, the two point here (A & B) and the two points here (C & D) are not the same.

189 Shira: The mass is different, I get it.

Thus, even though Ido is the main one to pursue the proportional solution and substantiate it, Shira is very active in her attempts to follow his logic, and to compare it with her own previous solution. Only then she is convince that the additive solution is invalid.

Conclusion

The Blocks task resulted in substantial learning which may be termed conceptual change, since under all conditions the students improved their solution strategies very significantly from the pre to the post – test. These are impressive findings that suggest the crucial role of design in triggering conceptual change. The additional results consistent with the assumptions based on previous researches (Schwarz and Lichevski, 2007) about the conditions that promote conceptual change. The very rich dialogue between Ido and Shira revealed the crucial role of task design in triggering conceptual change that lead to learning. In the pre-test both student initial strategy were proto-proportional reasoning. During the Learning stage (intervention) they both made a huge advance and promote their strategies reasoning to proportional as been founded in the post-test. The Blocks task design afforded and invited, as we saw in Shira and Ido very rich dialogue, a variety of reasoning strategies (Additive, Proto-proportional & Proportional). Shira and Ido considered those antithetic strategies by justify their claims and explain to each other their opinions this socio and cognitive conflict lead them to collaborate and argument in dyad and that lead to the desired conceptual change. Also in Ido and Shira case the scale's checking hypotheses "just" confirmed their solution. After the first task confirmation done with the scales, for Ido it was a trigger in the second task to continue searching for other option even if the AddS sound acceptable (120 Shira). The deep dialogue showed the power of the collaborative work, investigating each other ideas (an additive and a proto-proportional solutions) cause emerging of a new insight (proportional –solution). The case of Shira
and Ido exemplifies the importance of collaborative and argumentative scripts, of a tool for receiving feedback (the scale), of the arrangement in dyads, but foremost of the design of the task that led students with inferior strategies to arrive to wrong conclusions, to check them with the scale and to revise them accordingly. In conclusion, as the statistical result and Ido and Shira's dialogue showed, the task design allows the use of variety of confronting strategies that may led to socio- cognitive conflict between the dyads. In the statistical result we find that gap between students play a major role. Non-proportional students with hypothesis-testing condition is significantly advanced proportional reasoning when they work with proportional students. In Ido and Shira case also it looked they started with the same strategies we reveled in the rich dialogue gap between their strategies. when Shira used automatically additive strategy Ido looked for another option that explain his proto-proportional strategy. The hypothesis-testing condition that confirmed his first answer helped him to persist in finding satisfactory solution.

It seems that the next step is to expand the study to examine the effectiveness of the conditions defined in designing mathematical tasks in other areas.

From textbook to classroom: A research on teachers’ use of pedagogical resources in the context of primary school in the French speaking part of Switzerland

Audrey Daina
Geneva University and HEP Vaud, DiMaGe, Switzerland; audrey.daina@hepl.ch.

In French speaking Switzerland, primary school teachers use uniform textbooks edited by the government. These official textbooks are specific, they provide a source of activities but do not give information about how to organize the teaching. In this context, it is interesting to observe how teachers choose and organize in-class activities, the different ways they use textbooks, and the consequences in the classroom. Our research is a case study, which is based on interviews with teachers and classroom observation. The analysis we will present in this contribution were conducted using the model of Robert and Rogalski (2005), which allows us to describe teachers’ choices as a coherent system that does not depend only on learning objectives but also on characteristics of the profession and on certain constraints.

Keywords: teachers’ practice, textbooks, primary school, cross-analysis.

Introduction

School textbook is a field of research which has been widely increasing since the last three decades as described by Fan, Zhu and Zhenzhen (2013) survey study for the special issue of ZDM “Textbook Research in Mathematics Education”. The authors conclude this survey by suggesting future directions in this field of research:

it is necessary for researchers to establish a more solid fundamental conceptualization and theoretical underpinning of the role of textbooks and the relationship between textbooks and other variables not only in curriculum, teaching and learning but also in a wider educational and social context” (Ibid, p. 643)

The large-scale cross national research study TIMSS allowed us to have a wider vision on the role of textbook in connection with social or political issues as presented by Valverde and al. (2002) who analyze textbooks in terms of cross-national differences in educational opportunities “the configuration of social, political and pedagogical conditions to provide pupils chances to acquire knowledge, to develop skills and to form attitudes concerning school subjects” (Ibid, p. 6).

Our contribution goes in this direction by presenting the results based on our PhD theses (Daina 2013), which aimed to describe and analyze:

• the social and political context in which the uniform textbooks are designed in French speaking part of Switzerland, known as “Moyens d’Enseignement Romand pour les Mathématiques”(MERM);
• how five teachers in Geneva use this resource for mathematics, considering their “ordinary” practices.
Our research brings a different focus on the question of the connections between social and political issues and teachers practices by considering a qualitative methodology and a theoretical framework which allowed us to understand the practice we observe as a complex but coherent system that is dynamic and does not depend only on learning objectives but also on characteristics of the profession and on certain constraints we can infer from the study of the context (Robert & Rogalski, 2005).

**Research design**

Our research is a case study, which is based on interviews with teachers and classroom observation. The data were collected from April to June 2009 in five classrooms in Geneva in two different schools. In every class, we collected the following data: an interview before the teaching sequence; the observations in class with video recordings of the various activities of the teaching sequence on the theme of area measure; an interview at the end of the teaching sequence.

To understand the political and social issues connected to our context of study, we collected selected documents, which showed different aspects of the official textbook design process (institutional requirements, project design, review report, etc.)

**Theoretical frameworks and research questions**

Our project aimed to study how teachers use the textbook and prepare their lessons which is an “invisible” part of the teachers’ practices. In addition, we wanted to observe ordinary practices, with all the complexity implied. Therefore, to build our theoretical framework and our methodology we lean on two theoretical approaches: Margolinas’ model (2005) and the model of Robert and Rogalski (cross-analysis of the teacher’s activity). We did not combine this two framework, instead we asked different independent questions relating to these two theoretical frameworks which we study using tools and methodology from the relevant framework. In this presentation, we will focus on the second model and the results related to it.

**The model of Robert and Rogalski: Cross-analysis of the teacher’s activity**

This model combines two different approaches. Firstly, a didactic approach: teacher’s practices are linked with the learning objectives. In this sense, the knowledge content of the teaching and the way the teacher organizes his teaching are analyzed using a didactic theoretical framework. Secondly, a psychological approach from cognitive ergonomics: the teacher is considered as a professional whose practices are subject to a professional contract, with particular goals, repertories of action, representations of mathematical objects and their learning, and, more generally, personal competencies which determine his activity.

Robert and Rogalski (2002) determined five dimensions to analyze teacher’s activity.

- The cognitive and mediation dimensions which concern the set of teacher’s choices about the content and the organization of the knowledge before (cognitive dimension) and during the class-time (mediation dimension).

The combination of this two dimensions allows us to trace what “kind” of mathematics is proposed in the class « la fréquentation des mathématiques qui est installée, ce qui est valorisé par les scénarios et leur accompagnement et ce qui pourrait manquer » (Robert & Rogalski, 2002, p. 514).
This first part relates to the description of the teacher activity, then we would like to interpret and highlight what determines these practices. We refer to three dimensions:

- The social, the personal and the institutional dimensions which permit to define the constraints and the personal aspects of each teaching project.

These three dimensions are studied based on interviews, deduced from the observed teaching sequence and also from the study of the institutional and local context.

This bring us the following research questions:

- What type of mathematics is promoted by various teachers, according to different scenarios and their execution in different contexts? Which kind of logic of action can we observe? Are these practices compatible with the didactic and pedagogical choices of the MERM resource designers?

- What hypotheses can be formulated concerning the dimensions (social, personal, institutional) that determine the teachers’ practices of our study? How do the MERM influence the observed practices?

**Method of analysis**

The analysis was realised according to the following stages:

- A transcription of the lessons we observed was made using Transana, a software which allowed us to have permanently the video and the transcription on the same screen and give the possibility to introduce time codes and keywords. Referring to methodology used in various research using the double approach framework, we divide each lesson in temporal phases, which we call an episode and corresponds to a content unity.

- The scenario of the whole teaching sequence was then reconstituted and analysed to clarify on the one hand what kind of mathematical content is presented during the teaching (cognitive dimension) and, on the other hand, the dynamics in which the content appear during the classes (mediation dimension). The episodes we defined in the first stage of the analysis were coded according to the mathematical content and the teaching strategies (for more details, see Daina 2013).

- we wrote a report based on the interviews with teachers which allowed us to define the “profile” of each teacher, a synthesis of all the information we collected, which give information, among other aspects, on social, personal, institutional dimensions.

**Selected results**

**French speaking Switzerland context and pedagogical resources**

Switzerland has a highly decentralized system with no federal or national Ministry of Education. Each of the 26 cantons which composes the country has its own education legislation. However, four Regional Conferences, including French-speaking Switzerland which is represented by the CIIP (http://www.ciip.ch), have led to some effective coordination since the last five decades, drawing up common curricula, publishing material, jointly managing institutions and recognizing qualifications and admissions.

In the 1970s in all French speaking Switzerland a common official set of pedagogical resources, the MERM, was designed by the CIIP appointed group of experts and teachers from the different cantons. This first edition originates from a double necessity: a will of « inter-cantonal » coordination of
education (mathematics but more widely all the disciplines) and the introduction of a new curricula (CIRCE I), linked with the reform of the "modern mathematics ". In the 1990s, modern mathematics were abandoned and the pedagogical resources have been renewed in the 1990s according to a new educational paradigm based on problem solving, strongly influenced by the socio-constructivist approach.

Switzerland has therefore a long tradition of diverse cantonal educational policies but also the willingness to coordinate the educational system in order to facilitate in particular communication and student mobility. The MERM are the “symbol” of this process, especially in mathematics because they were the first to be done. In fact, the MERM are the result of a long process of discussions and compromises because they have to be approved and accepted by all the cantons of the French speaking part of Switzerland. It is necessary to allow three or four years to realize the MERM for one degree. We have to take into account this complex context in our observation and analysis of this resource (institutional dimension). The MERM must for example be compatible with all the plans of studies. They cannot thus be too prescriptive and require an opening.

Besides, the pedagogical resources are central to the reforms and innovations regarding mathematics education and more than just simple resources, they have the role of promoting innovation, in particular thanks to the teacher's textbook which describes the didactic and educational choices. They have to introduce the changes and harmonize the practices. This is also a critical element we have to take into account in our analysis (institutional dimension).

The MERM have been thought as a set of resources, therefore they mostly consist of a succession of activities for class, regrouped in 6 to 8 main themes, without hierarchy. Contrarily to textbooks in other countries, they do not give a day-to-day organised plan for teaching, which remains the teachers’ responsibility. To do this, the teacher must provide a considerable amount of preparation prior to the lesson and our PhD theses aimed to study the ordinary practices in connection with this resource in order to make visible this essential part of the work of the teacher.

**Case study: Mathilde and Sophie**

To exemplify our methodology and present some results of our research, we will now present two examples of our case study. We will first provide the chosen information about their “profile”, which gives information about the personal and social dimensions. Then we will present and compare their teaching sequences.

Mathilde and Sophie were both young teachers (4 and 5 years of experience) and they worked in the same school. The year of our experiment, they taught the same degree (6P) and they met twice a month and collaborated to develop mathematics lesson plans. Looking at the exchanges between the teachers during this meeting, we saw that they spoke little about the teaching objectives which seemed to be implicitly known and shared.

Mathilde said that the textbook was the reference and did not feel the need to talk more about the objectives. She specified during the interview that her colleagues “trust” her concerning the choice of the activity because it’s impossible, according to her, to choose the activities in the textbook without assistance. Sophie also speaks about "trust" during the interview what shows the importance of the collaboration in the preparation, by filling what is felt as a "lack" of the resource.
However, the study of Sophie’s and Mathilde’s profiles allows us to highlight that the objectives of both teachers are very different. For Sophie the calculating procedures in particular the introduction of the techniques of calculation of areas for triangles and parallelograms represent an important aim in the sequence. For her part, Mathilde considers that the main objective concerns the understanding of the notion of area and the formula to calculate the area of a square. Even though their objectives are different, this point remains implicit throughout their collaboration.

The scenarios analysis and their carrying out in class will allow to see how will evolve the educational projects of the two teachers whose starting point, by the way, is the same list of activities.

Figures 1 and 2 allow to have a global vision of Mathilde’s and Sophie’s scenarios. Mathilde provides a teaching sequence we analysed in three parts: an introductory session, three sessions dedicated to the area of square and rectangle and a session of introduction of the area of other polygons. This corresponds to what is proposed in the textbook.

![Figure 1 Mathilde’s scenarios](image)

The analysis of the series of activities proposed in Sophie’s classroom show a split teaching sequence where activity from the official textbook are often mixed with improvised tasks on the blackboard.

![Figure 2 Sophie’s scenarios](image)

We represented a structure in four parts: an introductory activity, a series of activities on the area of square and rectangle, an introduction in the measure of areas of the other regular polygons and a session of revision.

Although Sophie and Mathilde based there teaching sequence on the same common project, we see well how both scenarios evolved. While the starting point is almost identical, the gap is widening in the course of the sessions, leading to different mathematics promoted in each class (considering the cognitive dimension, Daina 2013). It is nevertheless interesting to note that in the interviews, Mathilde and Sophie did not seem conscious of these differences.

The analysis of the first session, while Sophie and Mathilde proposed the same activity, “Fraction of a field”, allowed to see more in details this difference.
8. Fraction of a field

Father Joseph has a square field. He splits it using three ropes passing through the vertices or the midpoints of the sides. One of his sons, Francis, will inherit the grey part of the field. What fraction of the field will he receive?

The table below synthesizes the succession of the phases during the carrying out of the activity in Sophie’s and Mathilde’s class.

<table>
<thead>
<tr>
<th>Sophie Phases</th>
<th>Mathilde Phases</th>
</tr>
</thead>
<tbody>
<tr>
<td>Instruction</td>
<td>Instruction</td>

<td>Pupils work on the activity</td>
</tr>
<tr>
<td>Parallel task on white board (interruption)</td>
<td>Aide mémoire</td>
</tr>
<tr>
<td>Parallel task on white board (interruption)</td>
<td>Pupils work on the activity</td>
</tr>
</tbody>
</table>

Here we see very clearly that, although the same activity was proposed to the pupils, its management in class is totally different between the two teachers (mediation dimension).

In the class of Mathilde the number of phases is limited. The instruction is very short. During the pooling, the interactions testify of a discussion between the teacher and the pupils who have an active participation in advancing the discussion. Corrections are made individually.

In the class of Sophie we observe at first a longer instruction time. Sophie testifies of a will to make sure that the pupils understand well « what they have to do ». The progression of the project is managed collectively. Sophie makes regular pooling in the course of which, she directs the pupils on a strategy of resolution which is going to become common. However, the task is also diverted on secondary tasks which are in connection with knowledge bound to calculate the area of parallelograms or triangles which are central objectives for her. Sophie’s more personal project enters thus in tension with the progress of the main activity which becomes a material medium to introduce new knowledge in a lecture style of teaching on whiteboard.

We can thus observe a big variability in the practices of these two teachers. What is really questioning is that these differences do not seem to worry them and in spite of their various ways of functioning, the teachers find an interest to prepare together the teaching sequences.

The space provided in this paper only allows to give a limited insight into our research result but some analysis made permit to identify tensions bound to the use of MER. The first cause of tension results from the “shape” of this resource. Indeed, the quantity of the activity proposed is too important and a novice teacher can’t know them all and make a real choice. As said in the introduction, there is no supplied sequence and not much piece of information given about each activity. This leads the teachers to follow what make other colleagues, even if sometimes they did not share the same objective and teaching strategy. Furthermore, as we show in the first part, the specific status of this resource will act as a strong constraint on the teacher who will use it to be in “conformity”, even if...
they do not follow the socio-constructivist approach and will finally distract from the goal of the activities.

Children’s performance on a mathematics task they were not taught to solve: A case study

Seán Delaney
Marino Institute of Education, Dublin, Ireland; sean.delaney@mie.ie

A teacher documents how a task was used to elicit children’s knowledge of multiplication as a precursor to learning the long multiplication algorithm. Data include samples of children’s written work, and transcripts of two 30-minute lessons. Children discussed solution strategies. The teacher used time between the two lessons to select and sequence representative strategies to share. Strategies used by the children were diverse showing a range of multiplication-related knowledge among the children ranging from knowledge of repeated addition to knowledge of place value and the additive decomposition of numbers to various applications of the distributive property.

Keywords: Long multiplication, problem solving, third grade, mathematics laboratory.

Introduction

A common pattern of mathematics teaching is for teachers to present a problem to children, demonstrate how to solve it, and then set similar problems for the children to solve applying the demonstrated strategy (Lyons, Lynch, Close, Sheerin, & Boland, 2003; Stigler & Hiebert, 1999). Calls have long been made for mathematics instruction to focus on teaching thinking strategies and to promote goals like creativity, forming and changing hypotheses, and reflecting on one’s own thinking and the thinking of others (e.g. Streefland, 1992). This case study describes one teacher using heuristics to introduce long multiplication to children who have completed third class.

Children in Ireland learn short multiplication in third class and long multiplication in fourth class. The study describes and analyses work done over two days in a mathematics laboratory school which took place in July 2016 in Dublin. Two research questions are addressed in this study. First, what knowledge did children draw on to solve a long multiplication problem they had not been taught to solve? Second, what knowledge does the class possess that prepares the children for future work on long multiplication? The data consist of children’s written work and transcripts of two 30-minute lessons on consecutive days.

Theoretical framework

Three research areas frame this study. The first is progressive schematisation or progressive mathematisation as inspired by the work of Freudenthal and Realistic Mathematics Education. It describes how children solve problems using their own ideas and informal strategies (Streefland, 1992). These ideas and methods become more sophisticated as students begin to understand and use formal, more efficient algorithms (Treffers, 1987). Although others have written about invented algorithms (e.g. Kamii, Lewis, & Livingston, 1993), Treffers (1987) formalises the process and refers to vertical mathematisation (where algorithms are reorganised and refined) and to horizontal mathematisation (connecting the mathematics to real-life) (Selter, 1998). The second area of research relates to the conceptual field of multiplication: the grounding of mathematical analysis of situations and problems, and the development of children’s ideas over time. It includes paying attention to children’s past and future learning to inform present learning (Vergnaud, 1988).
The third area of research framing this study is the teaching of multiplication (Lampert, 1986). Lampert identifies four categories of knowledge used when learning mathematics: intuitive, computational, concrete and principled. Intuitive (or naïve) knowledge refers to how people in particular contexts invent ways to calculate in order to do their work; it may not transfer well to other contexts. Computational knowledge is procedural knowledge, like standard algorithms, that children typically use in school. Concrete knowledge is used when objects are manipulated to find answers. This may include rectangular grids which are sometimes used to compute answers to multiplication problems. Finally, principled knowledge is knowledge children can use, without necessarily understanding the meaning of what they are doing. Such knowledge might involve children drawing on principles such as place value, the commutativity of addition or multiplication, or the distributive property of multiplication over addition.

This framework will help to identify stages in the heterogeneous work of a class (Selter, 1998) of children as they attempt to solve problems for which they do not have a solution. It will also help to categorise the knowledge that children used and shared in solving the problems.

**Method**

**Participants**

Twenty-four children – 17 girls and 7 boys – were in the class which lasted for two hours per day over five days. The children had just completed third class in ten different schools and therefore could be expected to be familiar with short multiplication but not to have worked on long multiplication. The mathematics laboratory class was taught by the author and was observed by twenty-five teachers who were completing a summer course in mathematics. Although several topics were taught in the summer school, the focus of this study is on the introduction of long multiplication. A word problem was chosen from Van de Walle: “The parade had 23 clowns. Each clown carried 18 balloons. How many balloons were there altogether?” (Van de Walle, 2001, p.182). Children worked on this problem collaboratively in pairs; they were encouraged to solve the problem and to be prepared to justify their solution.

**Data analysis**

Two data sources were used: samples of children’s written work and transcripts of dialogue from the lessons. Children did their written work in squared exercise books using black pen to ensure that they would not erase work they were unhappy with or that contained errors. This rationale was shared with the children. All lessons were video recorded by two cameras – one focused on the children and one focused on the teacher. The videos were used to prepare lesson transcripts.

The research questions relate to the knowledge used by the children and available to the class as a resource for future learning. All children’s written work completed in response to the problem was studied and compared to ensure that samples of every approach used were represented in the four samples of work selected for more detailed analysis. The chosen work samples were subsequently analysed to identify categories of knowledge that were evident in the work. The four categories outlined by Lampert (1986) guided this analysis. The transcripts were analysed for evidence of student mathematical knowledge. Although the categories identified by Lampert informed this
analysis, the analysis was open (Corbin & Strauss, 2008) so references to knowledge not covered by the four categories could be identified.

Results

Lesson plans

Children were asked to work on the multiplication problem in pairs. The following day the plan was to continue working on the same problem. Prior to lesson 2, the author (as teacher) looked at the children’s work to select and sequence four approaches to share with the entire class. The strategies selected involved repeated addition, repeated addition with some multiplication, multiplying using partial products and an attempt at the standard algorithm for long multiplication. The lesson plan refers to a pictorial representation of the problem that would help the children get an understanding of the dimensions of the problem. This was introduced in response to a similar approach used for various scenarios by Lampert (1986). The lesson plan concluded with the intention to ask the children to independently solve a second long multiplication problem.

Day 1

The calculation was embedded in a word problem referring to a setting familiar to most children in the culture – many clowns each holding several balloons. Two two-digit numbers needed to be multiplied. The combination of relatively low two-digit numbers and the concrete image of clowns with balloons made it relatively easy for children to draw the scenario if they decided to do so. After a class discussion of the problem conditions, children worked on it in pairs for seventeen minutes. The teacher circulated among the children monitoring the work of pairs. Teachers participating in the summer course walked around the class observing the children working. Although they were asked not to interact with the children, on one or two occasions some did.

After the children had worked in pairs, the teacher asked one pair of children – Sandra and Lisa – to tell the class how they went about solving the problem. They had added eighteen and eighteen to make thirty-six. Then they added another eighteen. The teacher asked the class if this strategy were implemented properly, would it yield the correct answer, and based on their responses reminded them of the need to be systematic in recording their work.

Two more children, Chuck and Róisín, shared a different approach. They wrote down twenty-three eighteens and multiplied twenty-three by eight and twenty-three by one. This represented an understandable mistake, forgetting that the one digit in the eighteens represents ten rather than one.

At this stage the teacher adjourned the discussion and moved to another mathematical topic. Having concluded that part of the work for the day, the teacher could examine and reflect on the children’s work in order to select and sequence material for discussion in the following day’s lesson.

Day 2

Overnight the teacher looked at each child’s work. No one had successfully used the long multiplication algorithm suggesting that, as expected, it had not been taught to the children prior to the summer school. Four examples were selected and sequenced in a way that was anticipated to tap into the children’s current understanding, to show increasing efficiency or sophistication of solutions – progressive mathematisation – and to prepare the children for subsequent work on long
multiplication. Although all children had worked in pairs, work to be shared was selected according to the clarity of the work recorded in individual children’s copybooks.

First was Christine who had used a straightforward repeated addition approach. She had a pictorial representation of the problem with twenty-three faces and eighteen balloons over seven of them (see Figure 1). Next was Donal who had no pictorial representation but who also used a repeated addition approach. He had grouped ten eights where possible to multiply them and had multiplied twenty-three by ten (see Figure 2). Third was Fintan who solved the problem by calculating ten eighteens, another ten eighteens and three eighteens and then added the three calculations (see Figure 3). All three students had the correct answer of 414. The fourth student, Eileen, got the wrong answer but the strategy used seemed closer to the standard long multiplication algorithm. She wrote an account of what she did and of how she was thinking rather than just recording the calculation. She multiplied the three from twenty-three by the eight in eighteen and got twenty-four. She then multiplied twenty by ten to get two hundred. She refers to multiplying two by one and it is unclear if that is a precursor to multiplying twenty by ten (see Figure 4).

Despite the fact that Christine had set up the calculation to be solved using repeated addition (see Figure 1), she stated that to solve the problem she and her partner “drew a picture and we did loads of dots and we counted them all up.” When challenged by the teacher about the repeated addition work in her copy, Christine responded that “I had a long sum but that didn’t really work because I kept on losing count.” This provided an opportunity to discuss a problem that arises with repeated addition, and to prepare the class for seeking more efficient ways to calculate using long multiplication. The teacher did not ask Christine why it was easier to keep track of counting the balloons individually than adding 18 twenty-three times and that may have yielded information about a system she had developed to keep track of the balloons already counted.

Donal had a more sophisticated way of working with repeated addition (Figure 2). Although his layout of the problem looks similar to Christine’s, he approached it as follows

\[(8 \times 10) + (8 \times 10) + (8 \times 3) + (10 \times 23)\]

In solving it this way Donal and his partner showed understanding of the distributive property of multiplication. They noted that the ones in the eighteens represented tens and not units. However, Donal’s written recording of the work and his oral explanation of it suggests that he was not yet familiar with multiplying numbers by ten. In contrast, his classmate David stated that “When I’m multiplying by tens, I just add on another zero at the end of the number.” Although the wording of “adding” another zero may not be helpful, he is referring to the fact that multiplying a number by ten shifts each digit one place to the left requiring zero as a placeholder in the units place.

A more condensed understanding of the distributive property was apparent in Fintan’s work (Figure 3). Unlike Donal or Christine he did not write out the calculation using repeated addition. Nor did he separate the tens and units in order to complete his calculation, which took the following form:

\[(18 \times 10) + (18 \times 10) + 18 + 18 + 18\]

Fintan sees his approach as being similar to Donal’s and he states that “we basically did the same as Donal; we used hundreds, tens, and units.” However, whereas Donal’s approach was limited by
apparently not being able to multiply two-digit numbers by ten, Fintan was able to make the calculation more efficient by multiplying eighteen by ten.

When the children were asked where the twenty-three (clowns) could be seen in Fintan’s strategy, two children (Katherine, Ethna) found it difficult to identify. One, Doireann, successfully constructed an explanation with the teacher in the following exchange.

Doireann: So the eighteen times ten is done twice. So that would be like twenty there. And then…
Teacher: So, you’re saying that this is ten clowns with eighteen balloons, and this is another ten clowns with eighteen balloons.
Doireann: Yeah.
Teacher: Is that what you’re saying?
Doireann: Yeah.
Teacher: Okay. And what then?
Doireann: And then if you add that together that’s twenty…
Teacher: Twenty clowns with eighteen balloons.
Doireann: Yeah, and down the bottom there, it’s three eighteens. Add them onto the twenty and it’s twenty-three.

When asked to choose a preferred strategy from those presented by Christine, Donal and Fintan, four children preferred Fintan’s approach on the basis that it is quicker and it requires less writing. Two claimed to prefer the repeated addition approach because it looked less complicated.

When children solved the first long multiplication problem, twelve of them used a variation of repeated addition, three used a form of the distributed property, three a variation of the conventional algorithm, the work of three children was unclear and one used counting. Following the discussion, seven children used repeated addition, four used a form of the distributive property, five used a form of the conventional algorithm, the work of six students was unclear and one used counting.

Finally, Eileen was asked to share her approach. Initially she stated that she and her partner got the wrong answer. After reassurance from the teacher that the class could learn from the wrong answer, she shared her approach. She writes that “in her head” she laid out the problem as it would be laid out in the conventional algorithm for long multiplication. She multiplied the three units by the eight units and got twenty-four. Then she multiplied the two tens (of twenty-three) by the one ten (of eighteen). She added them together and got 224. Although the teacher sequenced Eileen’s strategy after Fintan, it is conceivable that her understanding is more naïve than his because she may have been attempting to apply the algorithm for short multiplication to long multiplication without really understanding the distributive property. Nevertheless, it provided an opportunity for the teacher to introduce an illustration of the distributive property of multiplication to all children.

Eileen failed to multiply the eight by twenty and the ten by three. In order to help her and her classmates visualize this, the teacher proposed a drawing of the scenario based on Lampert (1986). In this drawing (see Figure 5) twenty clowns were on a bus travelling to the parade and three clowns
had to walk because there were only twenty seats on the bus. Twenty strings with balloons on them could be seen emerging from the bus, each string with one group of ten and one group of eight and the three clowns outside the bus held similar strings of balloons.

The class was asked how they could calculate the number of balloons held by the clowns altogether. The idea of the picture was to make it clear that the numbers that need to be multiplied are (20x10), (20x8), (3x10) and (3x8). The first two calculations correspond to the clowns sitting in the bus with the strings containing ten balloons and eight balloons and the second two calculations correspond to the clowns standing outside the bus holding strings with ten and eight balloons on them. The diagram helped children see that Eileen had neglected to calculate the (20x8) and the (3x10).

**Discussion and conclusion**

That multiplication was the operation needed to complete this task was uncontested by the children. In solving the problem, they drew on different categories of mathematical knowledge. Some relied on intuitive, context-specific knowledge and drew versions of the clowns in order to solve the problem. Computational knowledge of multiplication was widely held, as would be expected by children who had completed third class. Although occasional errors were made, children had access to multiplication table cards if they wanted them so that even a lack of computational knowledge would not pose a barrier to solving the problem.

Little evidence of the children using concrete knowledge emerged in the lessons. This may have been because no manipulable objects were made available to them to help them find an answer. Some children may have used the diagrams they drew as a form of concrete knowledge to support their solution but that is unclear from the data sources used.

Much evidence of principled knowledge emerged from the children. Donal and David showed understanding of place value, by separating the tens and the eights in eighteen (Donal) and in stating how numbers can be easily multiplied by ten (David). Several children had a tacit knowledge that numbers can be decomposed additively and of the distributive property of multiplication (e.g. Donal, David, Caitlin, Fintan and others). The teacher attempted to make this aspect more explicit by introducing the diagram with the clowns in and beside the bus. Students like Eileen have some understanding of the distributive property but it needs to become more explicit if she and others are to be ready to apply it in taking the next step to understand and use the long multiplication algorithm automatically. They need to grasp the principle that \((a+b)*(c+d)\) requires multiplying \(a\) by both \(c\) and \(d\) and multiplying \(b\) by both \(c\) and \(d\) and not just multiplying \(a\) by \(c\) and \(b\) by \(d\).

At the end of the week around fourteen children were still either using repeated addition for similar multiplication tasks, using counting or not showing evidence of how they found their answer. Nine showed willingness either to apply the distributive property of multiplication or to at least attempt the conventional algorithm. Of those who were still applying the repeated addition algorithm, four had become more sophisticated in using it (moving closer to Donal’s approach than to Christine’s) following the class discussion documented here. This highlights the importance of children learning from each other through working on and explicitly discussing their completion of a task.
Half the children used a form of repeated addition to solve the problem. However, additive reasoning differs from multiplicative reasoning (Nunes & Bryant, 1996). It remains unclear from this study if children reverted to additive reasoning because long multiplication was unfamiliar to them or if they have made the leap from additive reasoning to multiplicative reasoning at all. Future study could involve assessing children’s grasp of multiplicative reasoning in short multiplication scenarios (Sherin & Fuson, 2005), exploring the use of arrays (Fosnot & Dolk, 2001) and introducing long multiplication tasks that would more likely elicit responses that exhibited multiplicative reasoning.

Critical evaluation and design of mathematics tasks: Pre-service teachers

Majella Dempsey\textsuperscript{1} and Ann O'Shea\textsuperscript{2}

\textsuperscript{1}Maynooth University, Department of Education, Maynooth, Ireland; majella.dempsey@nuim.ie
\textsuperscript{2}Maynooth University, Department of Mathematics and Statistics, Ireland; ann.oshea@nuim.ie

This paper reports on a research project undertaken with a group (n=19) of Irish pre-service student teachers (PSTs) during the third year of a four-year undergraduate education course. A series of workshops were carried out on the critical evaluation and design of mathematics tasks. The research is presented as a case study using mixed methods to gather data. Through critically evaluating and designing mathematics tasks PSTs developed knowledge of cognitive demand, pedagogical design capacity and showed evidence of developing curriculum-making competences. The research highlights the need for PSTs to work together on evaluating and designing tasks.

Keywords: Mathematics, tasks, design, curriculum, pedagogy.

Introduction

This paper reports on a research project undertaken with a group (n=19) of Irish pre-service student teachers (PSTs) during the third year of a four-year undergraduate education course. A series of workshops were carried out on the critical evaluation and design of mathematics tasks. For the purpose of this research a ‘mathematical task’ is a problem or set of problems that address a specific mathematical idea, they are situated between teaching, learning and assessment (Smith & Stein, 1998). The types of tasks that students engage with have been shown to influence their development (Jonson et al., 2014), and studies have shown that students spend the majority of their time in mathematics classes working on tasks (Boston & Smith, 2009; Haggarty & Pepin, 2002). Furthermore, Smith and Stein (1998) asserted that the highest learning gains in mathematics were related to the how mathematics tasks were set up and implemented in teaching and highlighted the importance of students being engaged in high levels of cognitive thinking and reasoning (see also Swan, 2011; Boston, 2013). Many challenging questions arise from this assertion for pre-service mathematics teachers, such as, what is a good learning task? How is a good learning task set up? How is it implemented in a mathematics classroom? These questions are especially relevant in Ireland, given that a report on mathematics education found that traditional approaches to teaching and learning were widespread and recommended that students engage with more tasks which require higher order thinking skills such as problem-solving and justification (Jeffes et al., 2013).

Research questions

In what ways did pre-service teachers’ knowledge of the cognitive demands of mathematical tasks change following their participation in a module on critical evaluation and design of mathematical tasks?

How did this knowledge impact on their competences in curriculum making?

In this paper we present a review of some key research on mathematics task design. We provide an overview of the module implemented as part of the research project and the methodology used to
collect data. We present the key findings from the research and discuss the salient themes emerging as they pertain to pre-service teacher education. Finally, we summarise our recommendations and conclusions.

**Literature review**

The dependence of mathematics teachers on textbooks in their teaching appears to be a phenomenon in many countries (Haggarty & Pepin, 2002; Jeffes et al., 2013.). Haggarty and Pepin (2002) write about the dominance of the textbook in the mathematics classroom and conclude that without time to prepare for teaching, and, we would add, the skills to enrich the curriculum materials available, textbooks take on a prominence in “relation to teacher thinking and planning” (p.588). This is of concern as a recent review of mathematics books in Ireland found that all available books fell short of the standard needed to support mathematics teaching at that time and furthermore they especially fell short on the integration of technology, approaches to teaching for understanding and problem solving (O’Keeffe & O’Donoghue, 2011).

Synder, Bolin and Zumwalt (1992) describe three teacher curriculum approaches: the *fidelity approach*, where teachers are transmitters of the written curriculum without changing it; the *adaptation approach* where the teacher adapts the curriculum to suit their context; and the *enactment approach* where the teacher develops the curriculum in action depending on the student experience. Shawer (2010) builds on this work and identifies *curriculum-transmission strategies* where the textbook and teacher’s guide are the source of pedagogical instructions. He describes *curriculum-making strategies* as where the teacher develops their own materials in addition to those available in response to a needs assessment. *Curriculum-development strategies* on the other hand include experimentation, material writing and evaluation and involve both macro and micro level curriculum development. Within the Irish education system opportunities for curriculum-development strategies are limited since the curriculum is centrally devised with little space for school-based curriculum development, this coupled with a teaching culture that has a dependence on textbooks would point to a need for PSTs to engage with research on task development.

Studies have previously looked at this issue as part of professional development courses for in-service teachers. For example, Boston and Smith (2011) describe a *task-centric approach* to such courses where the focus is on teachers’ ability to select and implement cognitively demanding tasks. They found that after a series of workshops, where teachers analysed both the cognitive demand of tasks and the implementation of tasks, the participants increased their ability to select high-level tasks and this improvement was sustained over time. The workshops also influenced teachers to consider the impact of the tasks they selected on their students’ learning (Boston, 2013). Arbaugh and Brown (2005) used a similar approach and found that introducing teachers to criteria for high-level tasks influenced their task selection, and ultimately their pedagogical content knowledge.

A number of different frameworks have been developed to classify mathematical tasks and have proved useful in research, professional development and pre-service teacher education (Boston & Smith, 2011). In this research we used three different but complementary frameworks with the participants. The first framework is that of Smith and Stein (1998) which looks at the level of cognitive demand (LCD) of tasks. They identify two levels of LCD: Lower-level demands (with task types of Memorization and Procedures without connections to meaning), and higher-level
demands (*Procedures with connections to meaning* and *Doing Mathematics*). The distinction between tasks is relevant, as the level of cognitive demand in a task provides different learning opportunities for the learner and demands a different learning environment for the development of competences required by the task. Our second framework is the mathematical reasoning framework developed by Lithner (2008). This framework can be used to classify the opportunities for different types of mathematical reasoning afforded by tasks. Lithner (2008) describes two types of reasoning: Imitative Reasoning which consists of *Memorised reasoning* and *Algorithmic reasoning*; and Creative Reasoning which involves local and global *Creative mathematically founded reasoning*. Creative reasoning tasks fulfil the criteria of novelty, plausibility and mathematical foundation. Lithner (2008) is concerned with how tasks can be used to promote creative reasoning as opposed to imitative reasoning. He contends that the teacher’s task is to “arrange a suitable didactic situation in the form of a problem” (p.271) so that the learner can take responsibility for the problem solving process, and use creative reasoning.

These two frameworks can be used to classify tasks using either the degree of cognitive effort required or the type of reasoning needed. They both divide tasks into two broad categories - either high or low levels of cognitive demand in the case of Smith and Stein (1998) or imitative or creative reasoning in Lithner (2008). They have been used in professional development to alert teachers to the effects of different types of tasks (e.g. Arbaugh & Brown, 2005). In order to help the PSTs to move from classifying tasks to designing them, we introduced a third framework. Swan’s framework (2008) describes five task types that encourage concept development and provides very clear design principles to inform task development and implementation. There are many examples of Swan’s mathematics tasks available on-line (see, for example, Mathematics Assessment Project, n.d.). The five task types that he posits will encourage concept development are: classifying mathematical objects, interpreting multiple representations, evaluating mathematical statements, creating problems, and, analysing reasoning and solutions.

**Methodology**

Nineteen pre-service teachers in the second semester of year three of a four-year post-primary teacher education course took part in the research project. At the time of the research the PSTs were midway through their second school placement experience and were teaching a minimum of two hours per week. All participants were taking mathematics in their degree and one other science subject (either biology, chemistry or physics). The research is presented as a case study using mixed data collection methods looking at the group of PSTs as a whole, over a sustained period of time as they developed competences in task design (Yin, 2009). This allowed us to build on earlier research (Boston, 2013) and incorporate PSTs reflections on the design process. Jones and Pepin (2016) contend that when teachers interact with mathematical tasks, they develop knowledge; this is done individually in preparing and planning for teaching and collectively when they are afforded opportunities to develop and discuss tasks with peers. In designing curriculum materials PSTs need both *subject matter knowledge* (SMK) and *pedagogical content knowledge* (PCK) (Ball, Thames & Phelps, 2008). With this in mind we designed a module for the group of PSTs based on task evaluation and ultimately task design.
In order to investigate any gain in knowledge for the group over the course of the intervention, we administered a pre- and a post-test designed by Boston (2013). This test asked students to classify 16 tasks as either High Level or Low Level tasks, and to give a rationale for their choice. At the end of the module, the pre-service teachers were asked to complete an evaluation questionnaire which asked them: to report on a key learning moment during the module; whether their teaching had changed as a result of the module and if so, in what way; what they would change about the module; and to indicate their level of agreement with some statements about the reading from the Mathematics Education literature. 13 of the 19 students submitted the evaluation questionnaire.

The assessment for the module consisted of the assignment outlined in Figure 1. All 19 pre-service teachers submitted this assignment and gave their consent to use it for research purposes. The tasks designed by the PSTs were analysed using the LCD and Lithner Frameworks. The classification was conducted by two researchers who were familiar with the curriculum, assessment, and textbooks relevant to the classes taught by the PSTs. The researchers used their knowledge to decide if (in the context of the PSTs’ classes) the tasks should be classified as either high or low level tasks. We also looked for evidence that PSTs employed aspects of Swan’s (2008) framework in their design. A general inductive approach as advocated by Thomas (2006) was taken to analyse the students’ reflections on the differences between types of tasks. Analysis was guided by the research questions and a number of a priori themes (such as MKT), allowing flexibility for other themes to emerge.

**Task Development**

For a topic of your choice design (or significantly adapt) a series of tasks. One task/s should be suitable to be used in class while teaching, and, one for use as homework. Design an examination task/s for the topic. Present your rationale for each task based on your readings. Reflect on the differences between classroom task, homework task and examination tasks.

**Figure 1: End of module assessment**

**Findings**

**PSTs’ specific learning about cognitive demands**

Thirteen participants completed the Boston (2013) pre- and post-tests on levels of cognitive demand; a paired t-test was used to investigate whether the mean of the group had increased significantly over the course of the module, and found that it did ($p=0.037$). There was also evidence for PSTs developing knowledge about cognitive demand in their response to the question on the end of module evaluation asking what was their key learning moment.

Realising the different reasoning and thinking about the type of question. In the textbook, where homework is usually given from, questions are repeated, low demand. In the maths exam students are faced with high level conceptual questions so there is a big gap there that needs to be addressed. (S14)

Here we see that S14 is noticing the level of demand and reasoning in the artefacts available to them in their teaching, the textbook. This text-guided Algorithmic Reasoning (AR) is supported and encouraged by the rote use of the textbook for homework (Lithner, 2008). The recognition of this by the PSTs was notable in many comments such as:
Having completed this module, I seriously consider what I give my students as homework. Beforehand I generally gave a list of questions at the end of the chapter but now, having seen the different levels, I generally spend more time selecting and developing questions … (S16)

The PSTs seem to be linking the levels of cognitive demand with the level of reasoning required, bringing the two theories together in their own thinking about the mathematics curriculum and assessment. The knowledge of the different frameworks is enabling the PSTs to move from a role of curriculum transmitters dependent on the text book to being curriculum makers as described by Shawer (2010).

**Pedagogical design capacity and moving from curriculum transmission**

The analysis of the PSTs’ end of module assignments gave further evidence of them making this transition. All students showed that they were able to design or modify tasks to get high level questions. The PSTs classification of their tasks using the LCD and reasoning frameworks demonstrated that they were competent in using the frameworks for classification.

We noted the types of tasks designed by the PSTs for the three different situations of classroom tasks, homework tasks, and examination tasks. The types of tasks designed seemed to fall into two broad camps: open-ended exploratory tasks (which were mainly found in the classroom setting) and more traditional formats (which were mainly found in homework and examination tasks). The latter types of tasks mostly consisted of word problems with a real-life context; the PSTs designed a small number of other types of tasks for use as homework or examination questions, including tasks which required students to make a conjecture, provide an example, or evaluate a mathematical statement. In addition, one PST designed a homework task which involved a pre-class investigation. The majority (13 of 19) of the PSTs used card-matching designs for their classroom tasks. These tasks were based on Swan’s “Interpreting Multiple Representations” (Swan, 2008, p. 3) task type. The PSTs were introduced to this idea through the Swan (2008) article and also participated in a card-matching task (on the topic of fractions) during one of the module sessions. Three of the PSTs used games (such as ‘Battleships’ and dice games) to devise tasks for use in the classroom, two PSTs used investigations as the basis of their task, and one designed a series of worksheets with problems of increasing difficulty.

The PSTs showed creativity and an appreciation for tasks with high levels of cognitive demand. However, an analysis of their designed tasks showed that the design process was not without difficulty for the group. Some of the questions were not always clear due to missing or confusing instructions, and sometimes the context made the question ambiguous (this has also been a problem in state examinations in Ireland). Occasionally it seemed as if the PSTs did not have a clear understanding of the underlying mathematics themselves, possibly owing to their level of SMK, and sometimes their use of mathematical language caused difficulty (such as using the term ‘equation’ instead of ‘expression’ for something like $2x+1$). The learning trajectories for the tasks or sets of tasks were not always clear - sometimes it was not clear what understanding and what concept the PSTs were trying to develop.

**Pre-service teachers’ pedagogical content knowledge**

The PSTs’ knowledge of levels of cognitive demands challenged their deeply held view of how best to teach mathematics. Previous research with a similar co-hort of PSTs found that they focused on
content when planning for teaching and placed little emphasis on the learner or prior learning (Nolan, Dempsey, Lovatt & O’Shea, 2015). Most of the respondents said the module impacted on how they taught mathematics with the majority citing a change in how they asked questions, placing more emphasis on higher level of cognitive demand in questions. Prior to this module, these PSTs would have completed a module which included a significant input on questioning skills for teaching; they seem to have needed the knowledge of cognitive demand in order to have changed their questioning practices. It must be noted that this was reported but may not have been the reality when one takes into account the examples provided by the PSTs in their end of module assessment. However, an increased emphasis on discussing mathematics problems appears to be evident with comments such as

I try to think more about pushing my students to reason more when completing tasks. I try to ask questions, give tasks to my students with much less information, and I want my students to rely less on me giving them the answer. (S11)

This PST also spoke about the effect of the intervention on her teaching:

I never really thought much into the differences between the tasks that I give during class, homework or exams or the impact it could have on my students’ development in a subject. Having studied and researched the classification of math’s tasks and implementing my own selection/adaption of tasks into my class, I now feel that I have gained a deeper understanding into the effect my choice of tasks can have on the progression and learning... (S11)

The PSTs who implemented their tasks in their teaching placements, realised the effect that the teacher or set-up can have on the cognitive level of the task and this led to them thinking about different types of tasks or redesigning their original tasks:

The students struggled very much with it at the beginning and due to my own fault I went through an algorithm with them and then the task immediately became a lower demand one, just requiring the students to reproduce an algorithm each time. If I were to redesign the tasks, I would change tasks E and F [card-matching tasks] to tasks where the students have to spot a mistake in a question/statement and justify their reasoning and how they would alter the question/statement … in order to encourage them to develop critical thinking skills. (S12)

This reflection would suggest that the PST is developing her thinking on organising pedagogical content, adapting materials to suit students and adopting curriculum planning and making strategies (Shawer, 2010).

Discussion

Increasing the PSTs awareness of different levels of tasks and giving them an opportunity to design and modify tasks would appear to have allowed them to develop skills such as the ability to classify tasks and design tasks at different levels. They also seem to have developed knowledge especially PCK which linked to their knowledge of cognitive demand has enabled them to adapt their practice especially around questioning. We note though that the evidence we have presented in this regard is based on self-reported data. The importance of applying frameworks in order to increase awareness of concepts such as levels of cognitive demand is significant for PST education; awareness may be a crucial first step in knowledge acquisition. Similar to findings from Boston (2013) and Swan
(2007) who worked with practicing teachers, our research appears to demonstrate the need for an awareness of cognitive demand in order for mathematics educators to be able to select and develop rich and engaging tasks. This increase in knowledge and skills seems to be crucial in order to make the transition from curriculum transmitters to curriculum makers (Shawer, 2010). The space in our intervention for discussing textbook questions and State Examinations materials was cited as being the most impactful for the PSTs. They suggested that the module could be enhanced with more time devoted to this kind of peer interaction in task evaluation and design. This need for space for curriculum making and professional learning, and, the challenges therein has not been fully explored within PST education.

This research has highlighted a gap in the PSTs’ education on task design in the case study institution, and, as such will be used to make changes to the module design and implementation. PSTs’ practices and beliefs around tasks for homework merits further exploration. We intend to carry out more analysis on our data such as on the tasks assigned by PSTs (pre- and post-intervention) and of their reflections on tasks linking back to Lithner’s (2008) concept of sociocultural milieu.

Agency as a tool in design research collaborations
Andreas Eckert
Linnaeus University, Sweden; andreas.eckert@lnu.se

The aim in this paper is to shed light on interactional aspects of researcher and practitioner collaboration in design research in mathematics education. Symbolic interactionism is used to gain understanding of interactional aspects as it has potential to take both individual and social aspects of the interaction into account. Aims and agencies are in focus of the retrospective analysis of the collaboration between two researchers and two practitioners as they collaborate to develop instructional design. The analysis show how referring to authoritative disciplines as the mathematics community influence agency and therefore has great potential to influence how the negotiation of meaning progress and participants acts. I argue that agency could be viewed as an indirect tool that has the potential to direct the collaboration when designing tasks based on what aim different actors put in the foreground.

Keywords: Collaboration, agency, interaction, design research.

Introduction

Collaboration is at the core of design research in mathematics education. A key characteristic is that it is research conducted with researchers and practitioners in real-world settings (Plomp, 2013). This collaboration is often between one or more researchers and practicing teachers. It is essential that this team collectively has the competence to develop the design, conduct the lessons, and perform the retrospective analysis (Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003). This means that we have different actors in the activity, each with its interpretation of the aim and purpose, as well as of the actual activity and the mathematics involved. Since each actor has a specific set of competences and a vital role to play in the collaboration to develop the design, the question is how their differences influence the discussions during meetings and by extension the design? McClain (2011) explores this interplay of differences in the classroom interaction between students who performed the resulting tasks and the teacher who orchestrated the discussions. She views it as interplay between the students’ contribution, the task and what she calls the proactive role of the teacher. One key aspect of the interplay is where the authority over the topic, the agency, lies. Agency is thought of as a capacity to act in social interaction. McClain (2011) emphasizes that it is important for students’ learning that agency shifts between different actors in the activity.

The discussion in this paper focuses on the developing phases of design research. How does this shifting of agency that McClain (2011) identifies in the design research classroom appear in the development of tasks in between lessons? The aim of this paper is to further understand how the aim and agency fluctuate between the participants and its influence on how the negotiation develops as researchers and teachers collaborate to develop instructional design. Results could be viewed as a contribution to the mathematics design research methodology discourse of how collaboration between researchers and practitioners can support the design process.
Previous research

Design research in mathematics education is described as a research design that is interventionist; iterative; process, utility and theory oriented; and has involvement of practitioners (Plomp, 2013). The idea is to develop tasks and activities, test them in real classrooms, evaluate the outcomes and then revise the design in an iterative process involving practitioners from the field. All in all, the research design enables the team to pursue multiple goals in the same project. The aim is to understand the processes involved in utilizing the developed tasks from the point of view of a chosen theory, design usable material for users in real life context and lastly to contribute to further development of theory. Plomp (2013) calls it the twofold yield of design research, producing both research-based intervention and knowledge about interventions in the form of theory.

Beside the global aims of design research, an intention to develop theories and instructional designs, there are local aims as well. The instructional design has an aim, an intention to stimulate learning, in the form of a hypothesised learning process and goal for the subjects (Cobb et al., 2003). The so-called Hypothetical learning trajectory (HLT) is defined by Simon (1995) as follows:

The hypothetical learning trajectory is made up of three components: the learning goal that defines the direction, the learning activities, and the hypothetical learning process – a prediction of how the students’ thinking and understanding will evolve in the context of the learning activities. (p. 136)

Cobb (1999) argues that the learning goal of a HLT should be from a group perspective rather than an individual one. Simon (1995) amongst others talk about a prediction of individual learning processes and thinking whereas Cobb (1999) call this line of thinking highly idealized at best. Instead, he proposes a focus on collective mathematical development in the classroom community. A HLT then consists of an “envisioned sequence of classroom mathematical practices together with conjectures about the means of supporting their evolution from prior practices” (p. 9).

Global and local aims are both individual interpretations as well as objects for the research team to negotiate. In this paper, it is assumed that this process is a social interaction within the team. Interaction is described with the theoretical background of symbolic interactionism (Blumer, 1986). It proposes that humans act according to the meaning that objects have to them and that the meaning of objects arise out of social interaction. This is an interpretative process where humans constantly interpret others’ actions and the meanings they indicate before acting themselves (Blumer, 1986). It means that participants of the research team interact according to how they interpret the local aim of the design as well as their own global aims and interpretations of the mathematics in question. Voigt (1994) calls this the negotiation of meaning in the mathematics education context. It is a negotiation because the actors contribute to a discussion based on their interpretation of what is being discussed and at the same time re-evaluate their own understanding, thus creating a negotiation of what is viewed as the community’s meaning of the objects.

As global and local aims and the design itself are negotiated, participants position themselves through their contribution to the negotiation. Burr (2003) talks of the capacity to take up positions for one’s own purposes and that agency lies in responsive actions in interaction. In the mathematics classroom context, McClain, Zhao, Visnovska, and Bowen (2011) defines agency as “authority over both the mathematics being taught and the sequencing and presentation of that content” (p. 63).
Combined, they frame the agency concept for this paper. For the purpose of this paper agency is viewed as involving one’s intentions, sense of responsibility, as well as one’s expectations of recognition and reward in taking a particular action. As the participants of a research team interact in the development of the design, they act according to their interpretations and their positioning in a community, for example as a representative for the mathematical community, and act with the authority of that discipline. Participant act according to different agencies as fits their purposes and evaluate its impact on the negotiation, also known as the dance of agency (Pickering, 1995). As the negotiation progress, agency shift between the participants and within them. Shifting agency enables the participants to contribute in different ways and from multiple perspectives, for example as mathematicians, practitioners or researchers. The result is an effect on the design of the HLT in line with different actors’ fluctuating aims and their agency to contribute according to those aims.

Method

The data used here is generated from video recordings of a small-scale teaching experiment involving probability with students from year 5 and 6 in a Swedish elementary school. The aim of the task was for the students to become able to discuss matters of relative frequency data and the law of large numbers in a probability context. Relative frequency is a way of analysing data from repeated random events, such coin flips, where the number of observations of each outcome is divided by the total number of events. The law of large numbers then states that as the sample size increases, the likelihood of a difference between the relative frequency and the actual probability of the event decrease. Thus, can the relative frequency be used as a measure of probability. The research team consisted of the author of this paper, a senior researcher (here called Paul) and two teachers (here called Karen and Tilly). The whole process was initiated by the two teachers who felt that they needed inspiration and experience in teaching probability, which they had never done before. The balance of numbers provided a sense of balance between researchers and teachers, which later has been recognized by Stephan (2015) to be an important factor to highlight teachers’ unique knowledge in design research collaborations. The work was organized as such that after an introductory meeting, the two researchers drafted a design proposal in line with the requested topic. That design was further developed by a discussion within the team, which was video recorded, and then initiated by one of the teachers in the classroom. Minor adjustments were carried out between the two teachers’ lessons and major changes of the lesson sequence were carried out after both teachers had used each lesson plan. A total of 5 lessons were designed, although one of the teachers divided the last lesson into two because of time management issues.

The activity and hypothetical learning trajectory

The task design originated from a teaching experiment by Brousseau, Brousseau, and Warfield (2001), where the students were asked to investigate a chance event with an unknown sample space. The aim was to introduce basic principles of the Law of large numbers from probability as well as a frequency perspective on probability theory. We used an opaque soda bottle containing an unknown amount of small coloured balls (neither the students nor the teachers knew the content of the bottles) during the first lesson. When the bottle was turned over, the colour of one ball was revealed while remaining inside the bottle. Thus, creating a constant but unknown sample space. The activity was presented as a race in the first lesson with three contestants on a six-step track. As one of the three
colours was observed on a bottle turn, that colour advanced one step down the track. The students were asked to guess which colour would first get six observations during each race. Based on the topics discussed by the students in the first lessons, the following three lessons made use of a transparent bottle with a visible sample space. Here the students were asked to discuss chance, random variation, sample space, sampling and the law of large numbers. The importance of the sample space was highlighted in the second lesson because of ideas discussed in the first lesson. The students got to return to the opaque bottle in the last lesson(s) and again, in an organized manner, investigate the unknown sample space from the first lesson with the use of the law of large numbers. By producing a large enough sample, they could reason about the sample space in the opaque bottle by translating the relative frequency of each outcome into the probability of that outcome. Overall, one class needed a total of five lessons and the other class six lessons, to reach an agreement about the unknown sample space in the opaque bottle.

**Method of analysis**

The analysis of the transcript in the forthcoming section is inspired by retrospective analysis from the design research methodology. It is based on open inquiry and constant comparison (Glaser & Strauss, 1967) where you retrospectively analyse and compare small instances of data from the whole set with one another to gain insights into the processes (Gravemeijer & Cobb, 2013). Trustworthy accounts of possible meanings can be developed by immersing oneself in the social setting, using participant observation, alongside systematic coding of data in retrospective analysis (Cobb, Stephan, McClain, & Gravemeijer, 2001). Instances of active contribution to the negotiation, utterances by the teachers or researchers, are coded with open codes. These instances are then compared to each other to find differences and similarities in their actions as they indicate the participant’s interpretations, aims and agency. When looking at longer sequences, patterns are sought after, especially how participants’ aims and agency influence the development of the negotiation. Short excerpts used for constant comparisons are presented in the text and expanded upon. Tied to those excerpts are expansions on the continuing interactions not shown in the transcripts due to space limitations.

**Results**

The excerpts from the transcripts presented here are all from a meeting with the two researchers and the two teachers between Karen’s first lesson and Tilly’s first. The purpose was to engage in a mini-cycle to evaluate the initial design and revise it before Tilly used it in her classroom. One of the researchers, the author of this paper, was present during Karen’s lesson and the discussion utilized their experiences as a main source of data to analyse. In the first episode, the two teachers discuss Karen’s experience during the first lesson. She had asked the students to reflect on the notions statistics, chance and probability at the beginning of the lesson and then proceeded to carry out the design outlined here in an earlier section. Notice how the focus shifts from being about implicit aspects of the activity to being about students connecting knowledge.

Karen: What fascinated me was that their engagement induced the use of the concepts that we highlighted and reconnected to what we did at the beginning. Statistics, chance and probability, well, that Kim said “This is what I think! Statistics is what
we’re doing, and the balls drop by chance but you may still calculate the probability”. He started…

Tilly: He added that, you didn’t guide him?

Karen: No, he was like “This is what I think, I figured out this with statistics”. So, it kind of extracted their knowledge.

Tilly: They latched on on the correct incident somehow.

Karen: Exactly, and they could use the concepts to describe it, what we had done.

Karen acts with an interest in the activity as an eliciting factor for a student’s development of concepts. Tilly indicates that she is interested in how Karen carried out the activity in the classroom and both act as if their main aim is to further develop the task. Tilly then subtly indicates that she has shifted her focus towards the students’ learning process in the second utterance. She acts as if her interpretation of the aim has shifted towards the global aim of contributing to theory on students learning processes. The negotiation takes off in another direction, initially being about gaining understanding of the design aspect towards being about understanding aspects of learning. The global aim of understanding the students’ learning in respect of making connections as well as developing language is pursued long after this extract ends. The following episode picks up this chain of events further into the meeting. Karen admits that the development of the lesson had made her unsure of how she interpreted the three concepts statistics, chance and probability. We start off with her reading her own notes from what she found out from a dictionary after the lesson.

Karen: “Not be able to calculate in advance. Statistics, summarization of information, nah, Probability, the chances of getting” for example blue.

Paul: So what it becomes, Heads or Tails, aren’t known in advance. Is that what you mean?

Tilly: Why did you pose that question like that? What were you thinking? Since you do this professionally… Why did you ask that question?

Paul: Well, because I thought the sentence was incomplete. “we calculate in advance”, I just wanted to emphasise … what is it we can’t calculate in advance?

Tilly: Aaa, okay

The initial statement was copied from a dictionary and Karen acts as if she trusts and places the authority within that community. At least in the case of chance and probability, she relies on the dictionary and achieves agency with the use of it. The group’s prior negotiation of meaning of statistics makes her less confident in the case of statistics; she indicates that she gives primacy to the group’s interpretation. Paul questions this authority altogether. Tilly seems to pick up on Paul’s questioning and probes the nature of Paul’s agency; is he acting from a mathematics education researcher perspective, or a mathematical community perspective or something else? Paul continues by acting as if there are better interpretations of these concepts by questioning the wordings. He later on continues to negotiate the meaning of these concepts by means of examples and more mathematically precise definitions and thereby achieves agency by referring to the mathematical community. This exchange impacts the negotiation towards being even more focused on language.
It also becomes apparent that Paul’s agency influences how Karen and Tilly use technical terms in the remainder of the session. Paul’s aims and agencies remain in focus as they are given more space and remain unquestioned as the work progresses. The following episode is from the later parts of the meeting. It shows the impact of Karen’s and Tilly’s interaction in the first episode regarding the topic but also how Paul is left as an authority. Notice how Paul remains unopposed even though his claims and sentences are incomplete just as Karen’s were in the previous episode.

Paul: My question about statistics springs from that fact that statistics is a rather large subject… A large topic so to speak
Karen: Mm
Paul: And I think that the curriculum sort of… Even in our … our curriculum contains what this student is saying about the ratings of a TV-show. That you compare… often just think about observations, or we usually say frequencies, frequency tables and so on, so you limit the whole field of statistics to what one might call data collection, frequencies and such.
Tilly: Mm
Paul: What do you think, we could think about beginning to establish this type of concepts like… What is the frequency of blue? What is the frequency… How many observations of blue? How many observations of red? So, you insert this type of technical terms to become more precise. Specify a little bit more. That is, I imagine, a part of learning, that you learn to… You use a language and start to become a little bit more precise.

Paul acts as if he wants to shift focus to the local aim of the activity. He offers an alternative, or additional, learning goal in students developing their language through the activity. He pushes his agenda by referring to the authoritative mathematical community and therefore achieving agency. Both Karen and Tilly accept Paul’s agency and leave his claims unopposed and instead adjust their use of language after the episode to fit Paul’s. Paul’s agency also results in a shift of focus in the following interaction. The continuing negotiation still involves interpretations of language but also aspects of the design and how language development can be anticipated and sequenced in a HLT.

To sum up the analysis, I exemplify how rearranging the aims of the activity, placing the aim of understanding students’ learning in the foreground instead of the aim to develop the design, can have huge impacts on the course of the developmental process. Karen’s and Tilly’s interaction in the first extract refocused much of the remaining discussion towards negotiating the meaning of language use and development. An example of the dance of agency in designing educational activities has also been offered. Especially how some agency has higher authority and thus also more impact on the negotiation process.

Discussion

Shifts of agency emerged in the presented episodes. Karen and Tilly both seemed to mostly rely on personal agencies in their actions, trusting in their professional experience in teaching for learning and language development. Paul on the other hand was perceived to rely on agency achieved from highly regarded disciplines as the mathematics and mathematics education research communities.
when he contributes with examples and language. It corresponds with results from when Pickering (1995) studied mathematicians in their work. He saw that mathematicians often relied on their personal agency as they created initial ideas but “surrendered” to that of the discipline, as they needed to resort to following standard procedures of (for example) proofs. A similar phenomenon was observed in the episodes. Karen and Tilly relied on their personal agency until Paul referred to the mathematics community; Karen and Tilly then surrendered to the formalized language of the discipline to a greater extent. Further on it resulted in worksheets handed to the students using this formalized language and thus re-evaluating the HLT in light of formal use of concepts. I suggest that it emphasizes how the dance of agency (Pickering, 1995) is a principle to regard in collaboration between researchers and practitioners as it has the potential to be an indirect tool to guide the negotiation process in different directions.

Shifts in aims emerged in the data. Karen initially acts in line with the global aim of developing aspects of the design but soon shifts to align with Tilly to negotiate the meaning of a student’s language development. Paul later uses the mathematics community to achieve agency to shift focus towards developing the design once again and then sits back to evaluate its impact. Blumer (1986) argues that not only individual aims should be regarded but also that of the group. When multiple actors interact over a period of time a joint action is formed. It is a social construct that extends from being merely the sum of all actions, for example it also has its own aim that is negotiated by its participants. One might look at Karen’s, Tilly’s and Paul’s shifts in aims as attempts to negotiate what aim should be in focus or in the foreground while the others remain in the background. It becomes apparent in the topics discussed that the negotiation of aims for the joint action has impact. In the extended data, patterns emerge of how shifts in the joint aim redirect the following interaction until it was renegotiated. The result was an added activity in the HLT that was meant to challenge students’ ideas of chance. Reasons for why the participants chose to contribute in this way did not emerge from the existing data but one could speculate whether it has something to do with the respective role of the actors, being from a tradition of research or education. It presents a way forward to further advance our insight in the collaboration between researchers and practitioners in design research in mathematics education.

Implications

As Stephan (2015) highlights the importance of working with small groups of teachers instead of just one in design research collaborations, the dance of agency is yet another tool to create purposeful design research collaborations. In the case of Paul, agency is used to steer the negotiation of meaning towards more mathematically aligned use of vocabulary. In another setting, it is possible to rely on shifting agencies to empower teachers in the collaboration by placing it in the domain of mathematics teachers. There is also the possibility to put focus on the research agenda when discussions tend to steer away. One could also consider the interpretation that it has the potential to shift the power relations, creating an (even bigger?) imbalance between participants, making participants less likely to make substantial contributions to the development of the task. The conclusion is that conscious achievement of agency can be used as a tool for researchers in design research collaborations to manoeuvre the discussion and shape the HLT to fulfil different aims.

In order to identify mechanisms that can support mediation, this paper analyses the decision making process in a collaborative design of a digital learning resource by two different Communities of Interest (CoI). It focuses especially on the influence of both the CoI contexts and the socio-technical environment. This research was carried out within the framework of the “M C Squared” European project aiming at studying social creativity in the resource design. Specific conceptual and technical tools were used in this project to ease and document social interactions in the design of innovative learning resources promoting Creative Mathematical Thinking in the users. We focus on two main forces: tools and culture, which supported the collaborative design work between two CoIs.

Keywords: Community of Interest, context, socio-technical environment, collaborative task design, Creative Mathematical Thinking.

Introduction

This paper focuses on the analysis of a collaborative design of an innovative kind of digital educational resources for teaching and learning mathematics by different teams of designers. This research took place in the frame of the European Research and Development project called “M C Squared (MC2)” (http://mc2-project.eu/) where innovative digital resources have been produced to promote creative mathematical thinking (CMT). These resources have been designed by four Communities of Interest (CoI) (Fisher, 2001) constituted within the project: the English, French, Greek and Spanish CoIs. One of the objectives of the project was studying the processes of social creativity occurring during the design of resources and uncovering factors fostering it. Moreover, as the design was carried out in four different countries, the question of the influence of the cultural and institutional context on the design choices, as well as on the processes of social creativity, was raised naturally.

In this paper, we focus on the design process that involved a collaboration between two CoIs, the inter-CoI interaction being considered as a window on contextual issues impacting the design. We report the case of a resource called “Limits” that was initially designed by the French CoI members, redesigned by the Spanish CoI, and finally redesigned again in the cross-CoI collaboration between the two CoIs. In this framework of a collaborative design of a resource, we explore the influence of the context and of the conceptual and technical tools on the design process. In other words, we are particularly interested in how the CoI context influences the design process in a given socio-technical environment and which tools and mechanisms support the collaboration between different teams of designers in the process of task design.
The paper starts by presenting the context within which this research was carried out and its theoretical and methodological background. The design of the “Limits” resource is then described and analysed and the findings are discussed bringing to the fore elements of answers to the research questions.

**Context and socio-technical environment of the CoI**

**Communities of Interest (Cols) and their context**

According to Fischer (2001), Communities of Interest “bring together stakeholders from different CoPs [Communities of Practice] (Wenger, 1998) to solve a particular (design) problem of common concern". Four CoIs were constituted in the MC2 project gathering together, around a digital resource design, mathematics teachers, teacher educators, researches in mathematics education, educational software designers, artists, etc.

The French and the Spanish CoI, whose experience is reported in this paper, present different compositions and characteristics; we consider these as contextual aspects. The French CoI consists of 13 members with varied professional background, including researchers, school teachers, teacher educators, and educational technology developers. They share a socio-constructivist approach to mathematics learning rooted in the French didactical tradition of teaching and learning mathematics (CFEM, 2016). This approach has shaped the CoI representation of creative mathematical thinking (CMT) that manifests itself through (implicit) task design principles, such as designing tasks aiming at revealing specific students’ misconceptions, using multiple representations to enhance conceptualisation of mathematical notions, fostering social aspects through collaboration between students and affective aspects through challenging problems and games, or focusing on tasks calling for generalisation. The Spanish CoI, composed of about 20 members, involves people from different communities of practice, including researchers in and out of mathematics education, secondary school and university teachers and publishers. Most of the resources designed by the Spanish CoI present many design principles that are especially important for mathematical modelling, such as proposing real questions to students in order to face linking mathematics with other disciplines (social sciences, history, etc.), articulating questions posed and mathematical tools to engage students in modelling processes, enhancing the exploration or the contrast and validation of mathematical tools and models.

**The socio-technical environment and collaborative design**

The design of resources took place within a specific socio-technical environment developed in the MC2 project, called C-Book technology (http://mc2dme.appspot.com/mcs/). It integrates two main tools: i) an authoring environment enabling to create digital resources, called c-books (“c” for creative), which consist from pages including texts, pictures, hyperlinks, dynamic interactive widgets, and allowing to record successive versions of the c-book units; ii) a tool, named CoICode that provides a workspace to organize and enhance interactions among designers. CoICode enables each designer to post various kinds of ideas (“contributory”, “alternative”, “objection”, “off task” and “task organization”), each of them having a specific icon. When a designer posts an idea, the system captures several details: author’s name, date, title of the idea, comments, attached resources, hyperlinks, etc. The CoCode system provides designers from a CoI or a CoI-pair (two collaborating CoIs) with a space for collaborative design. In CoICode, the discussions can be visualised in form of threaded forum or in a mind-map view (Fig. 1), where nodes are ideas, and branches of the tree model.
the evolutions of an idea. The reports in the form of a graph provided by the system are the main data gathered for the study of social creativity. A voting system has been implemented in the CoICode allowing designers to evaluate in terms of creativity any idea posted by someone else. Such evaluation follows a “middle c” perspective of creativity (Moran, 2010), that views creativity as a competency developed through interactions between members of a community and through their participation in situations where they display their intentions and negotiate new alternatives for the interpretation of actions in situated activity systems.

The cross-CoI collaboration on the re-design of the “Limits” c-book was organized in the following five phases: (1) a part of the French CoI, acting as the primary designers, designed a first version of the c-book; (2) four members of the Spanish CoI (two secondary school teachers, one researcher in mathematics education and one researcher in Calculus) evaluated the CMT potential of the c-book; (3) these members of the Spanish CoI redesigned the c-book according to their own approach, which constituted the first phase of the redesign; (4) a second redesign phase was carried out by the CoI-pair comprising this Spanish sub-CoI and two members of the French CoI (one researcher in mathematics education and one secondary school teacher); and (5) four new members (two from each CoI not involved in the redesign) evaluated the CMT potential of the redesigned c-book.

**Theoretical and methodological background**

**Documentational and boundary crossing approaches**

Our focus on the genesis of the c-book resource leads us to adopt the *Documentational Approach to Didactics (DA)* (Gueudet&Trouche, 2009) and thus consider the design of this resource as a documentational genesis. The analysis of resources coming into play in this genesis and of their successive versions unveils designers’ mathematics knowledge, CMT representations and culture. In addition, considering the collaboration between two CoIs, which can be viewed as two different activity systems, allows inferring the influence of the contexts on the design choices.

The *Boundary Crossing approach* (Akkerman&Bakker, 2011) enables enlightening the interactions between these contexts. It allows to highlight discontinuities, i.e. boundaries. Boundary objects (Star & Griesemer, 1989) and brokers support the communication and the understanding between and within the CoIs, allow to build new norms and a common frame of reference. Moreover, highlighting the mechanisms of *identification* (i.e., consciousness of discontinuities, awareness of multifold cultural background, which allows pointing out differences), *coordination* (i.e., creation of continuities between domains and bridges between cultures, which enables the construction of a common frame of reference), *reflection* (i.e., perspective making, perspective taking on the problem
at stake, which supports divergent thinking), and transformation (i.e., confrontation, recognition of a shared problem space, hybridization or combining ideas, and crystallization or keeping a perspective, an idea) helps us to better understand the design process.

**Grid for the evaluation of c-book features fostering CMT**

The evaluation of the potential or affordances of a c-book to foster CMT was a central task in the MC2 project. Facing the necessity of CMT cross-evaluation, a need emerged for agreeing on and sharing common criteria, tools and methodologies, which had been developed independently in the first cycles of c-book production. A common CMT evaluation grid, which combines design criteria or principles proposed by the four CoIs involved in the project, has been elaborated by the researchers. This grid could be adapted by each CoI or CoI-pair to better fit its context, by adding specific criteria, and played a crucial role in the construction of a common frame of reference for all four CoIs.

The CMT evaluation grid is a questionnaire composed of three sections. The first and the widest section focuses on the evaluation up to what degree different dimensions of mathematical activity considered crucial for fostering CMT, such as conjecturing, questioning, evaluating, and establishing connections, are taken into account in the c-book design. With a total of 14 items expressing the indicators of different dimensions, evaluators of a c-book grade (from 1-4) their agreement on the items and explain their response according to the design being evaluated. For instance, the dimension of establishing connections is evaluated through the item: “The c-book provides users with opportunities to establish connections between various representations of the mathematical concepts at stake”, or the validation dimension through the item: “The c-book stimulates to think about, reflect, summarize and evaluate the mathematical work already developed”. The second section addresses social aspects through items like: “The c-book stimulates user's collaboration / cooperation / interaction with other users”. Finally, the third section focuses on affective aspects via items like: “The c-book actively promotes engagement by generating a perception of usefulness of mathematics, either in everyday life, or inside the mathematical context”. This grid, filled in for each c-book, provides the basis of the CMT study and development.

**CoICode analytics features**

In the MC2 project, a creative idea is defined as: (1) novel (original, unusual or new for the CoI members), (2) appropriate, that is it conforms to the characteristics and functions of the c-books, including their CMT affordances, bind to the CoI context, and (3) usable, that is available and ready to be used in the design of the c-book according to the designers’ (the CoI members’) estimation (Daskolia, 2015). CoICode voting mechanism allows any CoI member to express his/her opinion about the three attributes of any idea posted by any other CoI member. The expressed opinions are aggregated into the creative score of an idea defined as follows: “creative score of the idea i (CRi) = 0.5 x number of ‘novel’ votes + 0.25 x number of ‘appropriate’ votes + 0.25 x number of ‘usable’ votes, if the number of ‘novel’ votes is at least a half of the number of CoI members involved in the c-book design, otherwise CRi = 0”. This definition reflects the fact that novelty is the sine qua non condition for an idea to be deemed creative; this is why the corresponding weight is the highest (0.5). On the other hand, the “middle c” perspective of creativity leads to considering an idea creative if the majority of the CoI members share this opinion. Thus, the interactions recorded in CoICode allow
tracking communication among the designers during the design process and getting automatically the ranking of the ideas expressed according to their creativity score (Table 1).

Table 1. Quantitative measurement to identify creative ideas.

Data collection and observables for each phase

The ideas and their organisation in CoICode workspaces, the creativity score of ideas obtained automatically from CoICode, the CMT grids filled in by the evaluators of the c-book and the successive versions of the c-book constitute the main data we analyse in order to highlight the impact of context, and cultural evolutions on the design decisions taken, as well as the role of the tools in the design process.

C-book design process in the cross-CoI collaboration and its analysis

Our analysis focuses on two out of the five phases of the redesign of the c-book “Limits” (see above), namely phase (3), when the Spanish CoI redesigned the c-book and the phase (4) when the CoI-pair worked collaboratively on agreeing upon and conceptualizing the last changes of the redesigned c-book. We have chosen these two phases of the redesign process as they appear especially important with respect to our research questions.

Adopting the c-book and de- and re-contextualizing its design: mechanisms of coordination and reflection

The initial version of the c-book “Limits”, designed by the French CoI, covered the notion of infinity through its meaning in solving equations, constructing the Pythagorean tree, analysing geometric sequences, comparing growth of functions, and calculating limits of real functions. The CMT representation of the French CoI members shaped the design of the c-book. In particular, it led the designers to embed tasks that enable intra-mathematical connections, generalisation, competition and challenge as levers for the CMT development. Following these principles, they proposed tasks offering various representations of the mathematical notions at stake (limits and infinity), by using algebraic, calculus, and geometrical settings, with the aim to provide students with alternative ways to make sense of these difficult notions in calculus and to generalise some properties. Moreover, the educational technology developers, involved in the CoI, enabled the development of specific widgets with features deemed as important to foster CMT, such as relevant feedback, written collaboration and discussions (a chat tool), and a framework for designing playful activities affording students’ self-assessment. Hence, the involvement of software developers in the designers’ team impacted the c-book design by creating new widgets in line with the French CoI culture. They also worked in close collaboration with the C-book technology developers, thus playing the role of technical brokers within the CoI.

As soon as the phase (3) started, the Spanish CoI began with the redesign of the c-book. The designers structured the workspace dedicated to the intra-CoI redesign work according to the results of their CMT evaluation with the grid (see section 3). For instance, they found the c-book improvable.
regarding the connections that could be established with other disciplines or with other mathematical
topics. They appreciated some characteristics of the c-book such as connections between several
representations (numerical, geometric, and algebraic) of limits or the potential of the new widgets to
simulate functions, sequences, limits, etc. and their practical use in activities focusing on evaluating
students’ work and progress. The decision to maintain these features can be interpreted as the
agreement on the underpinning design criteria by both CoIs. They also detected several traits to
further improve the c-book redesign, some of them being central for their own CMT representation;
for example, they missed situations and questions that give sense and utility to the mathematical
notions at stake (infinity, limits, etc.) – questioning or problematisation. Likewise, they missed a
global articulation of some of the activities dealing with a more general narrative and questions to
focus on. This led the designers to organize the CoICode workspace around the eight design criteria
or indicators they considered as crucial to be prompted (validation, connections, articulation,
problematisation ...) according to their CMT approach (Fig. 2, first column on the left) to orient
further discussion. Therefore, the redesigned c-book urged students to investigate questions like the
ones about fractal constructions and properties (guiding part 1 of the redesigned c-book), or the one
about a cell phone password as the problem of the 9 points (guiding part 2), and to engage students
in recognizing patterns in the process of mathematization of a problem, and in using the
corresponding mathematical relations to check the validity of a conjecture.

In this episode, we can identify a mechanism of coordination initiated by the CMT evaluation which
supported the subsequent mechanism of reflexion sustained by the structure given to the workspace.
We note that the Spanish Col instrumentalized CoICode, with a strong purpose of enhancing the c-
book potential to foster CMT in students in line with their culture. Hence the mechanism of reflexion
enabled to open new perspectives, related to the Spanish context, by adding tasks on fractals, the
problem of 9 points and the mathematization of another problem.

**The Col-pair collaboration in the c-book redesign: mechanism of transformation**

The cross-Col collaboration (phase 4), started with the translation of the redesigned c-book into
English and the creation of a new workspace common to both CoIs. In order to organise and facilitate
the communication between the two CoIs, the workspace was structured according to the four main
sections of the c-book, and a summary of the main aims and changes introduced by the Spanish Col
in each section was added; the French team could thus compare the new version of the c-book with
its original design. During the CoI collaborative work, some design principles stemming from both CoIs were recognized and discussed to progressively become shared by both CoIs (confrontation and crystallisation of principles), such as the importance of tasks calling for conjectures, simulation, communication of results, and validation. Other design choices issued from the Spanish CoI were accepted by the primary designers of the c-book, such as the extra-mathematical connections included in the c-book or the new way of structuring and articulating activities in terms of chains of interrelated questions with increasing complexity. Furthermore, the quantitative information provided by the CoICode data analytics, in particular in terms of creative scores of ideas (see Table 1) appeared as a powerful tool to identify ideas worth to be further developed in the CoI-pair collaboration. The two ideas that obtained the highest creativity scores came from two comments made by two members of the French CoI while analysing the c-book redesigned by the Spanish CoI. The first idea was related to the first part of the c-book devoted to the study of fractal properties and the appearance of the notion of limit at infinity. A French CoI member provided a link to a widget he designed with Cinderella dynamic geometry system to simulate fractals and predict their tendency in the infinity (Table 1, idea n°45675). The widget was subsequently integrated at the end of this first section with new questions that CoI-pair members suggested. The other idea was suggested by another French CoI member concerning the possibilities embedded in chat tools, developed within the French CoI, to foster social aspects (Table 1, idea n°45901). Chat tools were subsequently integrated in the c-book to enable students to communicate their results or to pose new questions. These episodes can be interpreted as hybridisation and elaboration of ideas.

Besides the importance that this phase had on creating a new and common CoI-pair design context, our analysis shows that the CMT grid, the CoICode workspace the creative scores of ideas and the c-book versions used as boundary objects between the two CoIs constituted key meditation supports to enable the designers to agree on which ideas to accept (or not) and on the ways of further elaboration of some of these ideas, thus sustaining the mechanisms of coordination, reflection and transformation.

Discussion and conclusion

The analysis of the c-book “Limits” collaborative design shows that different CMT representations that both CoIs held, influenced by each CoI own culture and traditions, enriched the cross-CoI collaboration, acted as a boundary object and participated in the key mechanism of coordination for decisions making in the intra-CoI and cross-CoI design work (Barajas, 2016).

In the two phases of intra-CoI and cross-CoI work (phases 3 and 4), it appeared that redesigning does not mean a total transformation and complete re-contextualisation either of the initial unit, of the empirical setting envisioned or of the academic approach (Barquero, Papadopoulos, Barajas & Kynigos, 2016), but rather an improvement of some aspects, and it helped to establish confidence and trust atmosphere. On the contrary, some design principles shared by the two CoIs were reinforced, crystallised through the mechanism of transformation, such as connections between multiple representations, or making and investigating conjectures. Others, coming from only one CoI, were negotiated and became shared by both CoIs, such as extra-mathematical connections or interrelations between the c-book activities, yet others were abandoned. The CoI-pair created a new, wealthier design context thanks to two different cultures close enough to create some overlaps yielding a common frame of reference, which enabled to build understanding and fostered the mechanism of
coordination. The understanding and respect allowed to share design decisions with the help of mediation tools used as boundary objects (different versions of the c-book, CMT grid, creative scores of ideas) and to cross some boundaries (different CMT representations, school cultures, research approaches, distance collaboration). The mediation tools favoured the dialogue between the CoIs and facilitated decisions, in conjunction with common good practices and CoI moderation strategies. The workspaces in ColCode used as meditational artefact were instrumentalized to support reflection, enabling to make points of view explicit (perspective making) and to enrich ideas (hybridisation). The boundary objects, the structure of the workspaces and the moderation strategy played a major role in the mechanism of coordination, reflection and transformation.

This study brings to the fore two main forces that shaped decision making in the design process: tools and cultures (Fig. 3).

![Figure 3. Main forces shaping the decision making in a c-book design process.](image)

Both had either theoretical or conceptual dimensions, for example the CMT evaluation grid built on theoretical considerations about creativity, but they have socio-technical aspects as well because the C-Book technology, comprising authoring tools, widget factories and CoICode, is the MC2 project social management main tool. The cultural context of the CoI includes mathematics education theoretical tradition, composition of the CoI, familiarity and expertise with the variety of widgets. The background of the designers impacts their attitude towards these tools, their CMT representations, their position in the collaborative decision making and the widgets they use. Eased by the proximity of collaborating cultures, the interplay of culture and tools in cross-CoI collaboration had enriched the scope of the designed tasks.

Programming for 3rd graders, Scratch-based or unplugged?

Aaron Gaio¹

¹University of Palermo, Department of Mathematics and Computer Science, Palermo, Italy; aaron.gaio@dmi.unict.it

In this paper we describe a comparison between two different approaches to teach some algorithmic and computational thinking to children, mainly in 3rd grade. Children’s learning is taken into main consideration and we want to analyze the difficulties students encounter using the different approaches. Before that, an introduction is done, describing the research framework and methodology, offering the background for this research and outlining the larger research project from which the paper is derived. We then describe the tasks used and look at some examples of the difficulties children face, on one side dealing with the problem of abstract thinking while programming, and on the other having troubles relating more practical activity with what the calculator does.

Keywords: Primary education, curriculum, computer science, programming, algorithms.

Introduction

Computer Science and algorithms in education are gaining more and more importance as the use of digital technologies is nowadays part of everyone’s life. New educational trends are therefore emerging both from the computer science and mathematics education research community and from elementary and secondary school teachers (Franklin et al., 2015; Richtel, 2014). The question about how young children learn computer science is still a new area of research; and providing effective learning opportunities to K-5 students is a big challenge (Hills et al., 2015; Gelderblom & Kotze, 2009). Some good examples have been tried in the secondary school, while we feel that not much is present, at least in our country, in lower school grades. Topics in computer science and discrete mathematics are not clearly delimited in our curriculum and teachers are usually not aware that they actually could. We are thinking of our work as able to enhance the study of teaching and learning skills of mathematical practice through discrete mathematics problems, both general skills, such as reasoning and modeling, and skills particular to discrete mathematics, such as algorithmic and recursive thinking.

Background and context

Preliminary survey among teachers – relation with cryptography

We had a first survey, with results collected from about 150 teachers, mostly in service and quite evenly divided between primary, middle and secondary school. The survey was done with an online platform. The result analysis is mainly following a quantitative approach, the qualitative analysis was referred to the codification of some particular key words used by teachers.

Analysing the results, teachers, especially at lower levels, admit not to have the necessary knowledge to teach this in school. Question was about their previous experience in learning cryptography and graph theory, as well as the connection of these to mathematics and computer science. Some of these teachers see the connection between algorithms, cryptography and mathematics in general and computer science as quite necessary, while some don’t have this idea clear in their mind. Also,
teachers were asked if they had any previous experience in teaching the topic or if "they would be interested in teaching some algorithm, cryptography and other discrete mathematics topic to students”, and feeling from their answer is that this results can be taken as a first starting and promising point to make something of this into the national curriculum. A detailed analysis of these results is available in another article (Gaio & Di Paola, 2016, in press).

National Guidelines and teaching situation

The Italian Ministry for Education, University and Research published the current National Guidelines for the first cycle (kindergarten to middle school) of education (Ministero della Pubblica Istruzione, 2012). These guidelines are not any longer a detailed description of school curriculum to follow, but just want to provide concepts from which the single schools and institutes, and teachers, can take the basic goals and competences to reach. Some general standards are set with objectives for the educational achievements and learning goals. In the section talking about mathematics, there is a great importance given to reading and understanding texts with logical content, build lines of reasoning, having own ideas and defending and comparing them with others; a positive attitude towards mathematics, realizing how mathematical topics are useful in the real world. Algorithms and logical thinking as also referred to as important in the technology chapter of the guidelines, for all school grades. Following these guidelines, and our idea as well, “the first education cycle has a prominent role in the school curriculum considering the importance of this time in every student's life. Within this, the school attributes great relevance to the education and teaching methods that can fully activate energies and potentialities of every kid”.

Research question

Our main general research problem lies therefore in a proposal to alleviate the substantial lack of activities in the national school curriculum about discrete mathematics and computer algorithms, especially for primary and middle school. Both in the school programs and in textbooks, activities of this kind are missing almost entirely, despite many agree that they can be really useful to improve the skills mentioned above.

The purpose of this specific paper is to deal with the introduction of programming reasoning to children as young as 8 or 9 years old. The question is whether it is better to approach the subject with an unplugged approach and only later go on with computer-based coding or if it is ok to proceed using Scratch-based software and tools to serve the same purpose. We do this by describing two different approaches which have been used in the teaching of these computer science and discrete mathematics topics. We will in particular analyze and focus on certain difficulties students encounter while using both.

Theory and methodology

This is an overview, referring to our whole project’s methodology and background theory.

Background theory

Teaching methods follow the model of Realistic Mathematics Education (Gravemeijer, 1994) and Guided Reinvention of mathematics (Brousseau, 1997).

Guided Reinvention of mathematics is based on Hans Freudenthal concept of mathematics as human activity. Education should give students the "guided" opportunity to "re-invent" mathematics by
doing it. This means that in mathematics education, the focal point should not be on mathematics as a closed system but on the activity, on the process of mathematization (Freudenthal, 1973).

Realistic Mathematics Education (RME) is an instructional design theory which centers around the view of mathematics as a human activity (Freudenthal, 1991); “The idea is to allow learners to come to regard the knowledge that they acquire as their own private knowledge, knowledge for which they themselves are responsible.”(Gravemeijer, 1994). The main goal is to develop a local (i.e. domain-specific) instructional theory (LIT) that will allow students to “[invent] the mathematics themselves” (Larsen, 2008). This need two steps: Step 1, in which “students are engaged in activities designed to invoke powerful informal understandings” (Weber & Larsen, 2008); Step 2, in which “students are engaged in activities designed to support reflection on these informal notions in order to promote the development of formal concepts” (Weber & Larsen, 2008).

**Research methodology**

The methodology we are going to use is that of design research or design experiments (Cobb et al., 2003; Barab & Squire, 2004; Brown, 1992). For the purpose of this thesis, the developmental approach is taken into consideration (Plomp & Nieveen, 2007); development studies function is to design and develop a research based, intervention (Steffe, 1983) and constructing design principles in the process of developing it. The goal is to explore new learning and teaching environments, to verify their effectiveness; to develop somehow new methods, instruments and teaching actions to further improve in the field of problem solving and logical thinking, using somehow unusual topics as algorithms and cryptography are for primary school students. Doing this the goal is to contribute to the development of new teaching and learning theories, taking into consideration learning processes in the specific situation, with contents and goals clearly defined. Design research is quite appropriate in this situation, as we are facing a brand new experience in an environment that we need to analyze carefully, i.e. on a local scale, considering all the different elements in the learning environment. The intended design experiment will be a classroom experiment in which the researcher (or researchers) will cooperate with the teachers in assuming teaching responsibilities. On one hand, the teacher is a part of the design team and will be a key role in the development and reviewing of the activities, on the other, they have no previous knowledge and need a guide to experiment with this new experience and new content to present.

**Design, tasks, analysis and results**

As a first design step, based on theoretical framework and literature, two hypothetical learning trajectories were designed for the two different approaches. One approach is Scratch-based, and has been taken from the most popular book on curricular resources about Scratch programming in our country (Coding, DeAgostini publisher, Ferrara, Colombini, Bonanome, 2014). The second approach was developed by our research team, taking idea and inspiration from the Computer Science Unplugged project (Bell, Witten, Fellows, 1998, 2015 review) and other related sources (Casey et al., 1992), with a development, after a preliminary teaching experiment, to better adapt the activities to the school level and local situation and norms. The two HLTs are taking into account the theoretical framework presented above, both in the choice of tasks (e.g. some tasks are chosen for their RME approach, others for the group and cooperative work students have to do, and so on) and in the way of presenting them to the classroom or students.
The tasks we are going to describe are just some of the many sequences of tasks that were proposed to various schools and age groups during the 2015/2016 school year in the bigger research project. In a design research paradigm (Plomp & Nievenn, 2007), the activities were tried out many times, always with an a priori analysis together with the teachers and with a retrospective look after each lesson.

Table 1: Classes involved in different grades, with students numbers and curriculum used

**Scratch-based teaching and learning**

As mentioned above, the sequence of tasks we called “Scratch-based” is taken from this Coding book, which is getting popular in our country’s schools. Also we did use the M.I.T. official Scratch guide (Creative Computing, Brennan, Balch & Chung, 2014). It is following a similar approach to many school text books and even M.I.T.’s own guidelines on Scratch use and we feel it is good material for teachers. We did choose the tasks that are most popular among teachers already doing this kind of activity in their classroom, at least investigating the most popular in our area.

We did in particular choose tasks related to sequencing, selection and iteration. The goal is to have students learn basic ideas behind an algorithm (seen as a sequence of instructions), but also more complex concepts like selection instructions (i.e. do this only if something else happens) or iteration procedures. A sequence of tasks on those three topics were selected together with the classroom teacher and then tried out with the students during mathematics and technology lessons.

**Unplugged approach, teaching and learning**

Our “unplugged” sequence of tasks occupies 3 or 4 lesson slots of about one and a half to two hours and follows a brief introduction given on how computer works and binary numbers, in form of games (this was given also the groups using the other approach). Briefly describing the tasks, task 1 was an activity on paper, about binary image representation. Students had to color a grid which was provided with 0s and 1s and produce a drawing following the numbers. This task goal was about following instructions and beginning to understand how a computer transmits information.
Task 2 was about giving and receiving instructions. Students were divided in pairs and given a series of shapes and objects they could move on their table. One student (1) for each pair was to create a composition on his table; without looking at each other (physical barrier between the two), student 1 had to explain to the other how to reproduce the same composition with the objects and shapes. Children were required to be as precise as possible while the game went on, and to try to find out compositions that were harder to form. Only oral communication were left them, not to make them “correct” the other mistakes or looking at the other composition. Slightly different versions of the game were tried out, e.g. with just one student giving instructions to all others, or with different kinds of objects, even with just drawing something instead of moving objects, and so on.

The following tasks had the goal to make programming even more tangible for children. We wanted them to learn to give instruction as a calculator, through a path to walk on. One student (blinded) was the “robot” walking along this path on the ground and the others were the “programmers” having to give him instructions how to move to get to the end. We did this both speaking and then written. The written exercise does not give the possibility to correct the robot while you are actually giving the instructions, kind of how a real computer program works. Finally, with some of the classes we went on to construct some more complex sequence of instructions, posing different games to strengthen the concepts, but always with similar goals.

**Methods of video selection and analysis**

Analysis of the results is video-based, qualitative and fine-grained; both group activities and classroom discussion are recorded and we also have many of the transcripts, together with field notes, student’s sheets, and interviews as other sources of evidence. As already said, focus is put on students’ learning and thinking, in reaction to the different tasks proposed.

Following Zacks & Tverski theory, data is represented by events selected from the video recordings available. We used an inductive approach in video selecting, beginning with viewing the corpus in its entirety and focus on details later on. Indexing and summaries of videos, plus a content log, help in this process. Going on with the analysis some events which were particularly relevant were isolated. Although there are some recognizable recurring situation and choice of words we coded, our focus is more on a “play-by-play” description of these chosen events. We are, with this approach, analyzing selected episodes focusing on the same happening and constantly revising our finding and new hypothesis, as in Cobb and Whitenack (1996) with the involvement of “constantly reconciling provisional analytic categories with subsequent data and newly formulated categories”.

---

Proceedings of CERME10
Different difficulties emerging

The “events” we are focusing on do not pretend to show that one approach is better than the other, but which kind of, different, difficulties each of them can create in the children learning and thinking using the different approaches.

In the unplugged approach, children easily figure out what they are really and practically doing, drawing conclusions that they usually do not get in front of the computer. See for example the following figures where the transition from longer instruction in the first part to shorter instruction (switching to an iteration notation) in the second comes automatically. Almost every student quite naturally finds out that it takes a long time to write again and again the same instruction and is quickly asking himself if he might “make it somehow shorter”. This is probably due to the fact that they were left free to develop their own language with arrows, and they feel they can adapt it to what is more appropriate and efficient for the situation. Videos showing these moments when they realize this fact has been isolated from the data.

Figures 5 and 6: Showing the transition from sequential instruction to iteration

Or, on the other hand, as an example, see the following short transcript from a video (in front of a Scratch set of instruction on the computer), where the students do not realize the usefulness of shortening a computer program to make it simple and more efficient:

Teacher: Why aren’t you writing it in a shorter way (more compact?)? You don’t need to write an instruction 6 times, you could write “do this … times”.

Student: Well, but what’s the need for it? The computer is doing it anyways.

In these examples, students doing it unplugged quickly find out they are more efficient if they switch to an iterative mode of giving their instructions, while students doing it on the computer do not really realize this. On the contrary, they should learn one more command (or Scratch block) they do not already know to do it, so in the beginning it does not seem so appealing. From many events observed, quite surprisingly, this shortening is not immediate on the computer. Following our qualitative video analysis, in general, it seems that both selection and iteration instructions do not come naturally in
the Scratch environment as they do in an unplugged approach. Setting the activities and game in a real world scenario, especially at this young age, seems to give children a better idea of the advantages of iteration and the working principles of selection programming. Maybe creating some highly inefficient situation could force this process to happen in this case, too.

A second aspect to consider is errors done while writing a program. Analyzing error situation we can observe that it is actually easier for the students to spot the errors in a Computer-based environment. In the unplugged approach, sometimes, error fixing does not work at all, i.e. they cannot even spot the error if told that there is one. Our conclusion is that, as they are controlling their own game, they, more or less, unconsciously, get to a right solution even with a wrong set of instructions. On the computer-based environment, trying the program and making it running, given that the computer executes exactly what it has been told, students easily spots where the mistake is.

Another aspect we are facing at this young age is abstraction capability. As many references states (see Kramer, 2007), abstraction capability is the key to be a good programmer and to have future programming abilities. Abstraction is a very difficult process and Scratch helps a lot in this direction; on the other side, the unplugged approach makes activities somehow too distant from the abstraction of programming and makes it more difficult to children to relate what they are doing with what they will later do on the calculator, as some video excerpts from these moments show. Aspects of a real world mathematics surely can help the transition to the abstract world of programming (Futschek & Moschitz, 2011), but we have to be careful in the subtle connection between the two areas.

**Conclusions**

As conclusions, we could see pros and cons of both approaches, and we feel that obsessing over using just one is not the correct decision. Video and other data analysis show that there are aspects that ought to be dealt with in an unplugged way before writing them on the computer (algorithms, iteration processes and many others) and come really more natural to children if they use their own language, as can be seen in many “Aha! Moments” in the recordings. On the other side, it is really difficult for young children to relate the more real-world-oriented tasks to computer science, as we can see example when they get stuck in finding the connections. Future work will try to go into combining both approaches in a more comprehensive curriculum plan, creating new learning sequences that take both into account, which we will share with teachers and educators, in a relatively long developing process. Teachers willing to teach these topics are growing in number and they ought to be prepared for the challenge they will be facing.

Principles of redesigning an e-task based on a paper-and-pencil task:
The case of parametric functions

Galit Nagari Haddif
University of Haifa, Faculty of Education, Haifa, Israel; gnagarih@campus.haifa.ac.il

Paper tasks are often redesigned to function as digital tasks. The research and design literature (Pead, 2010; Burkhardt & Pead, 2003) has reported on the challenges of such a transformation. We report on a study exploring the design principles of an e-task, originally designed as a paper-and-pencil task and converted into an interactive diagram. We describe a paper task in the content area of parametric functions, and report on results from an experiment conducted with 39 high school students, who dealt with an e-task based on a paper task. Analyzing the results, we demonstrate that in a redesigned e-task based on a paper-and-pencil task, technology should allow self-reflection, promote learning, and guide the students to focus on the important details without unnecessary distractions.

Keywords: Design, e-task, parameter.

Goals and theoretical framework

In this paper, we explore design principles of an e-task that encourages exploration, based on a paper-and-pencil (P&P) task, in the area of parametric functions, which is central in algebra and is adequate for enhancing the abstraction of concrete situations (Drijvers, 2001). Solving parametric equations is different and more challenging than solving numerical algebraic equations, which are solved for an unknown that is a number. Naturally, when designing an e-task we should not translate from the paper but rather use successful principles of learning within the interactive environment to design the tasks. Research shows that many complex issues arise when transferring paper-and-pencil tasks to computers. For example, if students are not familiar with the tools, the online environment may be a potential source of an additional "cognitive load" (Pead, 2010). Interactivity can spoil some tasks: for example, by allowing students to check all their answers, or by encouraging them to persist in trial-and-error experimentation, rather than engaging in analysis (Burkhardt & Pead, 2003; Nagari Haddif & Yerushalmy, 2015). Although the transition from a paper-and-pencil task to an e-task is not trivial, there may be an added value in the use of technology. For example, multiple linked representations (MLRs) both support and require tasks that involve decision making and other problem-solving skills, such as estimation, selecting a representation, and mapping the changes across representations (e.g., Yerushalmy, 2006).

With the Cabri software, Healy (2000) introduced soft and robust construction and found that despite the intention to encourage students to build robust constructions, in practice, some students preferred to investigate a second type of Cabri-object, soft constructions, in which one of the chosen properties is deliberately constructed by eye in an empirical manner, under the control of the student. Laborde (2005) referred to soft constructions as the "private" side of the student’s work, which is part of the solving process and serves as a scaffold to a definite robust construction. We suggest using soft constructions as a way of exploring and identifying dependences between
properties, and as a gateway to a definite robust construction from a purely visual solution. Below we describe a task (Figure 1) taken from Taylor (1992, p. 204), and the reasons for which we decided to redesign it and convert it to an e-task. In general, Taylor’s rationale for this kind of task is to have a marked difference between being able to see ("sense") the solution geometrically and the ability to solve it algebraically. Interactive MLR technology offers dynamic interactions that can support the generalization of a graph into a family, offering sensuous support for finding an abstract parametric solution. This gap between interaction and abstraction is one of the challenges of using interactive MLR technology. The following description of the e-task design and of the experiment conducted with the students who worked with this e-task, demonstrates some basic considerations and principles of designing an e-task based on a P&P task.

**The original P&P task and its possible correct solutions**

Research on mathematicians’ conjecturing and proving activity suggests that use of examples plays a critical role both in the development of conjectures and in their exploration, as well as in the subsequent construction of proofs of these conjectures (Lockwood, Ellis, & Lynch, 2016). Therefore, when dealing with the task (Figure 1), we can expect work that would look like Figure 2 (a): the students would sketch for themselves some exemplary lines through the origin.

\[ y = x(x - 1)(x - 3). \]

At the right is the graph of the cubic equation \( y = x(x - 1)(x - 3) \). Consider the family of non-vertical lines through the origin. How many intersections does each line have with the curve? (I) Begin by making a conjecture based on the picture. (II) Describe the family of lines algebraically, and verify your conjecture.

![Figure 1: The original task as it appears in Taylor's book (Taylor, p. 204)](image)

In this case, it may be difficult to make a generalization and diagnose the three different numbers of common points: one, two, and three common points between the family of lines \( y = mx \) and the given function \( y = x(x - 1)(x - 3) \). Moreover, one could start to investigate algebraically the mutual relationship between the two functions required in part (II) (Figure 1), and skip part (I).

![Figure 2: (a) Typical free-hand sketching used to conjecture about the intersections; (b) The domains and values of parameter m for all cases of number of common points](image)
The abstraction and generalization needed to find and define algebraically the domains of the parameter \( m \) for each case number of common points (Figure 2 (b)) is a challenge. Generally, solving the case of two common points requires using two approaches, as shown in Figure 3.

| The algebraic approach | \[ x^3 - 4x^2 + 3x = mx \Rightarrow x^3 - 4x^2 + 3x - mx = 0 \Rightarrow x[x^2 - 4x + (3 - m)] = 0 \]  
|                         | \( x = 0 \) is one intersection point. Therefore, when the equation \( x^2 - 4x + (3 - m) = 0 \) has single solution: \( \Delta = b^2 - 4ac = 16 - 4(3 - m) = 0 \Rightarrow m = -1 \)  
|                         | The other case is when the equation \( x^2 - 4x + (3 - m) = 0 \) has two solutions, one of which is \( x = 0 \) \( \Rightarrow 0^2 - 4 \cdot 0 + (3 - m) = 0 \Rightarrow m = 3 \)  

| The calculus approach | \( m = f'(0) \Rightarrow f(x) = x^3 - 4x^2 + 3x \Rightarrow f'(x) = 3x^2 - 12x + 3 \Rightarrow f'(0) = 3 \Rightarrow m = 3 \)  
|                         | In the other case, let \( (t, t(t - 1)(t - 3)) \) be the point of tangency  
|                         | \( m = \frac{\Delta f}{\Delta t} = t(t - 1)(t - 3) - 0 \Rightarrow t - 0 = (t - 1)(t - 3) \)  
|                         | \( f(t) = t(t^2 - 4t + 3) = t^3 - 4t^2 + 3t \Rightarrow m = f'(t) = 3t^2 - 8t + 3 \)  
|                         | \( m = (t - 1)(t - 3) = 3t^2 - 8t + 3 \Rightarrow t^2 - 4t + 3 = 3t^2 - 8t + 3 \Rightarrow t = 2, 0 \Rightarrow m_1,2 = 3, -1 \)  

Figure 3: The two main ways of solving the case of two common points

In both the calculus and the algebraic approaches, there is an "easy" value of \( m \) and one that is less obvious. When grappling with this task, students should "see" (and be able to calculate) that there are two possible values for parameter \( m \), for which both functions have two common points: \( m = 3 \) or \( m = -1 \). Some students (see also Ron's thinking-aloud process in Figure 6) may skip one approach that reveals one of the values of \( m \) and move on to the other approach to obtain another value. A mathematical pedagogical discussion may address the manner in which the two approaches meet. This rich task concerns various mathematical concepts besides parametric functions: intersection points, tangency to a function, and mutual relationships between functions. It encourages making conjectures and aims to assess skills such as exploration, algebraic manipulation, and generalization of particular cases and examples.

**Study**

We redesigned the task (Figure 1) and converted it to an e-task. We conducted an experiment with 39 10th- and 11th-grade students who worked with the e-task. The students studied the standard curriculum with different teachers in the same school, without special emphasis on technology. Ron, one of the students, was thinking aloud during the solving process (Figure 6). The video recording of his thinking aloud enabled us to follow the process of task completion as it was taking place, rather than consider only its final product, and to listen to the problem-solving process.

**Design considerations and possible correct solutions: Parts A and B**

**MLR experimentation first.** In part A (Figure 4), the students used a dynamic applet that displays the function \( f(x) \) and the parametric family \( y = mx \) on the same coordinate system.
The following interactive diagram describes the functions \( f(x) = x(x - 1)(x - 3) \) and \( y = mx \). By dragging the red point, you can create different examples of mutual relationship between these functions.

**Part A:** How many common points are there for both functions? Submit three different screenshots, each one representing a different number of common points.

**Part B:** For which values of \( m \) does the functions have one common point? Two common points? Three common points? Indicate all the possible values.

Figure 4: The designed e-task: parts A and B

Students became familiar with the activity and the givens, and were asked to submit three screenshots of three different cases of numbers of common points, in other words, three different "soft constructions" (e.g., Healy, 2000; Laborde, 2005), designed to support their generalization process and symbolic work required in part B. In the case of the parametric family in the MLR environment, any change in the value of \( m \) changes simultaneously the graphic representation of the relevant line. In designing this part, we wanted to make sure that students experimented with the applet, understood all the details and givens, and were exposed to many examples of the parametric function, so that in part B they could concentrate on the exploration activity with as little cognitive load as possible. An example of a correct solution is shown in Figure 5. The student submitted three different mutual relationships of the two functions, each with a different number of common points.

Figure 5: Example of a correct solution for part A

**Minimal necessary tool set.** There are deliberately very few tools available to the student: zoom in, zoom out, and move the coordinate system. The tools are designed to enable users to sense the task qualitatively, allow them to focus on the relevant parts of the graphing picture, and not to provide numeric information. This minimal design conveyes the message that other parts of the tasks require numeric and symbolic calculation not provided by the interactive diagram. To summarize, the goals of part A are: (a) encourage student experimentation with the dynamic applet: feel/sense the givens and avoid cognitive load; (b) expose students to a variety of examples demonstrating the mutual relationship of the two functions; (c) engineer an experience-based conceptualization for solving the general case required in part B; and (d) assess the student's understanding of the givens and of what is expected of them (as well as some technical issues). Solutions for each number of common points appear in Figure 2 (b): one \( m < -1 \); two \( m = 3 \) or \( m = -1 \); three: \( -1 < m < 3 \) or \( m > 3 \).
Findings and data analysis: Parts A and B

(1) Part A: Most students submitted correct answers for part A (Table 1). This is not surprising, because the purpose of this part was to encourage students to "sense" the problem and its givens. But 15% of students missed one case (of one or two common points). Possible reasons for this are that students were not experienced enough with the applet, that they did not use the tools to view all cases, etc. As mentioned above (Figure 3), it is easy to reach one of the two possible values of m, but while experimenting with the interactive diagram one may notice that there is another possible value of m. In Figure 6 we describe Ron's thinking aloud about a solution for part B.

</tr>
</tbody>
</table>

Table 1: Submission characteristics of correct and incorrect answers to part A

In the beginning, Ron solved this part algebraically and found that m=-1 is the case in which the functions have two common points. By zooming in and out, he found that there is another value for m. The interactive diagram allowed Ron to connect between the algebraic and graphic approaches (Figure 6, line 9). Through experimentation, he tried to find the other value of m (Figure 6, lines 4-9). This demonstrates the power of technology as a tool that provides students means to reflect their solution, allowing learning to take place during a test. In practice, during the experiment some students noticed the missing value of m and tried to find it (not always successfully), either by expanding the solution using the same approach, or by changing the approach from algebraic to calculus or vice versa, as described in Figure 3.

(2) Part B (Error! Reference source not found.): 18 of the solutions included one or both correct values for m (m=-1, m=3).

<table>
<thead>
<tr>

<td>15 (38.5%)</td>
<td>17 (43.6%)</td>
</tr>
</tbody>
</table>

Table 2: Submission characteristics of correct and incorrect answers to part B

Only two students submitted a completely correct answer; 15 students did not submit an answer. Others submitted other values, probably as a result of calculation errors or because they were guessing. Only two students submitted a correct answer for the case of three common points (the same students who submitted correct solutions for the case of two common points). This may imply that in addition to the difficulty of finding both "critical" values of the parameter m (m=-1, 3), it is also difficult to generalize and formulate symbolically the possible domains of parameter m for the cases of three common points.
### Ron's thinking aloud | Ron's actions on and with the screen
--- | ---
1. This is equivalent to solving this equation. Right? Right. Zero is always one common point… then… Then I can divide simply by x. Then I investigate the quadratic equation: 
\[ mx = x(x - 1)(x - 3) \]
\[ m = (x - 1)(x - 3) \]
\[ x^2 - 4x + 3 - m = 0 \] | 
2. I check when it has two solutions, one solution, or zero solutions. These are two common points in my opinion. He looks at the case that is close to \( m=3 \). 
3. No, these are three common points… There is a certain \( m \)... It has to be minus 1 This is the value that he got through the algebraic calculations. 
4. Then where did I go wrong? Graphically, he sees that there is another positive \( m \), but he got only \( m=-1 \). 
5. I need to check this equation. Refers to \( mx = x(x - 1)(x - 3) \).
6. I always have one common point. Then I can simply divide by x. I have a neat equation. I have to see when it is equal to zero. We need to check when the discriminant is positive, negative, or zero. \( m \) must be different from zero to have two common points. Then \( m \) equals to -1. \( m=-1 \) for two solutions. He checks again his calculations: 
\[ mx = x(x - 1)(x - 3) \]
\[ m = (x - 1)(x - 3) \]
\[ x^2 - 4x + 3 - m = 0 \] 
7. I need to zoom in. Ron uses the zoom in and out buttons to explore and distinguish between different cases. 
8. I don't know what is my analytic mistake... 
9. This is the tangent, the tangent. He finds the graphic meaning of the case of two common points. Using calculus, Ron finds the other value of \( m \). 

**Figure 6: Ron's thinking aloud while working on part B**

### Discussion

Our first conjecture, that a dynamic and interactive MLR environment supports the generalization of a graph into a family was only partially confirmed. The results of part B reveal the complexity of the concepts involved in the tasks. Results may suggest the presence of a permanent tension when designing mathematical e-tasks. On one hand, we want to design an e-task for exploration that can be automatically checked. Therefore, we tend to give students the opportunity to explore without any hints and without leading them to the solution. On the other hand, the task may be too difficult, and we may have difficulty assessing the students' knowledge and mistakes. In retrospect, this exploration e-task was too difficult; we should have divided the e-task into more than two stages and ranked the sub-tasks: first concentrate on the case of two common points, and only later on other cases. We are currently considering a refined design of this e-task.

Below we describe some basic design principles we gleaned from the experiment described above. Other design principles are described in Yerushalmy, Haddif, and Olsher (under review), Haddif and Yerushalmy (under review). **When re-designing an e-task based on a P&P task, technology should provide the following:** (1) **Allow self-reflection:** When solving a P&P task, we have few means to reflect on our solution, especially not instantaneously. Use of an interactive diagram in an
MLR environment together with manual calculations helps students control their actions and reflect on them during assessment, and check whether they are right or wrong, without telling them directly what the correct solution is. (2) **Promote learning:** Using an interactive diagram with parametric functions allows seeing many instances of the same family. This is an opportunity to see the parameter serve as a "generator" of functions that belong to the same parametric family. Experiencing with the dynamic diagram also encourages students to make conjectures and conduct interactive exploration. As demonstrated in Ron's case, technology has the potential to create a cognitive conflict and thereby provide a learning opportunity (Figure 6, line 4). Ron tries and succeeds in solving the conflict between the manual solution and the graphic representation on the screen. Had he solved the original task, he may not have noticed the "conflict" between the graphic representation and the symbolic calculation. (3) **Guide students to focus on the important details, without unnecessary distractions:** Although it is tempting to use the varied capabilities of technology, these might distract the students and produce negative effects. Therefore, it is necessary to focus on the real needs of the students and redesign the e-task to make students concentrate on the important details, without unnecessary distractions. This also implies that students understand how to approach the question. The design must reflect in some way the purpose for which the tool was created (Yerushalmy, 1999), and the cognitive load must be reduced as much as possible. We demonstrated several ways of doing this: (a) designing the task in a way that students move in stages away from using sensory knowledge in soft constructions toward experimenting with the interactive diagram to produce robust constructions, abstraction, and generalization. (b) designing the environment and the required solution in a way that defers engagement in numeric and symbolic activity: for example, eliminating grids and the option to enter expressions conveys the message that conjecturing comes before computations. (c) determining the minimal necessary tool set that is familiar to the students and common to other e-tasks. In Yerushalmy et al. (ibid.) we described in detail the tool set needed for calculus e-tasks, which enables automatic checking of the students' submissions.

Context based tasks on differential equations to improve students’ beliefs about the relevance of mathematics

Dié Gijsbers and Birgit Pepin
Eindhoven University of Technology, ESoE, The Netherlands; d.gijsbers@gymnasiumbeekvliet.nl
Eindhoven University of Technology, ESoE, The Netherlands; b.e.u.pepin@tue.nl

Motivated and talented mathematics students are not always convinced about the relevance of mathematics. More insight into applications of mathematics can be beneficial for students in terms of preparing them for their future study and career. Using design research a particular intervention had been developed which differentiated by student interest, in order to improve students’ beliefs about the relevance of mathematics. The students selected were those studying advanced mathematics at upper secondary school in the Netherlands. The intervention had been designed to teach differential equations through tasks with science-, medicine-, or economics-related contexts. The results show that the students appreciated the context-rich tasks, which provided them with insights into how mathematics can be applied in other sciences and contributed to the improvement of their beliefs about the relevance of mathematics.

Keywords: Mathematics education, task design, relevance of mathematics, differential equations, differentiation by interest.

Introduction

Students’ beliefs about the relevance of mathematics has been a topic of much research over the last decades. However, in most studies the main reason for studying students’ views on the relevance of mathematics has been the assumption that a positive notion of the importance of mathematics contributes to a positive attitude towards learning mathematics (Schoenfeld, 1989). Hence, most research studies conducted in this area have aimed at understanding and improving students’ attitudes towards mathematics, and ultimately improving their performance in mathematics at school (Farooq & Shah, 2008; Mohamed & Waheed, 2011).

However, we start from the premise that already motivated and talented students can also benefit from a clear view on the usefulness of mathematics for their future education and career. Dutch secondary school students in an advanced mathematics course (aimed at improving students’ algebraic skills and elaborating the connection between mathematics and other sciences) praised the course as being challenging and fun, but they also mentioned that it was not clear to them how the mathematics would be useful for their future study (Van Elst, 2013).

In our research project a design research approach has been used to develop and intervene with tasks aimed at simultaneously teaching a new (for students) mathematical concept (differential equations) and improving students’ beliefs about the relevance of mathematics in general, and in particular with respect to their future study and career ambitions. The students sampled were those taking the advanced mathematics course (in their final year before university entry) in Dutch upper secondary schooling.

The mathematical topic of the designed intervention was the theory of analyzing, solving and interpreting first order differential equations. Differential equations are an important subject in any
undergraduate university curriculum in a broad range of domains, such as engineering, physics, biology and economics, which makes it a suitable topic for an intervention with a focus on the relevance of mathematics.

To improve the odds that the real-life problems posed in the designed tasks would appeal to the students, the designed intervention differentiated by student interest. Students were offered the opportunity to choose between different real-life problems, whilst ensuring that regardless of their choice they learned the same mathematical concepts of differential equations.

The research question of the study was the following: How does a learning strategy based on differentiation by interest for teaching ordinary differential equations (to upper secondary students in a “strong mathematics” course) improve the view of students on the relevance of mathematics for their future study and career?

In the subsequent section, we provide an overview of the relevant literature. Next, the research design including the context of the study and the data collection strategies used are described. Finally, we provide a discussion of the results and our conclusions.

**Literature**

Students’ beliefs about the relevance of mathematics is considered as one of the factors that can play an important role in their attitude and motivation. Several questionnaires measuring the attitude of students towards (learning) mathematics use a scale for measuring students’ beliefs about the usefulness of mathematics: for example, the Attitude scale towards Math (Martinot, et al., 1988) contains a scale named Relevance of Mathematics.

Most studies using these surveys do not emphasize the improvement of students’ beliefs about the relevance of mathematics, as they are aimed at students’ attitudes towards mathematics. However, a recent study of first year university students in engineering focused on improving perceptions of the relevance of mathematics in engineering. In this study Flegg (2012) has described the use of context-based learning by applying mathematics to real-life problems as a promising approach.

The teaching of differential equations has undergone some major changes over the past decades in favor of more contextualized, problem-based education, and a less traditional, analytical approach (Boyce, 1994). This was in line with our planned design to incorporate real-life problems in the assignments. At university level several initiatives have reported good results using this new teaching approach (e.g. Huber, 2010) and the development of new course material using Realistic Mathematics Education (e.g. Rasmussen & King, 2000). In a comparison of a traditional textbook with a textbook that incorporated discipline-specific perspectives to teach the mathematical knowledge to engineering students, Czocher and Baker (2010) conclude that a contextual approach is also more in line with recommendations from the research literature.
Task design is widely recognized as an important, albeit complex activity that is at the core of mathematics education. The term ‘task’ is used to describe a wide variety of student activities aimed at learning mathematics (Watson & Ohtani, 2012). In our research tasks are guided group assignments about a real-life problem.

The study

The context

The Dutch education system consists of eight years of primary education, and 4-6 years of secondary education (depending on the level of education). The highest level of secondary education is the pre-university education called VWO (voorbereidend wetenschappelijk onderwijs) with a duration of six years, which provides students access to university. For every student at VWO level mathematics is a mandatory course. However, in the last three years students can choose between two different mathematics courses: “wiskunde A” (mathematics A) and “wiskunde B” (mathematics B), the latter being the more mathematically demanding course, which is obligatory for technical and engineering studies at university.

In 2007 an advanced mathematics course called “wiskunde D” (mathematics D) was introduced to offer challenging and engaging mathematics, and where the relevance of mathematics and its connection to other sciences should become clearly visible (cTWO 2007). This course is aimed at students with an interest in sciences and engineering, and it includes mathematical topics, which are part of every first year university curriculum: e.g. complex numbers; analytic geometry; and differential equations. Students with ‘wiskunde B’ are offered the opportunity to take this advanced course in mathematics in addition to their regular course.

It might be expected that students who take this advanced course in mathematics are convinced about the relevance of mathematics, which is likely to fuel their obvious motivation to learn mathematics by taking this advanced course. However, studies on the implementation of ‘wiskunde D’ tell a different story. In a study by Van Elst (2013) students praised the course as being challenging and fun, but they also mentioned that it was not clear to them why the mathematics in the course was useful for their future study and career. According to a study by Cheung (2012) teachers of ‘wiskunde D’ stated that the course was well suited as a preparation for a future study in a technical or engineering environment, but they also stated that the curriculum did not emphasize enough the applications of mathematics and the connections to other sciences (Cheung, 2012).

To be able to understand the theory of ordinary differential equations, secondary school students require almost all basic mathematical knowledge taught in secondary education as pre-knowledge. Hence, this topic is scheduled near the end of the final (6th) year, to make sure all major mathematics/‘wiskunde B’ and mathematics/‘wiskunde D’ topics have been covered. It can also be expected that at that time the students have a good idea of their intended future study. This might motivate the students to choose tasks with real-life problems associated with their future study.

The real-life problems in the study by Flegg (2012) all had an engineering context, which was in line with students’ study (of engineering at university). However, from our experience secondary school students taking the ‘wiskunde D’ course are not all interested in engineering. Students typically also enroll for medical or economics studies after graduating with ‘wiskunde D’. Hence,
only focusing on real-life problems in engineering would have been a too narrow approach. To give students a good view of applications of mathematics to solve real-life problems, the learning strategy should offer differentiated instruction, based on students’ interest.

Beside this “practical” reason to give students a choice of which problems they wanted to investigate, research shows that differentiated instruction based on students’ interest supports their autonomy and improves students’ motivation for the task at hand (Katz & Assor, 2006). Differentiation is commonly used to accommodate the different learning styles of the students; however, it can also serve to accommodate other differences between the students, such as their interests and plans for their future study and career (Tomlinson et al., 2003).

**Research design and data collection strategies**

For the development of the intervention, a module consisting of tasks on real-life problems, a design research approach was chosen. The design process comprised of three phases: a preliminary phase; a iterative development phase; and a final evaluation phase. The preliminary phase included a context analysis and a literature review. The learning goals for teaching differential equations were defined, based on the five strands of mathematical proficiency (Kilpatrick et al., 2001).

In the second phase a partial prototype of the module was developed. In March 2015, a small pilot test was conducted, with a prototype consisting of only three tasks. In a second design cycle a module was developed, which comprised of 14 tasks covering five different types of differential equations. Validation of separate tasks was done (1) by expert appraisals from university experts in mathematics education, focusing mainly on relevance and consistency of the design; and (2) by secondary school teachers focusing on the consistency and expected practicality of the design.

The designed intervention was carried out from January to March 2016. Three classes of ‘wiskunde D’ students of two different schools in the Netherlands, in total 49 students, participated. The three classes all had a different teacher, one being a researcher in this study.

The data collection strategies for the intervention included

- two student surveys (before and after the intervention) asking the students about their future study plans and their views on the relevance of mathematics, using the 8 question scale Relevance of Mathematics (Relevance scale) from The Attitude scale towards Math (Martinot et al., 1988);

- a student survey after the intervention to evaluate the module and the tasks;

- student interviews after the intervention about the module and the relevance of mathematics in general, and in particular for their own future study and career;

- the video recording of a teacher meeting about their experiences during the intervention;

- the collection of exam results after the intervention at one school. These results were compared to the results of the ‘wiskunde D’ students of the previous exam years, who were taught the same theory of differential equations but in the traditional classroom setting.
The intervention

The intervention module comprised of five tasks, each covering a different type of differential equation. Of each task up to three different versions were developed, which applied the same mathematical concept to entirely different contexts. Prior to the first task students were given time to read short descriptions of each problem and were given the opportunity to make, for each of the five subsequent tasks, a choice which context (real-life problem) appealed to them most.

The different contexts for each of the tasks consisted of: a science/engineering related problem; a biological/medical problem; and an economical/social problem. Regardless of students’ choices of contexts for the five tasks, the students worked with and learned the same mathematical concepts during their work on these parallel tasks. The students were guided through the process of modelling the problem and exploring the mathematical model analytically, graphically and numerically. After solving the mathematical problem the students were asked to interpret the results within the context of the chosen assignment. Table 1 gives an overview of the 14 tasks.

Table 1: Overview of the real-life problems used in the module

Results

40 out of the 49 participating students filled in the survey about the module. Responses to most questions were measured on a five-point scale, ranging from “I strongly disagree” to “I strongly agree”. The students were generally quite positive about the whole module. Asked to grade the whole intervention on a scale of 1 to 10, they rated the module 6.5 on average. Interestingly, this mean score differed greatly between the three groups, with one group scoring surprisingly lower than the other two (see Table 2). Additional comments in the survey from this group suggest that they lacked proper guidance of their teacher. Hence, the practicality and effectiveness of the intervention can substantially benefit from a good description of the role of the teacher as coach, helping the students to advance in their assignments. In the teacher meeting the same recommendation was made.

Overall, 28 out of 40 students agreed (of which 6 strongly) with the statement “The tasks gave me a good view on how mathematics is applied in other sciences”, and only 3 students disagreed with this statement. The negative statement “I think that these tasks were not very realistic” was disagreed by 29 students (of which 12 strongly) and only two students agreed with this statement.
The survey also contained open questions asking students what they liked about the module and what in their opinion should be improved. Positive points were working in groups (11 times) and the application of mathematics in other sciences (15 times) with statements like: “it was fun to experience that math is useful”, “clear applications of math” and “you get a better view on how mathematics can be applied”.

Some negative comments were about ICT problems encountered during the intervention (e.g. “slow laptops”). However, the majority of the feedback was about the way the mathematical concepts of differential equations were introduced to them. For example, they complained that having to read the theory by themselves made it harder to grasp the concepts. Some also missed the “traditional” teacher-led instruction, where the “basic” theory is explained by the teacher before the students start working on the assignments.

The student interviews were conducted by the teacher/researcher (one of the authors). In the interviews the students voiced the same concerns about the lack of teacher instruction and the ICT problems. However, they were positive about the tasks and the application of mathematics to real-life problems, as the extract shows.

Interviewer: Did the tasks have some added value?

Student 1: Yes, I think so. I think it adds quite a lot. It helps…

Interviewer: It helps? In what way?

Student 1: To give a lot of people the idea what can be done with mathematics. That there is mathematics behind everything. Not a lot of students would have realized that before, I think.

Comparison of the ‘wiskunde D’ exam results of the 36 students from school A with the results on a similar exam by the 27 ‘wiskunde D’ students of the previous year did not show a significant change in the grades. As can be seen in Table 3, the students of 2016 scored slightly better than their peers in 2015 but that was to be expected as their average grade before the exam was also better.

The intervention was not intended to improve the exam results, and the findings showed that the dual focus on both the mathematical concepts of differential equations and the relevance of mathematics to other sciences did not affect the grades of the students in a negative way.

Table 3: Exam grades of the students in 2015 and 2016

From the Relevance of Mathematics scale, conducted before and after the intervention, we obtained some promising results. Only 33 out of the 49 students completed both the pre and post survey, as shown in the last column of table 2.

A one-sided paired-samples t-test was conducted to compare the answers of the 33 students on 8 items of the Relevance of Mathematics scale before and after the intervention. The result of this test for the whole group of 33 respondents did not show a significant improvement with a p-value of 0.19. But the same test on the 18 results from the high response group gave a p-value of less than 0.02 indicating a significant positive change in their response to the questions about the relevance of mathematics. Due to the low response rate of the two other groups we were not able to get any significant results from these separate groups.

We also conducted the paired t-test on the answers of the 17 students who had the lowest scores on the pretest. They had scored relatively low on their beliefs about the relevance of mathematics, all with an average score between 2.38 and 3.63 for the 8 items on the five point Likert scale. On the same test after the intervention their average scores ranged between 2.63 and 4.63. 12 of these 17 students scored higher on the test after the intervention resulting in a p-value of 0.002, which indicates a strong significant positive change in these students’ beliefs about the relevance of mathematics. This result indicates that students who do not already have strong beliefs about the relevance of mathematics benefit most from the context-based tasks.

**Conclusion**

The intervention had positive effects on selected student views about the relevance of mathematics without affecting the examination results. Providing students with purposefully designed tasks where mathematics is applied to real-life problems cannot only challenge their assumptions about the relevance of mathematics, but also improve their awareness of its usefulness.

Teacher professional development is a topic for further study that will be the focus of a new design cycle of the module. Applications like a teacher meeting, where the goals of the module are explained and an extension of the teacher manual with guidelines how to introduce the module and how to coach the students during the group assignments, are expected to contribute to a better understanding of the role of the teacher during future interventions.

Teachers’ collective documentation work: A case study on tolerance intervals

Ghislaine Gueudet¹ and Veronica Parra²

¹CREAD, ESPE Bretagne, University of Brest, France, ghislaine.gueudet@espe-bretagne.fr
²CREAD, ESPE Bretagne, University of Brest, France, and NIECyT. UNCPBA. CONICET; Tandil, Argentina, vparra@exa.unicen.edu.ar

In this paper we use the documentational approach to investigate teachers’ collective work. We follow two teachers, preparing together a lesson on tolerance intervals for grade 11. We identify Mathematical Knowledge for Teaching (MKT) that influences the use of resources by the teachers. We evidence that their collective work fosters important documentation work; but we observe significant differences between the documents developed by the two teachers.

Keywords: Documentation work, resources, teachers’ knowledge, tolerance intervals, variability.

Introduction

Teachers interact with curriculum resources in and out-of-class (TWG22 call for papers). In previous works we have identified the importance of these interactions in terms of teachers’ professional development (Gueudet, Pepin & Trouche 2012), and we have evidenced that teachers often work collectively with resources. In this paper we study further this collective work of teachers with resources and its consequences.

The work presented here takes place within the French national project REVEA¹ (Living Resources for Teaching and Learning). We consider the case of two mathematics teachers at upper secondary school in France teaching sampling variability in statistics in grade 11. We firstly expose the theoretical perspective we use and our methods. Then we present the data we collected, and the context of teaching sampling variability in France. Finally we expose our analyses of the teachers’ work and of its links with teachers’ knowledge in particular.

Investigating teachers’ documentational work: Theory and method

We use for our research the theoretical and methodological perspective of the documentational approach (Gueudet et al. 2012). Mathematics teachers interact in their work with a large range of resources (Adler 2000). Resources designed for teaching purposes like textbooks or software, resources coming from the students, e-mails exchanged with colleagues etc. Teachers choose resources, transform them, use them in class; we call this work “teachers’ documentational work”. In previous research, we have evidenced that this work is closely linked with teachers’ professional knowledge. The choice of resources by teachers, the way teachers modify and use the resources is driven by their professional knowledge (and this is called an instrumentalisation process, drawing on Rabardel’s instrumentation theory, Rabardel 1995). In a reverse way, the features of the resources used modify teachers’ knowledge (in an instrumentation process). In the documentational approach, we consider that from a set of resources teachers develop a document: transformed

¹ https://www.anr-revea.fr/
resources associated with a scheme of use (Vergnaud 1998). A scheme of use comprises the aim of the activity, rules of action and professional knowledge. The development of a document is called a documentational genesis.

Teachers’ Communities of Practice (CoP, Wenger 1998) have a shared repertoire that the documentational approach interprets as shared resources. In previous works (Gueudet, Pepin & Trouche 2016) we have investigated the documentation work of a CoP (Sésamath, an association of teachers in France) designing online resources and identified the development of shared documents. Here we study a more “ordinary” CoP, composed of two teachers working together for the preparation of their courses. We are interested in particular in the commonalities and differences in professional knowledge within the documents developed by these teachers. The research question we investigate can be formulated as:

How do professional knowledge and resources interact in the collective design and implementation of a lesson?

Concerning teachers’ professional knowledge involved in the schemes, we are especially interested in the identification of Mathematical Knowledge for Teaching (MKT, Ball, Thames & Phelps 2008): professional knowledge linked with the mathematical content to be taught.

The documentational approach is associated with a specific method, called “the reflexive investigation method”. Documentational geneses are long term processes; moreover documentational work can take place everywhere and at any time. Thus we follow teachers over long periods of time; and involve them actively in the collection of data. These data are interviews of the teacher; videos of the teacher’s work in class and out-of-class (videos of collective work, if teachers work together); resources chosen and transformed by the teacher.

For analyzing the data, we start with the transcribed interviews of the teachers. We identify in them the aims of the teacher’s activity. For each aim, we search in the data for the resources used, and the other components of the document (rules of action and professional knowledge). We submit these elements to the teacher who corrects and complements them if needed. We present in the next section the data collected for the case we study here.

**Data collected and context**

We follow since 2014 two mathematics teachers in an upper secondary school of a middle-sized town in France: Valeria and Gwen. They are both very experienced: Valeria teaches for 34 years, Gwen for 36 years, they both regularly follow teacher education sessions and are trainers for new teachers in their school. They also regularly work together, we consider them as a CoP (Wenger 1998). In 2015-2016, they decided to take two grade 11 classes called “economics and science”, a specialty they taught for the first time. We followed their work for these classes, in particular for a chapter entitled: “sampling variability” (that they both used to teach grade 11 “science”, with a similar content). For this chapter, we video recorded their common preparation (one hour), their individual courses (four hours each), and for each of them an individual post-teaching interview. We collected all the resources they used and produced, and the students’ productions for the final assessment of the chapter. For both teachers we identify the professional knowledge/beliefs, the
possible origin of these beliefs, the consequences in terms of the activities/resources produced and
the resources used.

Sampling variability is taught in France since 2010. This teaching starts in grade 10 where the idea
of sampling variability is introduced using material like coins and dice and simulations on the
calculator and on the spreadsheet. In the curriculum in France, the concept of tolerance interval is
central in the teaching of sampling variability. In grade 10 the students have to learn how to identify
the population; the sample and its size \(n\); the probability \(p\) of a given feature in the population, and
the frequency \(f\) of this feature in the sample. A first tolerance interval is introduced, without
justification: \([p-1/\sqrt{n}, p+1/\sqrt{n}]\). If \(f\) does not belong to this interval, the students learn to reject the
hypothesis “the sample follows the population’s law” with a 5% risk level. At grade 11 (scientific or
economics and scientific) the binomial distribution is introduced; it provides another tolerance
interval, which can be found using the table of the binomial distribution produced for example with
a calculator or a spreadsheet. The chapter we followed concerns the introduction and use of this
interval. At grade 12, the normal distribution is presented; this leads to a new interval (the
asymptotical tolerance interval).

Many research works have investigated teaching variability; they emphasized the specific nature of
reasoning in probability (Steinbring 1991) and the need for particular knowledge to teach this
subject (González 2013). Eckert and Nilsson (2013) used the notion of Mathematical Knowledge
for Teaching Probability (MKTP) for characterizing the specific knowledge needed by the teachers
in probability and statistics, and for sampling variability in particular. Finding situations in relevant
contexts; emphasizing the idea of variability, using the different kinds of possible representations all
require specific knowledge from the teacher. Our aim here is to investigate how the interactions
with resources are shaped by, and contribute to MKTP.

**Results**

In this results section, we firstly consider the two teachers’ documentation work, during the
common preparation session, the lessons taught by each teacher and finally during the design of a
common assessment. Then we present our analyses of the most important aspects of this
documentation work (in terms of MKT involved), focusing on the collective-individual articulation.

**A collective documentation work**

During the common preparation, Valeria and Gwen used several textbooks (9 different textbooks).
They did not actually chose resources together, but drew on exercises and problems in the textbook
to illustrate their declarations. They also talked about resources they intended to use: exercises,
software (GeoGebra, spreadsheet) and the calculator.

Their discussion during the common preparation started by stating a difference: Valeria intended to
use the spreadsheet from the beginning and during the whole lesson. The students have learned, in
the “binomial law” chapter to produce with the spreadsheet and read tables displaying the value of
\(P(X=k)\) and \(P(X\leq k)\), when \(X\) is a random variable following a binomial law of parameters \(N\) and \(p\).
Valeria wanted to recall this, then to introduce the binomial law tolerance interval and the method
for finding it, using the \(P(X\leq k)\) table produced with the spreadsheet. Gwen, in contrast, intended to
use only the calculator, and no other software. After introducing the binomial law tolerance interval,
she wanted to ask students to write and implement on their calculator a program producing the tolerance interval.

In the other aspects of the common preparation, Valeria and Gwen agreed on all the points they discussed. They mentioned in particular the need to recall the grade 10 tolerance interval and to compare it with the new interval introduced.

All these aspects discussed during the common preparation are present in the lessons actually taught by Valeria and Gwen. We analysed these lessons drawing on the observations and videos in class, the resources collected and the post-lesson interview.

Valeria started indeed by recalling how to produce and read the binomial law table with the spreadsheet. She also recalled the grade 10 interval with exercises chosen in a textbook’s “revision section”. Then she introduced the new interval through a problem concerning overweight in USA. This problem came from another textbook, and she modified it in particular by suppressing the table giving \( P(X \leq k) \), because she wanted the students to produce it themselves with their calculator. She presented how to find the interval from the table \( P(X \leq k) \). Valeria insisted on the need to formulate very precisely the decision rule. At the end of the chapter, she worked with her students on the algorithm: the students implemented it on their calculator, but this program was actually not used as a tool to find the interval in exercises.

Gwen started with a problem that she built herself, about red-haired people in Scotland (inspired by a textbook problem with a different context). The first part of the problem recalled the grade 10 interval, and more generally the idea of sampling variability. The second part of the problem introduced the new interval. Just after this session, Gwen worked with the students on the production of an algorithm and its implementation on the calculator to find the binomial law interval. Afterwards this program was always used to find the interval. Gwen said that she found the binomial law interval too technical, she did not want her students to learn how to find it. She preferred to use it as an opportunity to work on algorithms. She distributed a sheet to the students presenting the interval and a diagram. Then she proposed different exercises about decisions; in particular one exercise with samples of different sizes.

The final assessment of this chapter was also the final assessment of the year for the two Grade 11 ES classes. Valeria and Gwen wrote it together; we analyse their documentation work drawing on the resources they used and produced; the e-mail they exchanged and their interviews. The control text comprised one exercise on tolerance intervals. This exercise, with an introductory text (figure 1) and three questions, concerned the rate of twins in India; it came from a textbook. Valeria and Gwen modified the initial text which was, in their opinion, too long and complex.

```
"India: Kodinji, the mysterious twins village"

In the state of Kerala (south-west India), there is an amazing village. The rate of twins is much higher than the national average. 440 twins live indeed in this town for 14600 inhabitants. This average is outstanding, since the national average is 16 twins for 1000 births”. Extract of an article (Courrier International, 2009)

Let \( X \) be the random variable counting the number of twins in a 14600 Indians sample.
```

Figure 1: Introductory text of the control exercise (our translation)
They modified the first question: in the textbook the parameters of the binomial law followed by X were given; they wanted the students themselves to find the parameters. They also changed the second question, where the students are asked to produce the tolerance interval, to display the two different methods expected for each class: use of a table (given in the text) for Valeria’s class, use of the calculator’s program in Gwen’s class. Question 3 was left unchanged.

42 students were present at the final assessment. In the first question, 35 students justified that X followed a binomial law of parameters \( n \) and \( p \); 29 students determined correctly the value of \( n \), but only 15 the value of \( p \). In the second question, 19 students determined correctly the endpoints of the tolerance interval. In the third question, 19 students justified correctly the rejection of the hypothesis (“the Kodinji village follows the national figures”).

Valeria and Gwen documentation work and use of resources: General statements

We can notice that like other research works using the documentational approach (Gueudet et al. 2012) this description evidences that Valeria and Gwen are designers of their own resources. They use various curriculum resources, but transform most of them. Only some exercises texts are left unchanged, and one textbook extract presenting the binomial law interval (for Gwen). Moreover, textbooks (on paper, they do not use digital textbooks) are central resources, used as a reference to discuss the lesson plan, and to choose exercises for practicing the new methods, for the assessment/test, or to find an introductory problem (for Valeria). More surprisingly, they did not search the Internet for resources – this can be a consequence of their common preparation: Valeria and Gwen sometimes search the Internet for preparing their lessons, but always at home. For the common preparation they were at school with no Internet access. Another result already well known in the documentational approach is that the observation of students (their written texts, or oral discussions in class) constitute a very important resource for the teachers, leading to a constant modification of the resources produced along the documentation work. Both Valeria and Gwen intend to modify this lesson on tolerance intervals next year, because they consider that the students made too many mistakes in the final assessment/test.

Documents developed by Valeria and Gwen

In this section we analyse our data in terms of documents developed by Valeria and Gwen. Since our focus is on MKT, we do not give a complete description of each scheme of use but only mention the aim of the activity and the MKT involved. We have chosen three examples of documents, corresponding to different situations in terms of similarities or differences.

Valeria and Gwen had a shared aim that can be described as “Recalling previous knowledge needed for the binomial law tolerance interval”. They both considered that this new chapter must start by recalling the grade 10 interval, because they knew from their observation of students during the year that “many students do not remember this interval” (Gwen even added that some students perhaps never saw it, since some colleagues keep this content for the end of the year and run out of time). This shared MKT lead however to two different documents for this aim, because of the teachers’ different resources: Valeria used a lot the classroom textbook, and thus proposed revision exercises coming from this textbook, while Gwen wrote her own problem text.

Valeria and Gwen also shared a general aim that can be presented as: “Teaching how to find a tolerance interval with a binomial law”. During the previous years, Valeria has developed for this
aim a document including various resources: the spreadsheet (as software or in the calculator), exercise texts, the illustrating diagram, and MKTP: “The students must learn to find the endpoints of the interval by reading the table”. This knowledge can have different sources; we claim that it comes in particular from institutional texts (the official curriculum) and from textbooks. For the same aim, Gwen has developed a different document, including: the calculator, an algorithm, the illustrating diagram, exercise texts as resources; and MKTP like: “The binomial law interval is too technical”; “there are no questions about the binomial law interval at the baccalaureate”; and the MKT “it is important to work with students on algorithms”. This knowledge comes from reading the texts of the baccalaureate, and from a personal mathematical difficulty: Gwen declared that she “cannot remember [herself] how to find the endpoint of the interval”. Moreover she considered that this grade 11 curriculum is only a transition between the grade 10 interval and the grade 12 interval (with the normal distribution) while algorithms are always present in the baccalaureate texts. Valeria and Gwen discussed this difference during the common preparation. Valeria integrated in her lesson the programming of the algorithm on the calculator, but she did not want her students to use it, because she feared that the students do not really understand the algorithm and use their calculator as a “black box”.

For the aim: “Assessing the students’ ability to determine and interpret a tolerance interval”, Valeria and Gwen used shared resources: they wrote the assessment text together drawing on the same textbook exercise. The choice of this exercise was guided by MKT firstly expressed by Gwen, and adopted by Valeria: “the students must learn to find information in a text”. Nevertheless, the text produced was also transformed to incorporate the use of two possible methods, because of their different MKT concerning how to find the binomial law tolerance interval.

In Table 1 below, we synthesise these three documents, evidencing the common and different elements.

---

2 In France, the final secondary school assessment, at the end of Grade 12.
Recalling previous knowledge

Valeria: Revision exercises in the classroom textbook

Gwen: Her own problem text

“Many students do not remember the grade 10 tolerance interval”

Teaching how to find a tolerance interval with the binomial law

Valeria: Problem and exercises texts from different textbooks, the spreadsheet, algorithm on the calculator (coming from the collective work)

Gwen: Problem composed herself, exercises from different textbooks, algorithm on the calculator

Valeria: “The students must learn to find the endpoints of the interval by reading the table”; “they must not use the calculator as a black box”

Assessing the students’ ability to find and interpret a tolerance interval

Shared assessment text written together from a textbook exercise, but integrating two possible methods.

“THE students must be able to identify information in a text” (shared)

+ MKT/MKTP described in the above line

Table 1: Synthetic presentation of documents developed by Valeria and Gwen. Shared elements are in italics.

Conclusion

In this paper we investigated the research question: “How do professional knowledge and resources interact in the collective design and implementation of a lesson?” in the case of a lesson on tolerance intervals for Grade 11 students in France. In the frame of the documentational approach, investigating how professional knowledge and resources interact means investigating the documents developed by teachers. For each of the two teachers we followed, we observed that they developed an important design work, choosing resources, associating and modifying them. This work was guided by their professional knowledge, in particular MKT and MKTP. We observe that this MKT is mostly of the type: “Knowledge of Content and Students”; deepening the analysis in terms of types of MKT is an interesting perspective for further work. In a reverse way, resources influenced the development of MKT, and this MKT can be different for each individual teacher. For example the official curriculum influenced Valeria and Gwen in different ways: while Valeria aligned with the curriculum about tolerance intervals, Gwen attached more importance to the algorithms. She developed a personal interpretation of the official curriculum, not focusing on the chapter she taught but taking into account the whole year.

In previous works (Gueudet et al. 2012) we evidenced that collective work is present in many aspects of teachers’ activity and that it is a stimulator of documentation work, especially when it takes place within CoPs. In (Gueudet et al. 2016) we analysed the common documentation work in a CoP: an association of teacher designing an e-textbook. We evidenced that they developed
common documents, drawing on their individual documents. In the present study we investigated a CoP composed by two teachers preparing their courses together. We evidenced that, in spite of the collective work the documents developed by the two teachers for the same aim are never completely identical. The consequence of the collective work is that these documents sometimes share common elements. The main reason for the differences seems to be the long experience of both teachers: they already developed in previous years documents for the same aims, and thus have MKT or MKTP associated with these aims and also specific resources. The collective work can bring new resources (the algorithm on the calculator for Valeria) or new knowledge (the students must be able to find information in a text, for Valeria again), but the previous knowledge developed during interactions with resources over many years is still present and produces differences in the documents.

These teachers will go on working together; with a longer common work, evolutions may take place, and we will try to analyse these evolutions. We also hypothesize that evolutions of practice are more likely to take place in teachers’ CoPs when the members of the CoP are involved in a common design activity (for example in the Sésamath case, Gueudet et al. 2016, or in the context of professional development, Pepin & Miyakawa 20016). We intend to investigate this hypothesis in further research.

Pre-service teachers’ reflections on task design and implementation

⁴Ulus Private Hebrew High School, Turkey; pelindonmez99@gmail.com

In this paper, we will present a part of findings of a larger study in which we investigated both pre-service teachers’ pedagogical content knowledge and middle school students’ mathematical skills. A total of 17 pre-service teachers worked with 7th grade students on the mathematical tasks for a semester. The data was collected through inventories, videos of task implementations and written reflections. The analysis of inventories and written reflections revealed that the pre-service teachers had positive beliefs about using mathematical tasks in the lessons. They were able to evaluate the success or failure of a task by analyzing the implementation process. They recognized the importance of preparing appropriate tasks for students and implemented them as intended. They also noted that mathematical tasks provided them an opportunity to learn about students’ mathematical understanding as well as to develop their scaffolding practices.

Keywords: Pre-service, middle school, mathematical tasks, reflection, teacher knowledge.

Introduction

The studies on mathematical tasks provide an opportunity to discuss not only students’ mathematical thinking and understanding but also teachers’ knowledge and skills (Zaslavsky, 2007). Tasks are accepted to be one of the curricular tools that help teachers to scaffold, foster and assess students’ understanding when used appropriately (Stein, Grover, & Henningsen, 1996; Watson & Mason, 2007). Research on task design and implementation shows that “good” tasks or cognitively demanding tasks (Stein et al., 1996) have positive impacts on students’ thinking and understanding (Henningsen & Stein, 2002). Such tasks encourage students to think about what mathematical concepts are conveyed in the task, what they know about them, how they are related to other concepts and which strategies, representations or materials are helpful in terms of arriving at a meaningful solution or answer. On the other hand, designing, selecting and implementing cognitively demanding tasks are related to teachers’ pedagogical content knowledge (PCK) as well as to their content knowledge (Charalambous, 2010; Liljedahl, Chernoff, & Zazkis, 2007; Stylianides & Stylianides, 2008). Teachers’ decisions about whether a task is appropriate for their students in terms of its complexity or if their students possess the necessary prior knowledge or the task’s goal aligns with the lesson’s objectives emerge from their PCK (Hill, Ball, & Schilling, 2008). The studies on task design and implementation showed that when pre-service teachers (PSTs) were given opportunities to develop and implement tasks, they were able to prepare “good” tasks in which they used real life context and multiple representations and they asked for explanation, interpretation or justification (Ozgen & Alkan, 2014).

In this study, we aimed to investigate how PSTs’ involvement in task design and implementation process influenced their views about tasks and their PCK. We used tasks as a tool to build up an environment for PST-student and student-student interactions where the PSTs observed how students worked on the tasks both individually and as a group and then joined their discussions to elicit students’ thinking and support their understanding. Thus, the PSTs had opportunity to learn
about students’ mathematical skills and also to gain experience about how to implement a task without loss of fidelity, to scaffold students’ understanding, and to manage the group work. In this paper, however, we will present some findings about PSTs’ reflections on this task design and implementation process in terms of effectiveness of the tasks and their professional gains from this intervention study.

**Methodology**

**Research setting**

This study was conducted under university-school collaboration between the mathematics education department and a local middle school in Istanbul in Turkey. A total of 17 PSTs (10 of them in Fall 2015 and 7 of them in Spring 2016) and one of the 7th grade classes (aged between 12-13) from the partner school volunteered to participate in this study. We arranged the students as mixed-ability groups of 4 students based on the results of an achievement test. We randomly assigned the PSTs to these groups. The PSTs worked with students in a 40-minute lesson for each week, a total of 11 weeks during the Fall and 12 weeks during the Spring.

All PSTs were senior students who volunteered to take an elective course that was carried out specifically for this study. During the first couple of weeks of the course, we talked about the design and implementation of tasks, effective ways of communicating with students and assessment of students’ mathematical understanding through samples. Then, each week, prior to implementation, we discussed the tasks that they would use with the students and made revisions on the tasks when necessary. After each implementation in the school, we met the PSTs again and discussed how the implementation went. We wanted PSTs to write reflection on each implementation by analyzing the implementation videos of their own group and students’ worksheets. We also asked PSTs to prepare and implement a set of tasks for their own group at the end of the semester.

**The tasks**

We prepared the tasks in alignment with the 7th grade mathematics curriculum. In the Fall semester we prepared 10 tasks which were about integers, fractions, rational numbers and algebra. In the Spring term we prepared 11 sets of tasks which were about geometry, algebra and data and statistics. Each set of tasks consisted of 3 to 4 sub-tasks with some additional problems. The tasks were set up around a common theme which related to the use of mathematics in daily life. For instance, in one of the data analysis tasks, we conducted a short survey on students’ preferences in the class such that we gave them a list of foods where each student would choose 5 of the foods from the list. Then we wrote down the frequencies for each food on the board and then asked them to answer questions about their preferences such as finding out the most popular food, making a bar graph of the drinks, etc. The majority of the tasks that we used were selected from the ones that we implemented in the previous years. However, we revised those tasks before the implementation based on the needs and performances of the students in our new sample.

---

1 The school was located in a crowded neighborhood in terms of school-age children. There were 40 students in the class, average size according to national education statistics, but in the Spring semester 4 students dropped out. Since we had only 7 volunteers in the Spring semester, two researchers from the research team worked with two of the groups.
Data collection

The data was collected through pre and post questionnaires, videos of PSTs’ task implementations and group discussions, and PSTs’ written reflections and assignments. One of the questionnaires (Kayan, Haser, & Isiksal-Bostan, 2013) consisted of 26 5-point Likert-type items asking for PSTs’ beliefs about mathematics and mathematics teaching. The other questionnaire was developed by the research team and it consisted of open-ended questions where in the pre questionnaire the PSTs were asked to write about their prior teaching experiences and their expectations from the study and in the post questionnaire they wrote about whether their expectations were met or not and what they had learned from this intervention, etc. In their written reflections, we wanted PSTs to discuss about how the implementation went. Among the other questions, we asked them to comment on whether the students were able to complete the tasks, whether the tasks achieved their goals or not and why, and what they would do as follow up. At the end of the semester, we wanted them to discuss in which tasks the students experienced the most difficulty and what their suggestions would be to revise those tasks. Furthermore, we asked them to prepare tasks for their own groups and provide the rationale behind those tasks.

Data analysis

We have not analyzed all data yet. However, because the knowledge of students’ thinking and understanding, the ability of selecting or developing appropriate tasks, and using appropriate teaching strategies for particular groups of students are counted in teachers’ PCK (Hill et al., 2008), we are basically looking for any instances that could be counted as an influence of task design and implementation process on the PSTs’ PCK and their views about tasks. For instance, whether they paid attention to the students’ earlier performances while preparing their own tasks, how accurate assumptions they were able to make about students’ performances on the new tasks, etc. Yet, we did document analysis such that we analyzed the items related to task design and implementation from the questionnaires, written reflections and assignments. We attempted to figure out the frequencies of common issues that emerged from those instruments. We found out the mean scores of the items in the Likert-type questionnaire but we did not compare pre and post results because of low number of participants. We examined pre and post open-ended questionnaires, the assignments asking for making overall evaluation of the study and the reflection reports including PSTs’ reflections on the implementation of their own tasks. We developed a coding scheme for the common issues that emerged from the reflection reports. For instance, when discussing the reasoning behind the success of the tasks, if the PSTs wrote that “they liked it” or “they enjoyed it” or “they had fun with it” then we coded that reasoning as “enjoyable” (see Table 1). However, out of possible 194 reflection reports, 6 of them were missing. Therefore, we coded a total of 188 reports. We achieved 90% agreement in initial coding. We discussed the discrepancies by re-reading the PSTs’ reports and then we came with an agreement. Moreover, we all agreed on the common issues that emerged from the open-ended questionnaire and the assignments.

Findings

PSTs’ thoughts about use of tasks in mathematics

The analysis of items in the Likert-type questionnaire showed that the PSTs agreed that teachers should encourage students to be active learners (The average of 3 related items; pre $\bar{x} = 4.38$; post
The tasks are important for students’ learning and understanding (The average of 2 related items; pre \( \bar{x} = 4.36 \); post \( \bar{x} = 4.61 \)) and manipulatives and materials facilitate students’ understanding (The average of 3 related items; pre \( \bar{x} = 4.09 \); post \( \bar{x} = 4.60 \)). Their answers in the open-ended questionnaires were compatible with these results. The PSTs noted that doing mathematics through tasks enables students to participate in the lesson (\( f = 5 \)), love mathematics (\( f = 4 \)), discover or review mathematical concepts or facts (\( f = 4 \)), and use materials or manipulatives (\( f = 4 \)).

**PSTs’ reflections on the implementation of the tasks**

In the reflection reports, we asked the PSTs to comment on the following questions: 1a) Were the students able to complete the task? 1b) Did the task attain its goal or not? 1c) Why did the task attain its goal or not? 2) What more would you like to do about this implementation? 3) What is your suggestion for the follow up of the task? The PSTs gave various answers to these questions. For instance, for question 1a they noted that some of the students completed the task or just one student could not finish all of them, etc. Although we coded them separately, we re-coded them in terms of whether their answers were most likely “Yes” or “No”. Similarly, we defined 12 different answers for question 1c. However, we preferred to present only the most frequent ones. In Table 1, the frequencies of PSTs’ answers to these questions are given.

### Table 1: Frequencies of PSTs’ answers to the questions

</tr>
</tbody>
</table>
As seen in the table, the PSTs noted that in a 40-minute lesson the students were able to complete the given tasks and discuss their answers (76%). However, some of the PSTs wrote that the tasks were difficult for their students and they only answered one of the sub-tasks. For some of the tasks, the PSTs noted that although the students completed the tasks, there was no time for themselves to discuss students’ answers as a group discussion.

The PSTs wrote that some of the tasks did not attain their goals (28%) mainly because of lack of students’ prior knowledge (27%). In a few cases, they noted that the students did not understand the task because the text was unclear (3%). Some of the PSTs attributed the success of the tasks to use of materials (6%) and context of the tasks that attracted students’ attention (8%). Furthermore, some of the PSTs wrote that the tasks attained their goal because during the group discussion the students recognized their own mistakes and learned from each other (14%). However, in 25% of the reports, the PSTs did not write anything about the reasoning behind the success or failure of the task. Furthermore, we analyzed the pattern in PSTs’ perceived cause-and-effect relationship between Q1b and Q1c. Among the total of 141 responses to Q1c, the PSTs wrote that the tasks achieved their goals because students learned from each other while engaging in the task (f: 25), they used materials (f: 12) and they enjoyed it (f: 15). They noted that the tasks were not successful mostly because of students’ lack of prior knowledge (f: 38).

As an answer to Q2, the PSTs noted that they were able to do whatever they wanted to do during the implementation (40%). However, some of them noted that there was not enough time to explore how students thought about the given tasks or they were unsure whether the students understood the reasoning behind the answers to the tasks or not, therefore they would like to discuss more about those issues (28%). In some of the cases, especially in the Fall term, because of students’ lack of knowledge about fractions and rational numbers, the students could not finish the given tasks. In such cases, the PSTs wrote that they would like to teach about those concepts before or after the implementation if they had enough time (19%). On a total of 6% of the reports, the PSTs did not write relevant answers but summarized how the implementation went.

For the third question, 12% of the reports (not shown in the table) included irrelevant answers such as the PSTs suggested encouraging students to read more books to improve their reading skills or they criticized themselves in terms of not managing time better. In a few reports, they wrote that the tasks were difficult for the students; there should be easier tasks on the same content domain (5%). However, they mostly suggested making review exercises for students to reinforce their understanding of the tasks as well as the content domain (47%). When they realized that the students did not know much about the content, they suggested remedial lessons for them (23%).
PSTs’ reflections on the tasks and the intervention study

At the end of the semester, we asked the PSTs to evaluate this intervention study including the effectiveness of the tasks and the contributions to their own professional development. We specifically asked them to determine five mathematical issues in which students had experienced the most difficulty and two tasks that they would like to revise. We also asked them to give the reasoning behind the selection of those tasks and their revisions.

According to the PSTs, among the others, the students had difficulty in the tasks which were about fractions and rational numbers ($f = 16$), algebraic expressions ($f = 9$), solving equations ($f = 7$), area problems ($f = 7$), and discovering patterns ($f = 5$). They wrote that the students could not do these tasks completely because of their lack of prior knowledge ($f = 17$), lack of attention ($f = 7$), lack of review exercises done at home ($f = 5$), lack of understanding of the tasks ($f = 3$), and personal insecurity ($f = 2$). Specifically, they noted that students had difficulty in fractions, rational numbers and area problems because they did not know the algorithm for four operations with rational numbers as well as the area formulas of quadrilaterals and circle. They wrote that students failed in doing operations and discovering patterns because they did not practice enough at home or did not pay attention to the operations and procedures. However, the tasks that they would like to revise were mostly about integers ($f = 7$), algebraic expressions ($f = 4$), fractions and rational numbers ($f = 3$), area problems ($f = 3$), and transformations ($f = 3$). The PSTs wanted to make revisions to the tasks about integers not because of students’ lack of knowledge but because the context of the tasks was confusing for the students. Therefore, they noted that they would rephrase the text and change the order of the sub-tasks in those tasks. They decided to make the tasks about fractions and area problems easier because students did not possess the required knowledge to complete the tasks. Furthermore, in some cases the PSTs preferred to change the tasks that were done by the students but they were uncertain whether they understood them thoroughly or not.

The PSTs prepared a set of tasks for their own group of students at the end of the semester. Their rationale for their tasks was either to focus on the issues where the students experienced the most difficulty ($f = 13$) or to make an overall review of what was done during that semester ($f = 4$). In parallel with their comments about the students’ mathematical difficulties, they prepared tasks about integers, fractions and rational numbers, area problems, algebraic expressions and solving equations. Some of the PSTs kept their tasks as simple as possible because of their students’ poor performance on earlier tasks. Furthermore, 7 of the PSTs prepared their tasks around a common theme as we did in this study but 10 of them prepared separate problems related to the content domain that they focused on.

In the post open-ended questionnaire, the PSTs wrote that this intervention study contributed to their professional knowledge in several ways. Among the others, they noted that they practiced how to scaffold students’ understanding without directly telling them the solution or answer ($f = 7$), they got better in anticipating students’ possible difficulties in mathematics ($f = 5$), they learned to be patient ($f = 4$), and they learned what kind of tasks attract students’ attention more ($f = 3$).
Discussion

The findings of this study have potential to contribute to the relevant literature that teachers learn from their own task design and implementation practices in terms of better understanding of students’ mathematical thinking and how to use or tailor tasks to scaffold students’ understanding (Zaslavsky, 2007). Although we have not yet analyzed all data, we recognized that the PSTs were able to evaluate the task implementation process in terms of the facts related to the task itself, the organization, the students and their own professional development.

When we asked the PSTs to write their thoughts about the success or failure of the tasks, they were able to make reasonable inferences from the implementation. They recognized that the tasks were successful because the students were actively involved in the solution and discussion process (14%, see Table 1, Q1c), the materials were appropriate for the tasks (6%, see Table 1, Q1c), the tasks were aligned with the 7th grade curriculum and they were in the role of facilitator of group discussion (28%, see Table 1, Q1c and results of post questionnaire). In only a few of the cases, they noted that the students failed to complete the task because the task was unclear for the students (3%). For the other cases, they did not blame the tasks but the students because they did not possess necessary prior knowledge that they learned in previous grade levels or in their regular mathematics lessons (27%, see Table 1, Q1c). The PSTs’ interpretations revealed that they began to recognize students’ mathematical understanding as well as the importance of preparing tasks both aligned with the curriculum and appropriate for a particular group of students (Hill et al., 2008). For instance, while preparing their tasks, they preferred not to use higher cognitive demand tasks but the easier ones because some of their students did not know about the procedures required to solve given tasks, such as the rules of four operations with rational numbers. The PSTs also commented that students should revise the issues discussed in their mathematics lessons in order to understand the mathematics conveyed in the tasks (47%, see Table 1, Q3). Moreover, as we inferred from their answers in the questionnaire they appreciated the facilitator role of the teacher during the task implementation. They stated that they suppressed their feelings of telling and teaching when students could not figure out the solutions. Briefly, their reflections on the tasks and the implementations indicated that they were aware of the task implementation process which begins with selection of appropriate tasks, continues with implementation of the tasks and ends with evaluation of students’ learning (Stein et al., 1996). Because orchestration of task implementation process is involved in teachers’ PCK, such awareness of the PSTs can be counted as a sign of their PCK (Charalambous, 2010). However, because we have not yet analyzed the implementation videos, we are not able to validate PSTs’ reflections on the tasks implementation process, especially whether they were able to implement the tasks without loss of fidelity and manage the group discussions appropriately. Indeed, it is hard for teachers, even more so for PSTs, to keep the cognitive demand of the tasks such that they might have provided hints or helped students when the students did not possess the required knowledge (Stylianides & Stylianides, 2008). Therefore, we are not able to comment on their “PCK in practice” even though we could make inferences about their PCK from their written reflections.

Finally, the analysis of pre and post questionnaires revealed that the PSTs had positive beliefs about use of student-centered teaching strategies, mathematical tasks and manipulatives while teaching mathematics and such beliefs sustained and even increased throughout the study. They recognized
that tasks provided an opportunity for them to elicit students’ mathematical understanding and they could be used as a tool to foster students’ mathematical understanding.

Students’ utilizations of feedback provided by an interactive mathematics e-textbook for primary level

Sebastian Rezat

University of Paderborn, Germany; srezat@math.upb.de

Feedback is acknowledged as an important influential factor on learning and achievement. An affordance of digital learning tools is that they provide different kinds of feedback to students. Research on the effectiveness of feedback has mainly focused on different forms of feedback and its timing assuming that different students react homogeneously to feedback. This paper provides a qualitative in-depth analysis of two third grade students’ responses to feedback in an interactive e-textbook environment. Students responses to feedback are conceptualized in terms of utilization schemes within an instrumental approach. Results indicate that students utilize feedback differently, which has consequences for the effectiveness of the feedback.

Keywords: Feedback, e-textbook, instrumental genesis.

Introduction

Feedback is widely acknowledged as an important influential factor on learning and achievement (Hattie & Timperley, 2007). The fact that interactive digital learning tools constantly provide feedback to the learners’ actions with the contents is indeed one of the most emphasized advantages of learning with digital tools (e.g. Mason & Bruning, 2001). In fact, an outstanding defining aspect of interactivity is that users get immediate feedback to their actions with the tool.

According to Hattie and Timperley (2007, p. 81) feedback is understood as “information provided by an agent (e.g., teacher, peer, book, parent, self, experience) regarding aspects of one’s performance or understanding”. The goal of feedback is to support understanding and/or performance. In line with this, Shute (2008, p. 154) defines formative feedback as “information communicated to the learner that is intended to modify his or her thinking or behavior for the purpose of improving learning”. According to Hattie and Timperley (2007, p. 87) effective feedback has to address three questions: “Where am I going? How am I going? Where to next?”.

Research related to feedback aims at identifying features of feedback that increase its efficiency. Two aspects seem to be important for effective feedback: 1) the information provided by feedback and 2) the timing of feedback. Mory (2004, p. 753) distinguishes five categories of feedback regarding information complexity: “1. No feedback means the learner is presented a question and is required to respond, but no indication is provided as to the correctness of the learner’s response. 2. Simple verification feedback or knowledge of results (KR) informs the learner of a correct or incorrect response. 3. Correct response feedback or knowledge or correct response (KCR) informs the learner what the correct response should be. 4. Elaborated feedback provides an explanation for why the learner’s response is correct or incorrect or allows the learner to review part of the instruction. 5. Try-again feedback informs the learner when an incorrect response and allows the learner to one or more additional attempts to try again.”

Research has shown that both, the wrong form of feedback and the wrong timing might even have negative effects on learning and achievement (Fyfe & Rittle-Johnson, 2016a; Hattie & Timperley,
The majority of studies in this context quantitatively measures effect sizes of different forms or timings of feedback in order to draw conclusions regarding the effectiveness of feedback. The underlying assumption in these settings is that students will react consistently to the respective form or timing of feedback. While different conditions of providing feedback that might influence its effectiveness have been studied, e.g. prior knowledge (Fyfe & Rittle-Johnson, 2016b) or feedback specificity (c.f. Shute, 2008) students’ individual ways of responding to and making use of feedback have scarcely been studied in mathematics education. Bokhove (2010) presents an exception. He reports from a study where student inquiry about desired feedback was used in order to develop a feedback design of a digital tool to learn algebra. He concludes that “asking students when to use what feedback can improve a digital tool“ (Bokhove, 2010, p. 125). Most of the research on feedback is based on experimental testing (Shute, 2008, p. 156). Shute (2008, p. 156) summarizes that „the specific mechanisms relating feedback to learning are still mostly murky, with very few (if any) general conclusions“. The aim of this paper is to contribute to the understanding of the mechanisms relating feedback to learning. In particular, the focus is on two research questions: 1) How do students individually utilize feedback in order to improve their understanding and performance?; 2) What are the consequences of students’ individual utilizations of feedback with regard to the efficiency of feedback?

**Theoretical framework and methodology**

In this paper, feedback is regarded as an artifact, which is developed in order to improve students’ learning and achievement. According to Rabardel (2002) an artifact is transformed into an instrument in use. An instrument is a psychological entity that consists of an artifact component and a scheme component. In using the artifact with particular intentions the subject develops and adjusts utilization schemes, which are shaped by both, the artifact and the subject. This process is referred to as “instrumental genesis” (Rabardel, 2002). According to Vergnaud (1998, p. 167) a scheme is “the invariant organization of behavior for a certain class of situations”. Vergnaud (1998) suggests that schemes are in particular characterized by two operational invariants, which refer to the knowledge included in schemes: theorems-in-action and concepts-in-action. The difference between both operational invariants is that of relevance and truth. While “concepts-in-action are relevant, or not relevant, or more or less relevant, to identifying and selecting information”, “theorems-in-action can be true or false” (Vergnaud, 1998, p. 173).

With regard to research question 1, students’ utilization of feedback is conceptualized in terms of their concepts-in-action and theorems-in-action, which guide their utilization schemes of the feedback. The situation that the scheme refers to is defined by the type of task with respective feedback.

**Methods**

The study presented in this paper is part of a larger study, which aims at understanding students’ learning with interactive e-textbooks at primary level. Therefore, we used an interactive e-textbook that is available on the German market. The e-textbook “Denken und Rechnen interaktiv 3”\(^1\) was the only interactive textbook for primary level that was available on the German market when the study

\(^1\) [http://www.denken-und-rechnen-interaktiv.de](http://www.denken-und-rechnen-interaktiv.de)
was carried out. The e-textbook was not developed for the sake of this investigation, but by one of the leading German publishing companies for textbooks. Consequently, the design principles for the feedback are not known and do not necessarily take into account the current state of research in this field.

In this paper, a case study with altogether 12 cases is presented. All students were at the end of third grade with an age between 8 and 9 years. Each case works on a tablet in experimental conditions on tasks from one unit of a beta-version of the web based interactive mathematics e-textbook. During data collection the students encountered the interactive e-textbook for the first time. The students were asked to verbalize their thoughts (thinking aloud). Additionally, the interviewer asks questions in order to understand the students’ actions and thoughts. The interviewer also gives hints in order to assist students’ instrumental genesis. The work of the students was video recorded. Data was transcribed and analyzed in terms of concepts-in-action and theorems-in-action. As the name of these concepts indicates, these are mainly inferred from students’ actions. Only sometimes students explicate the concepts and theorems guiding their actions verbally. Concepts-in-action were inferred from the data by constantly asking ‘what are the concepts / relevant categories / notions guiding the student’s action?’. Accordingly, theorems-in-action were inferred from the data by asking ‘what assertions / beliefs assumed as true by the student guides the student’s action?’

Since utilization schemes are defined as “invariant organization of behavior” (Vergnaud, 1998) it might seem questionable to investigate them with children that encounter an e-textbook for the first time. However, utilization schemes do not develop from scratch, but can be understood as adjustments (accommodation) of existing schemes. In fact, this experimental setting allows for analyzing the instrumental genesis in terms of accommodation of existing schemes.

Analysis

Analysis of the artifact

An analysis of the task and related feedback is a prerequisite in order to understand students’ utilization schemes of the feedback, because they are influenced by the affordances and constraints of the artifact in the instrumentation process (Rabardel, 2002). Task no. 2 on page no. 73 and related feedback is analyzed for the scope of this paper. It is depicted in figure 1. The task is to find solids in the picture (“Which solid shapes do you find?”) and to enter their names into the empty fields. After pressing the OK-button on lower right corner of the screen the software provides knowledge of results (KR) feedback. Correct inputs are shown in green color with a green frame, wrong inputs stay as they were entered for a few seconds. Afterwards they disappear and the empty fields are shown again (figure 2). Correct answers stay on the screen and the student can enter new inputs into the empty fields. Students get the opportunity to correct their wrong inputs twice. After their third try knowledge of correct response (KCR) feedback is provided by showing all the correct answers in green color. The ones that were entered correctly by the student are framed. An answer is evaluated as correct if

---

2 This was the task in the beta-version of the interactive textbook. In the latest online-version of the textbook the task was changed to “Enter befittingly sphere, cube, cylinder or pyramid“.
the student entered the correct name of the solid in the correct spelling. The feedback does not differentiate between incorrect spelling mistakes or incorrect solid names.

Figure 1: Task

Figure 2: Task-level-feedback (KR) and screen for second try

Analysis of students’ utilization schemes of the feedback

In this section data of two cases will be analyzed. The analysis of both cases starts at the moment, when the students have filled in most of or all empty fields and press the OK-button at the lower right corner of the screen. After pressing the OK-button the KR-feedback appears on the screen.

Case 1: Farrell

On Farrell’s feedback screen four out of seven answers are depicted in green color and with a frame and stay on the screen while three of his answers remain as they were entered and disappear after a few seconds. He gets the feedback “Sorry, wrong”.

13’03” Interviewer What happened?
13’08” Farrell Correct answers are green and what is gone now was wrong
13’18” Interviewer Ok. And do you have an idea why it was wrong?
13’22” Farrell Wrong spelling? And wrong entry.
13’30” Interviewer Could be. … Think about it. What else could you write or how could you write it differently if you think it also might be because of the spelling
13’35” Farrell Tips into an empty field and starts typing ‘Cube’ in correct spelling.
13’54” Interviewer Uhuh, now you say it’s a cube. What did you enter before?
13’56” Farrell Square.
And why do you think it is the cube now?

Because, before, the square is not an object, no symmetrical figure

Ah, ok, and now you believe it’s the cube.

Yes, because the square can only be seen and not touched

Ah, ok.

Types ‘cuboid’ in one empty field in the same wrong spelling as the first time.

Which form could that be?

Can the book help you somehow?

Presses the ‘?’-button and choses “help” (the help screen appears). He reads the help screen.

Does that help you somehow? What do you see?

There is everything that could give me a hint.

Hm, ok. … And does that help you for the task?

No.

No. Is there maybe another function that could help you?

I will check. Presses the ‘?’-button and points on the option ‘Lexikon’.

Yeah, click it.

Farrell explores the lexicon. The interviewer asks questions, which are related to the use of the lexicon. He looks for ‘form’ and “solid”.

I believe it starts with a ‘Q’. At the same time, he opens the letter ‘Q’ in the lexicon and looks at the entries.

No, but I found something different.

Ok. What did you find?

The cuboid (in German: Quader) Returns to the screen/tab with the task and tips into the field with the entry “Qader”.

You already wrote cuboid there. So what did you find?

That in-between the Q and the A there is a U.

Ah, that means the lexicon helped you a little.

After completing to type the word ‘cuboid’ he presses the OK-button. All his entries are shown in green color with a frame. He gets the feedback “No, not correct yet.”

And, what now?

I looked if what I wrote now is already correct.

And, how does it look?

Correct.

The relevant concepts that guide Farrell’s revision of his answers are verbalized in the beginning of the episode: Farrell verbalizes his interpretation of the feedback at 13’08” and also explicates two concepts of possible mistakes at 13’22”. Accordingly, Farrell’s utilization scheme of the feedback is guided by two concepts-in-action: 1) Correct answers are shown in green; wrong answers are shown in red (not explicit, but likely) and disappear (13’08”); 2) His concept-in-action of mistakes indicates that two kinds of mistakes are possible: Wrong names of the solids or wrong spelling of the names
(13’22”). The latter concept-in-action is supported by his way of proceeding with the task. On the one hand he thinks about different entries (13’35”) and on the other hand he is sensitive about the spelling (18’58”-19’12”).

Case 2: Edda

Edda gets the feedback “No, that it not quite correct”. On the screen, the fields around her entries disappear and all her entries stay on the screen. An analysis of her answers reveals that five of her answers (from left to right and bottom to top: 1, 3, 4, 5, 7) named the solid correctly but were spelled wrong with no capital first letter, while two of her answers (2, 6) also contained a wrong name of the solid.

23’51” Edda It says that it is all not quite correct. *Looks at the screen*

23’55” Edda *All (wrong) entries disappear. All fields are displayed empty again. Ah, boy!*

24’02” Edda *Looks at the screen. Hm.*

24’07” Edda But this must be a sphere.

24’12” Interviewer Do you have an idea what may could have been wrong? …

24’16” Edda Yes, this and this (points at the two empty fields at the right side of the picture) … because everything disappeared.

24’27” Edda Well, this can’t be a cone. … Then I simply do again … It’s a sphere, definitely. *Types ‘sphere’ in the same (wrong) spelling as before in the empty field.*

25’00” Edda Hm, it’s bad, now I don’t know what was wrong and now one cannot …

25’10” Interviewer What is it that you can’t?

25’12” Edda … ehm, know what is wrong, I know … ehm … I have to do everything from scratch … (not understandable) this and this was wrong (points at the two empty fields at the right side of the picture)

Edda’s feedback screen shows all her entries in the way that she typed them. She seems frustrated that all her entries disappear from the screen (23’55”). Her answer to the interviewer’s question at 24’12” reveals that she does not infer from the feedback that all her answers were wrong, but has her own beliefs about her wrong answers (24’16”). Her belief that her two answers on the right side of the picture were wrong seems to be stable throughout the episode (25’12”). However, these beliefs are not congruent with her actual performance on the task. At 25’00” it becomes apparent that she does not have the concepts available to make sense of the feedback given by the tool.

Although she does not say it explicitly, her actions seem to be guided by the concept-in-action that she has to enter the correct names of the solids. There is no indication of her being aware that it is not only the name of the solid that is relevant, but that correct spelling is also a relevant aspect of the name related to this task.

**Discussion**

The analysis of students’ utilization schemes of feedback shows that both students do not activate the same concepts-in-action when they utilize the software’s feedback (research question 1). While Farrell’s utilization scheme is guided by the two relevant concepts-in-action “name of the solid” and “spelling of the name”, Edda’s interpretation only refers to the “name of the solid”. Edda seems surprised and disappointed that all her entries disappear on the screen and her belief that only two of
her entries were wrong seems to be stable. This indicates that she does not seem to have relevant concepts available in order to utilize the feedback.

However, it is important to note that the different utilization schemes of Farrell and Edda appear under different conditions. The intended interpretation of the feedback occurs in a situation when the student has got correct and wrong answers. In the case of Edda, it becomes apparent that she has difficulties to utilize the feedback. This is supported by findings from other cases in the study that have got all answers wrong in their first attempt. Two hypotheses can be inferred from this observation (research question 2): 1) In order to make effective use of the feedback it is important that students have both, correct and incorrect answers. If all answers are wrong it is more difficult to utilize the feedback, because it is more difficult to make sense of the feedback. 2) On the other hand, the findings might hint at an overall connection between the mathematical ability of the students and their ability to utilize the feedback effectively. Students who need the feedback most in order to improve their mathematical performance, because they have got many answers wrong in their first attempt have the most difficulties to utilize the feedback for improvement.

**Conclusions**

The analysis of two cases’ utilization-schemes of feedback in an interactive mathematics e-textbook, which was used for the first time, is too limited in order to draw far reaching conclusions. However, the results show that the feedback of this task can be optimized. For some students it seems to be important to get more detailed feedback about the kind of mistake they made, especially if mistakes from different domains such as mathematics and language are relevant for the evaluation of the solutions. Altogether, the results support the call for adaptive feedback systems in digital learning systems (Vasilyeva, Puuronen, Pechenizkiy, & Räsänen, 2007).

The fact, that the feedback of the software is not sensitive to different kinds of mistakes can in fact be appraised differently depending on the pedagogic perspective. From the perspective of concept development, it is a constraint of the feedback that it is not sensitive to the kind of mistake, because it does not provide detailed information related to the question “Where to next?”, i.e. detailed information about “what is and what is not understood” (Hattie & Timperley, 2007, p. 90). Research has shown that “that feedback is significantly more effective when it provides details of how to improve the answer rather than just indicating whether the student’s work is correct or not” (Shute, 2008, p. 157). From the perspective of integrated mathematics and language learning it might even be an affordance that the name and the spelling of the name of the solid have to be correct in order to be evaluated as a correct answer.

On the other hand, the reconstructed concepts-in-action and theorems-in-action that guide students’ utilization schemes of feedback indicate that students interpret feedback differently. Therefore, the efficiency of feedback is not only a question of the features of the feedback, but also a question of students’ utilization-schemes of feedback. Like with any other artifact, students have to instrumentalize and develop utilization-schemes of the feedback so that it becomes an instrument for improving understanding and performance.

Documentational trajectory: A tool for analyzing the genesis of a teacher’s resource system across her collective work
Katiane de Moraes Rocha and Luc Trouche
École Normale Supérieure, French Institute of Education, Lyon, France
katiane.de-moraes-rocha@ens-lyon.fr; luc.trouche@ens-lyon.fr

Our contribution to TWG 22 is dedicated to discussing teachers’ interactions with resources for planning their classroom instruction, particularly in the context of collective work. Each teacher during his or her professional life uses and creates many resources. To analyse the history of teachers’ work with resources, we propose the concept of the “documentational trajectory”. This idea is based on and aims to contribute to the development of the documentational approach to didactics. We will present a case study of one middle school teacher. The data related to this teacher’s work allowed us to consider her documentational trajectory. We then used the teacher’s documentational trajectory to analyze her professional development. The teacher’s documentational trajectory demonstrates a strong participation in collective work, in particular a collective named SESAMES, has an essential role. This participation contributes to the emergence of a particular resource, called a metaresource, to structure her documentation work.

Keywords: Documentational approach to didactics, documentational trajectory, metaresource, reflective investigation, professional development.

Introduction
The new possibilities arising from communication and information technologies have had a significant impact on discussions on mathematics education, due to their impact on resources available to teachers and the way of designing them. This has led to a new conceptualization of teaching resources (Adler, 2000) and the consideration of teachers’ new relationships with these resources (Remillard, 2005). Drawing on these studies, Gueudet and Trouche (2009) have analyzed teachers’ professional development through the lens of resources: they introduced the documentational approach to didactics to analyze how teachers select, use, and produce their resources, along with a process called documentation work (ibid, 2009). More recently, Bozkurt and Ruthven (2015) have shown how digital resources structure classroom practices, evidencing five main features: working environment, resource system, activity format, curriculum script, and time economy. In this article, we will rely on and develop these approaches for analyzing teachers’ history of their resource usage. We will propose a new concept for modeling this history: the teacher’s documentational trajectory. We will mainly discuss here the effects of a teacher’s collective work on his or her documentational trajectory. In order to do this, we will organize our contribution in four sections. In the first, we will introduce the keys concepts that structure our analysis. In the second, we will present our methodological choices. Next, we will develop a case study based on a middle school teacher, Anna. And in the last section, we will propose some final considerations and openings for future research.
Theoretical framework and research issues

We will present and develop in this section the theoretical approaches that form the basis of our analysis: the documentational approach to didactics, the structuring features of teachers’ practices, and the notion of thought collective. Then we will present our own propositions.

As stated by Gueudet and Trouche (2012, p. 24) “teachers interact with resources, select them and work on them (adapting, revising, reorganizing, etc.) within processes where design and enacting are intertwined”. This process is the central focus of the Documentational Approach to Didactics (Gueudet & Trouche, 2012) that grounds our work. In this approach, the term resource is used in a broad sense, as everything that nourishes teachers’ work. To prepare their teaching, teachers work on resources, and the result of this process is called a document. A document is made of resources that have been modified and re-organized, and by the knowledge, both guiding, and produced by, teacher’s work. The document is therefore subjective, because it is created through a process of knowledge development on the part of the subject. And the new resources generated or used in this process take place in a very structured set of teachers’ resources, called a teacher’s resource system. To develop this system, some resources introduced by Prieur (2016) as metaresources play a critical role. They design resources that support and guide the creation of other resources and, beside that, favor teacher’s reflection about their documentation work.

Teachers’ documentation work grounds teachers’ classroom practices, structured, according to Bozkurt and Ruthven (2012) by five features: the working environment, where class takes place (infrastructure, social organization, etc.); the activity format, which comprises the body of work in the classroom, such as routines and models of interactions between teacher and student along teaching and learning; the resource system, which gathers tools and materials for class. The curriculum script is to be understood in the cognitive sense of structured organization of activity guiding a teacher’s work in the classroom: goals, actions, activities, potential difficulties of students, among others. And time economy, based on the comparison between the teaching time and the learning time of students. Bozkurt and Ruthven use this framework for analyzing teachers’ integration of new digital resources into classroom practices. We will extend this usage for analyzing teachers’ design and usages of resources. Thus, we will retain the notion of a resource system as proposed by Gueudet and Trouche (2012):

“we consider here as resource system does not fully coincide with Ruthven’s definition, because of the broader meaning of resources we retained. The resource system comprises material elements, but also other elements that are more difficult to collect, like conversations between teachers” (p. 27).

We consider that teachers’ interactions with colleagues are likely to foster their documentation work and professional development (Gueudet & Trouche, 2012). This is the reason why we give a primary importance to collectives. We have retained the broad definition of thought collective (Fleck, 1934, p. 44) that exist when “two or more people are exchanging thoughts” and generating a thought style “characterized by standard features in the problems of interest to a thought collective, by the judgment which the thought collective considers evident, and by the methods which it applies as a means of cognition” (ibidem, p. 99). We will differentiate the natures of collectives, according to their duration.
(stable vs. unstable), their organization (formal vs. informal) and type of participation (voluntary vs. obligatory).

Finally, our proposition for modeling a teacher’s history with resources based on the notions of resource, collective, and event. An event is something that happens in a teacher’s professional life, and that he or she has remembered as important regarding her documentation work. We define the teacher’s documentational trajectory (Rocha, 2016) as the interplay, over time, between events and resources. This interplay is socially situated, because it happens in schools or collectives, or because the events or the resources themselves are social products. The design of a teacher’s documentational trajectory is then a way to analyze when, where, why, how and which resources are created. We will focus in this article on the documentational trajectory as a tool for analyzing the development of a teacher’s resource system across their collective work. We describe, in the following section, our methodological choices for such a design.

**Methodological design**

Our methodology is inspired by the four principles of reflective investigation proposed by Gueudet and Trouche (2012): “long-term follow-up”, “in- and out-of-class follow-up”, “reflective follow-up” and “broad collection of the material resources”. This methodology gives a major importance to specific drawings made by a teacher (for example the ‘schematic representation of their resource system’). To retain this way of reflective investigation by the teacher of her documentation work, we propose some evolutions: instead of the word “representation”, we propose (Rocha, 2016) the word “mapping”, integrating the metaphor of a progressive exploration of a new territory. And we propose two kinds of mapping: reflective (made by the teacher herself) vs. inferred (made by the researcher) mapping. We differentiate then Reflective, vs. Inferred Mapping of a teacher’s Resource System; Reflective vs. Inferred Mapping of a teacher’s Documentational Trajectory. For the design and analysis of a documentational trajectory, we also use: interviews, follow-up of lesson preparation, and classroom observation, and a logbook filled by teachers.

Our current research is mainly based on case studies. To choose teachers, we searched teachers that had Sésamath textbooks as official textbooks in their class. Sésamath (http://www.sesamath.net/) is an association of mathematics teachers in France that collaboratively designs online resources (software, textbooks, etc.) at a very large scale, opening a window for us on advanced teachers’ design, use and sharing of resources. We present here the case of Anna, a middle school mathematics teacher, whose school had chosen a Sésamath textbook. She has a strong partnership with a colleague from her school, Cindy, and both of them participate in various collectives and use a lot of digital resources beyond the Sésamath textbook.

Our work with Anna started in March 2015, when we followed her 6th grade class for three months. During this period, Anna created and shared with us a Dropbox folder, where she uploads resources that she used in her lesson or to prepare it. In addition, we also recorded four moments of interaction involving her documentation work. In the first one, she made a reflexive mapping of her documentational trajectory. In the second one, she reviewed her reflexive mapping (focusing on a particular resource and a specific year). In the third one, she prepared a lesson with Cindy about a new curricular subject. In the last one, she spoke about her usages of a particular digital tool, a padlet.
(https://padlet.com/) used to save and organize resources found online. Also, we had her use a logbook to complement our data collection when we could not follow her documentation work.

We will explore in this paper different mappings of Anna’s documentational trajectory: inferred and reflexive mapping. To obtain the initial reflexive mapping, we asked her to write down above a timeline the main events that have influenced her use of teaching resources teaching, or the way of conceiving them, and to write down, below the same timeline, the resources associated with the event at stake. To help Anna, we gave her a sample of possible events: the arrival of a new person in her school; the participation in a new collective, an unexpected interaction with a student or colleague; a change of program; a change of teaching level or of textbook; a training course or the discovery of a new resource related to mathematics teaching (book, movie, website, etc.).

Our method of analysis is in development. In this article, we transcribed our first interview with Anna and we did a digital transposition of her reflexive mapping. Afterwards, we identified on the map, among the events she exposed, those related with collective work, following our hypothesis that knowledge is socially situated. After that, we identified the effects of collective work on her documentation work through associated resources at the event. Afterwards, we inferred from Anna’s speech her role in collectives and the nature of each of these collectives, following the hypothesis that some features could inform us on the collective effect on a teacher’s documentation work. For example, a collective where teachers are voluntary and have a long or permanent engagement nourishes teachers’ work differently than an obligatory collective where they have a short time engagement. Then, we searched collectives that have an important status in Anna’s documentational work. For this purpose, we looked for the collectives that appeared more frequently and related to other events in the map. Afterwards, we analyzed how these collectives nourished her documentational work exploring associated resources, and identifying in her words features relating resources and collective work. We will present the main results of this analysis in the following section. This work is still in progress.

**Analysis**

This analysis is divided into two parts: (1) Anna’s participation in collectives along her documentational trajectory and the structuring role of a particular collective, SESAMES in it; and, (2) the structuring role of a particular resource, “Mise en train”, on Anna’s individual and collective documentation work.

**Anna’s documentation work in collectives along her documentational trajectory and relationships with SESAMES.”**

We start analyzing the first reflexive mapping drawn by Anna (Figure 1). The analysis of the events evidences Anna’s strong involvement in collective work (she says: “I cannot work alone”). Eight (E6, E7, E8, E9, E10, E12, E13 and E14) over 14 events are related to collectives. For deepening the analysis, we study the properties of collectives, the roles of Anna in these collectives, and the functions of the resources that are designed.

The collectives have different natures:

- some of them are transient, as a short episode of coworking with Sésamath (E4), or Assist Me (E12, linked to a European project), or M@gistère (E13, linked to the design of a
teacher training path); some of them are ‘permanent’ (meaning that, once Anna enters this collective and stays in it), as APMEP (E10/E11, the French national mathematics teacher association), or LéA (E9, collective linking Anna’ middle school and the French Institute of Education), or SESAMES \(^1\) (E6, a team associating researchers and teachers for renewing Algebra teaching);

- some of them are obligatory (as E14, meeting with parents), some of them are voluntary (as E7 the close partnership with Cindy).

In these collectives, Anna can have six different roles: member, reading and using their resources (E8 and E10); author, conceiving articles and resources for readers external to the group (E6, E8, E10, among others); teacher trainer, training middle school teachers (E6, E8, and E10); teacher researcher, reflecting about mathematics teaching (E6, E12 and E8); partner, exchanging and co-producing resources with colleagues (E6 and E10).

Each collective contributes in different ways to her documentation work. However, they are entangled in a way that it is difficult to attribute a single function to each of them. The interviews with Anna help us to distinguish some structuring features of Anna’s documentation work: elaborating her resources for teaching algebra; elaborating activities for teaching mathematical concepts and interpreting curriculum materials; elaborating resources for developing and evaluating students’ competencies; creating lessons and curricular scripts for her class; reflecting about using digital resources; creating new resources according to pedagogical changes in the school, supporting her participation in other collectives outside of school, writing papers, and teacher training.

These functions are not supported by all collectives, but all of them are exploited in Sésames, where Anna and Cindy used to work together. In addition, SESAMES gives Anna new possibilities for participating in new collectives and establishing new partnerships. Figure 2 shows how SESAMES resources nourish the resources of other collectives. Develop a critical thinking on their practice.

When she was invited to join SESAMES, Anna hesitated “that was a change, anyway. I accepted, finally, to join ... to join SESAMES. [...] It was a real challenge...”.

\(^{1}\) In spite of the likeness of the acronyms, Sésamath, a mathematics teacher association designing resources at a large scale, is totally different of SESAMES, a small team gathering researchers and teachers for re-thinking algebra education.
SESAMES ² had a big impact on Anna’s collective work. We can see (Figure 1) that she joined Assist me, M@gistère and Léa as a consequence of her engagement in SESAMES. It gave the opportunity for a new partnership with Camille. It helped her understand the competencies emphasized in the new French curriculum, leading to the design of a teacher training path at IREM, resulting in a chance to join this institute.

SESAMES has two sets of principles guiding Anna’s documentation work (cf. the SESAMES website, Pégame: http://pegame.ens-lyon.fr/), mirroring the thought style of SESAMES. The first set is composed of three principles for teaching algebra: justifying computation throughout algebraic rules; proposing proof activities and exploiting formulas to introduce the concept of a function. The second set is composed of four principles for teaching mathematics: providing students with sufficiently rich and open problems; giving them a chance to explore; giving them a chance to speculate; giving concrete meaning to concepts taught.

These principles gave birth to resources emblematic of SESAMES thought style, guiding the whole process of collaborative resource design in this group. It’s exactly the characteristic of the metaresources we have already introduced in this paper. One of them is Mise en train, and we will analyze in the following section its impact on Anna’s documentation work.

The structuring role of a metaresource on Anna’s individual and collective documentation

The Mise en train (MET) corresponds to a specific activity format: it aims to organize teacher’s work at the beginning (around 15 minutes) of each class. The expression Mise en train has three meanings: the direct one is warming up (like for an athlete at the beginning of his training); the second one derives from a literal translation, “put on a train”, meaning ‘cutting a mathematics subject in short successive parts (allowing to store them in the successive wagons of a train); the third meaning derives from an acronym (created by Anna): Travail de Recherche ou d’Approfondissement avec prise d’InItiative (Research and Deepening Work with Initiative Taken). The global meaning of Mise en Train has to be understood as the compilation of these three interpretations. In the following, we have chosen to keep this acronym MET, incorporating this global meaning. This global meaning evidences some features of MET resources’ design. MET is exactly a metaresource, as it gives a way to produce new resources and stimulates teacher’s reflection on their documentation work and its effect on students’ activity.

MET appears as emerging, in SESAMES, from the documentation work of Anna and her colleagues. Anna explains factors leading them to create this metaresource: the loss of time at the beginning of each class (teacher being mobilized by administrative tasks); the good experience with the short sections of reflecting calculations; and her exchange with English teachers dividing students’ activity in short articulated moments for a more dynamic activity format.

Once created, MET deeply changed Anna’s documentation work (cf. Figure 4). It affects all five structuring features of classroom practice. The working environment changed, e.g. students entering class late did not disturb class activity. The activity format is also altered, because the class is divided into two moments: MET vs. main class.

The **curriculum script** is modified, including new goals and activities. Anna has then three possibilities for developing a lesson: MET then the regular course; the regular course, then MET; or beginning with MET… and going on with MET, for giving more responsibility to students for the advancement of the knowledge in the classroom. Regarding Anna’s **resource system**, new resources are created (new curriculum script, new notebooks for students, new lesson plans with MET activities, slides that contain MET activities linked to a given notion, new articles (APMEP, IREM, Pégane website) for disseminating SESAMES resources. Last, but not least, the **time economy** changed, for example, Anna removed the initial “call to students” at the beginning of each lesson.

MET also affects Anna’s work in other collectives: in her school, the new curricular script is shared by all teachers, as Cindy and Anna explain the principles of MET, and present their interest for their practice; outside of her school, Anna disseminates this metaresource in SESAMES training, IREM group, and training, APMEP group and training. Finally, this metaresource, initially constructed in SESAMES group to teach algebra, was extended to other mathematical topics. For us, the metaresource **MET** is a point of convergence between Anna’s need and SESAMES’ interest.

**Final considerations and perspectives**

Our original question was: *What are the effects of a teacher’s collective work on their documentational trajectory?* Our initial analysis of Anna’s documentation work gives us some clues. Our exploration of Anna’s documentation work in collectives allows us to understand her resource system better. We saw a diversity of collectives that she participates or participated in, and how her different roles contributed to her work. Among them, SESAMES appears as an important collective, having a strong impact on Anna’s documentational trajectory. It contributes to developing new collective work, resources and thought styles. In this collective, she contributes to create a metaresource that structures her documentation work afterwards: this metaresource is exploited in various collectives and structures her way to create resources.
We proposed the concept of documentational trajectory for modelling a teacher’s history with resources. In this modeling, the reflective and inferred mapping of the documentational trajectory allows us to evidence some critical aspects of this history. It should be noted that these maps constitute a picture at a given moment, and in a given context. This temporal aspect is linked to the fact that Anna’s documentation work is still ongoing. The context aspect is also linked to the relationships the researcher can build with the teacher.

The combination of the *Structuring Features of Classroom Practice* and the *Documentary Approach to Didactics* helps us to analyze teachers’ documentational trajectory, demonstrating the structuring role of SESAMES and a metaresource associated to a thought collective. Finally, we retain from this analysis that the development of the concept of documentational trajectory was relevant for analyzing interactions between resources, collective work and teacher’s practice.

Designing for responsibility and authority in experiment based instruction in mathematics: The case of reasoning with uncertainty

Abdel Seidouvy¹ and Andreas Eckert²

¹Örebro University, Sweden; abdel.seidou@oru.se
²Linnaeus University, Sweden; andreas.eckert@lnu.se

Abstract: This study examines principles of task design concerning the concept of uncertainty in the area of statistics. A purpose is to promote and support students reasoning competency involving the aspects authority and responsibility. By using inferential role semantics as a background theory, we examine students’ reasoning by means of how they show authority and responsibility for statements in the reasoning process. Statistical tasks where students generate and analyze their own data formed the basis for this pilot study conducted with seventh grade students in Sweden. The students were able to reflect on how their actions and consequences of their actions influence their reasoning with uncertainty. The study describes the findings, and presents principles to inform the design of innovative learning environments that promote authority and responsibility in reasoning in the domain of uncertainty.

Keywords: Design principles, uncertainty, responsibility, authority.

Introduction

Designing lessons and tasks has been an important part of developing theories of instruction in mathematics for over a century (Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003) and emerging from this practice is the design-research methodology. Plomp (2013) speaks of a twofold yield in design research-projects, both producing an intervention that offers a solution to a problem in the practice and what he calls re-usable design principles. In the present study, we are aiming for the latter. Design principles are to be seen as heuristics as they do not guarantee success. The principles rather suggest design elements that could support the development of a prototype design of a task (Plomp, 2013). Design principles are guides that answer questions like “What should the lesson look like?” or “How should the lesson be developed?” (Van den Akker, 1999). They should connect task design with both a practical and theoretical understanding of the topic and inform the teaching practice as well as the research practice.

This paper begins in the idea of developing tasks for experiment based instruction in mathematics and the special case of stochastic. Groth (2013), amongst others, argues that stochastic education should be researched in particular since the nature of mathematical reasoning is largely deterministic whereas that of stochastic is with uncertainty. Our task design principles are therefore not focused on the creation of new knowledge but on eliciting stochastic reasoning and developing students’ understanding. In the present study, we examine design principles in relation to how meaning making is described in the semantic theory of inferentialism (Brandom, 1994). Our guiding research question is:

- What are the design principles that trigger students’ authority and responsibility in reasoning with stochastic uncertainty?
Plomp (2013) stresses the importance of reviewing similar examples when articulating design principles for the first time. Hence, the following section will elaborate on previous examples of experimentation-oriented tasks for stochastic education in the research literature to create a deeper understanding of design principles in stochastic education. Furthermore, the theoretical background of inferentialism gives the tools to see authority and responsibility in student’s reasoning connected to the design of the task.

**Related works**

In the Dutch tradition of RME, three principles inform task design: guided reinvention, didactical phenomenology, and emerging modelling (Freudenthal, 1973; Gravemeijer, 1994). According to the principle of guided reinvention, mathematical tasks should offer students opportunities to experience a process similar to that linked to the invention of a specific topic. On the didactical phenomenological account, task designers should consider how mathematical “thought objects” will be used by the students to structure and organize phenomena in reality. Emerging modelling emphasizes the process on progressive abstraction, from a model of a situation (experimentally real for the student) to a more general mathematical model (Gravemeijer, 1994). Overall, in RME, mathematical tasks are often rooted in Freudenthal’s vision of “mathematics as a human activity”, and are designed to resemble realistic problems in context. Another school of thought close to RME is authentic teaching and learning in mathematics. The design principles of an authentic practice are used to perform certain actions and procedures, and knowledge as a tool to perform and achieve particular goals (Dierdorp, Bakker, Eijkelhof & van Maanen, 2011). The underlying conjecture in authentic mathematics is that students will be motivated and engaged in rich discussions if authentic practices are used as a source of inspiration in designing mathematical tasks. Ainley, Pratt and Hansen (2006) used *purpose and utility* as design principles in mathematical tasks. According to Ainley, Pratt and Hansen (2006), purpose means that a meaningful outcome of a task is crucial for student learning. Utility refers to acknowledging the power of mathematics ideas. Chance-maker microworld (Pratt, 2000) is an example of a learning environment in which purpose and utility are implemented. The chance-maker is a microworld program with a series of gadgets, simulations of everyday random generators such as spinner, coins and dice. The students are challenged to find the gadgets that according to them do not work (The students were told that the gadgets were programmed) and mend them. The purposeful activity, for the students, of mending the gadgets led to the understanding of the utility of representations (connection between probability and data distribution), and the importance of the law of large number. The students are supposed to discover the relevance of mathematical ideas through realistic situations created in classrooms, real life (Ainley, Pratt and Hansen, 2006) or in the microworld (Pratt, 2000).

Our hypothesis is that a mathematical task that can trigger students’ authority and responsibility increases student awareness on the data generation process and, has the potential to develop students’ reasoning with uncertainty.

**Theoretical framework: The Game of Giving and Asking for Reasons – GoGAR**

The framework of our research is the game of giving and asking for reasons (GoGAR); it is a metaphor used by Brandom (1994, 2000) to describe the linguistic practices in inferentialism, which
is the background theory of this study. An inferentialist view on knowledge entails giving priority to inference in reasoning in account of what it is to grasp a concept:

To grasp or understand […] a concept is to have practical mastery over the inferences it is involved in – to know, in the practical sense of being able to distinguish, what follows from the applicability of a concept, and what it follows from. (Brandom, 2000, p. 48)

It corresponds to the practical mastery of concept and, to the increasing awareness that reasoning is central to statistics and statistics education (Bakker & Derry, 2011). “The game of giving and asking for reasons is an essentially social practice” (Brandom, 2000, p.163), and the purpose of GoGAR is to make explicit reasons that are implicit in our linguistic practice (Brandom, 2000; Bransen, 2002). According to Brandom (1994, 2000), one way of understanding how reasons are made explicit in talk is in terms of interaction of inferentially articulated authority and responsibility. Authority of a claim is a process, capturing the influence of a claim in the GoGAR. However, “Authority is not found in nature” (Brandom, 1994, p.51) but is gained in taking responsibility by providing evidence for one’s claims. Students are expected to make claims that are related in a certain way, justify and explain their claims. Responsibility can be defined as a quest for authority, and it also expresses the quality of requirement for performing and maintaining authority (Hansson, 2010). By using GoGAR we aim to show how, independently of the quality of the reasoning, elements of task design eliciting authority and responsibility influences how students reason in the domain of uncertainty.

Method

The present paper focuses on reaching an understanding of the data generation process connected to a mathematical task (Cobb et al., 2003). The data generation process involves clarifying the significance of the phenomenon under investigation, delineating key aspects of the phenomenon that should be measured, and considering how they might be measured (Cobb and McClain, 2004, p.386).

The analytical process of this paper is that of an abductive approach (Alvesson & Sköldberg, 2009). The aim of this approach is to create an initial analytical lens to view the data through, and then allow for the emerging design principles to influence the initial theorization. The specific analytical tool is retrospective analysis by the use of constant comparisons (Gravemeijer & Cobb, 2013). Instances of data are compared to find similarities and differences related to authority and responsibility in the data.

The data set used in this analysis are transcripts of video recorded lessons in a pilot study. The purpose of the study was to document our starting point (Cobb & Gravemeijer, 2003) prior to an initial cycle of a design experiment (Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003). The design experiment utilizes the idea of engaging students in actual data generation and asking them to reason about the results. Our aim is that the task would trigger students to develop authority and responsibility due to
their active involvement in the
data generation. The empirical
study was performed with a
class of 20 students in grade 7
(aged 12/13) in Sweden using
an experiment based task
focusing on statistics. The
“helicopter task” (figure 1) is a
modified version of a task that
originates from Ainley, Pratt
and Nardi (2001). It involves
constructing an auto-rotating
helicopter out of paper and
measuring five flight times per
rotor length. The class dealt
with the helicopter problem in
two lessons. In the first lesson,
the students were involved in the data generation by e.g. testing paper-helicopters of varying rotor
lengths (3cm to 14cm) and measuring flight times. In the second lesson, the class interpreted and
evaluated the data in groups, guided by questions provided by the teacher. This was followed by a
whole class discussion. The transcripts used here are meant to illustrate the ideas developed in the
paper and are chosen because they portray typical student reasoning elicited by the task while using
a relatively small amount of space in the paper. The reader is then invited to evaluate the plausibility
of our interpretations and thereby assess the trustworthiness of our claims as an alternative to
reliability and validity more suitable for this type of research (Lincoln & Guba, 1985)

**Results**

The transcript elaborated on below is used to shed light on aspects of how responsibility and authority, embedded in the task, elicit reasoning with uncertainty. It is part of a whole class discussion in the second lesson where one of the groups presents their findings. The questions from the helicopter task in focus here are: *Which is the best rotor length? How sure are you?* (…) means that portions are inaudible and [...] means that we omitted a segment because of space limitation that we feel does not add to the reader’s understanding of our analysis. Table 1 contains the students’ results.

[1] Teacher: Before we move on, may I ask how you noticed that it was a failure with the rotors
[2] Gabriel: Because sometimes were like three, and then some were only 1 second

---

[1] Teacher: Before we move on, may I ask how you noticed that it was a failure with the rotors
[2] Gabriel: Because sometimes were like three, and then some were only 1 second
James: We aren’t so sure because the experiment is done in a small scale therefore we don’t have enough data on the functioning of the helicopter, which makes it hard to know which length is the best.

Eric: it also depends on the angle of the rotors (…), it depends on the height differences.

Eric: (…) some might be 4 seconds and others might be 1.48.

Jennie: It also depends on how you drop the rotors, wait, this? (…) You could’ve calculated it with the median which we should have done.

Maria: But we remembered that afterwards.

Jennie: But we did it with the mean which made it take longer time.

Teacher: why should you have measured the mean then?

Jennie: Because the differences were so big, and the times (…)

Teacher: would the results have been better if you used the median?

James: Yes

Teacher: Why do you think so?

Jennie: Because the differences were so big and the times

Teacher: okay, why did it become such big differences? Was it the failure or?

Maria: Because maybe you drop it from the exact same spot, maybe you drop it further down one time and another time further up.

Responsibility in justifying uncertainty

If we compare instances [2], [4], [6] and [16] there are similarities and differences. All four instances are parts of GoGAR about the level of uncertainty. There are differences as well, for instance how their claims are accepted in the GoGAR and how they situate the responsibility for their claims. In [2], Gabriel reasons that the failure of the rotors becomes apparent in his data, but the reasoning is underdeveloped and no one else acknowledges his authority in the following discussion. In the following lines, not included because of space limitation, instead focus is put on the definition of margin used earlier. Eric’s reasoning in [4] on the other hand situates responsibility explicitly in the activity of data generation. He draws on the experience of having been a part of the data generation and claims that both the angle of the wings and the drop height could be sources of uncertainty. Jennie acknowledges Eric’s authority on line [6] by referring to the action of releasing the helicopter. We call this Responsibility in justifying uncertainty. Both students and teacher recognize that there is a measure of uncertainty in the results and use various informal concepts to indicate it, for example “hard to know” on line [3] and “differences are so big” on line [10]. Both Eric’s and Jennie’s giving and asking for reasons for the level of uncertainty situate responsibility in the act of data generation. Maria acknowledges that Eric’s and Jennie’s claims still have authority in the GoGAR on line [16] by relating the mathematical discussion of mean, median and uncertainty to the act of data generation.

Exercising authority by making claims

From our analysis, it appears that students in this study exercise their authority through two types of claims: terminology related claims and context related claims. While the terminology claims are related to students’ previous formal knowledge, context related claims are from observations through perception. Terminology related claim: We noted that all the students in the group were given the opportunity to express themselves. As whole, the group took the chance and made a considerable number of claims in a limited time period. As mentioned earlier, making claims is one way of
exercising authority. In [2], Gabriel answers to the teacher’s question in [1]. A close look at Gabriel’s utterance, indicates that Gabriel’s authority is grounded in comparing one second to three seconds. In other words, formal logic is what lies behind his authority. In [5], Eric acknowledges Gabriel’s claim [2] and undertakes it. We, therefore conclude that “Gabriel lends his authority to Eric”. The same line of reasoning is observed in [10] and confirmed in [14]. Other students in their reasoning about uncertainty in GoGAR can use these claims. In [7] and [10], concepts such as mean and median are brought to the discussion. The students’ involvement in data generation creates conditions in which students can make use of their previous formal knowledge. In this case the consequence of their actions in generating data, and the uncertainty that follows activates the use of mean and median while talking about uncertainty. Context related claims: it is evident that Eric’s claim in [4], “it depends on high difference”, is also accepted by the class. Hence [4] is based on observations during the data generation. One argument that supports our interpretation is that (here and otherwise in the data) the whole class has reported that it was almost impossible to drop the helicopter from the same height. Eric’s claim is licensed by a context. The same observation is made by Jennie in [6]. Further, Eric points out that the angle of the rotor is reason for variation and uncertainty. This observation was specific to Eric’s group. However, we believe the rest of the group will use it as a premise in their reasoning with uncertainty if needed. The context created by the data generation enables students to make claims that can be used in reasoning with uncertainty.

Discussion

We organize the discussion around three questions connected to the design that seem to trigger authority and responsibility.

Which different opportunities in the task are given by the students to accept responsibility for their claims? The students reason naturally with uncertainty since they have the practical experience of manually generating data in the task to situate their responsibility. In contrast, Pratt (1998) found that many students in his study based on the chance-maker microworld software had to convince themselves that the gadgets in the game were indeed random and that the mode of reasoning should be with uncertainty rather than a deterministic reasoning. As long as the students had the opportunity to influence, for example, the strength of a simulated dice throw, they were more prone to accept that it was random. One explanation could be that the students working with the chance-maker had to situate responsibility inside a black box, being the software, which led them to believe that the results were predetermined. Our analysis in [2] and [4] show how the task provides opportunity for the students to situate the responsibility of the failure in the measurement. The cause-effect opportunities created by the task initiate fruitful GoGARs in the domain of uncertainty, which also seems to fit with Pratt’s (1998) findings.

Which different opportunities in the task give the students the ability to create authority for their claims? From Roth’s (1996) study, we know that students show difficulties in analyzing data when they have not been actively involved in the data generation. This view is supported by Noss, Pozzi & Hoyles (1999). Our analysis showed in [2] [3] and [4] that the task enabled the students to act as experts. The students were able to connect data analysis and inferences to data generation while reasoning with uncertainty. The experiment based instruction, which entails manual data generation, opens up for students to take control over the process. Leaving the data generation process to students, triggers their authority and responsibility and, students are more motivated than if they would just be
limited to data collection and get “the right data” (Cobb & McClain, 2004). Getting students to reflect on how their own actions influence the results is the first step in acting with authority and responsibility.

**Which different opportunities in the task are given to the students to shift responsibility and authority between different domains?** Designing tasks with manual data generation based on principles of authority and responsibility is not the general solution to improve statistics education. In fact, creating large data sets, suggested by Pratt (1998) as being a cornerstone in statistics instruction, becomes almost impossible with this focus on manual data generation during lessons. We merely suggest that there are merits to these design principles in statistics education as it naturally elicits GoGARs in the domain of uncertainty and empowers students to take responsibility and use mathematics to back up their claims. In [6] and [8] our analysis in [6] and [8] show how the task provides opportunity for the students’ quest of authority as they shift responsibility between the empirical and theoretical domain.

We show that designing tasks with manual data generation elicit fruitful situations for shifting authority and responsibility between context and concept levels. Thus the students used their previous concepts to act upon the context, and also looked for evidence in the context to strengthen their authority and responsibility. In sum, creating a learning environment where students can exercise authority by using their previous formal knowledge and most importantly “our imperfect perception” can promote a fruitful GoGAR in the area of uncertainty, and in mathematics in general.

Promoting prospective elementary teachers’ knowledge about the role of assumptions in mathematical activity

Andreas J. Stylianides¹ and Gabriel J. Stylianides²

²University of Oxford, Department of Education, UK; gabriel.stylianides@education.ox.ac.uk

Although the notion of assumptions is important in the discipline of mathematics and permeates (often tacitly) mathematical activity in school classrooms, instruction in the elementary school pays little attention to it. This situation is unlikely to change unless elementary teachers have a good understanding of the role of assumptions in mathematical activity and an appreciation of the pedagogical implications of that role. In this paper, we investigate how teacher education can promote this dual goal by illustrating a promising, task-based approach to supporting prospective elementary teachers to develop pedagogically functional mathematical knowledge about the role of assumptions in mathematical activity. We developed the approach in a 4-year design experiment we conducted in a mathematics course for prospective elementary teachers in the United States.

Keywords: Assumptions, elementary grades, prospective teachers, task design, teacher knowledge.

Introduction

Assumptions denote the statements doers of mathematics use or accept (often implicitly) and on which their claims are based (Fawcett, 1938) and, thus, assumptions are fundamental to any mathematical activity at all levels. In school mathematics, however, assumptions often receive little explicit attention, especially at the elementary school level. The notion of assumptions has received also relatively little explicit attention in the mathematics education literature.

A small number of studies addressed the role of assumptions in the particular area of proving at the secondary school (Fawcett, 1938; Jahnke & Wambach, 2013) and elementary school (Stylianides, 2016) levels. However, there is a scarcity of relevant research at the teacher education level. This is problematic: unless teachers are supported to develop a good understanding of the role of assumptions in mathematical activity and an appreciation of its pedagogical implications, it is unlikely that teachers will offer to their students productive learning opportunities in the area of assumptions.

In this paper, we investigate how teacher education can promote prospective elementary teachers’ knowledge about the role of assumptions in mathematical activity. We focus on the design and implementation of tasks that can support Mathematical Knowledge for Teaching (MKfT).

Research background

The notion of MKfT (Ball et al., 2008) denotes the kind of “pedagogically functional mathematical knowledge” (Ball & Bass, 2000, p. 95) that teachers need to have to be able to manage the mathematical demands of their practice. It has been noted that “there is a specificity to the mathematics that teachers need to know and know how to use” (Adler & Davis, 2006, p. 271) and that teacher education should aim to create learning opportunities for prospective teachers (PTs) that would enable them “not only to know, but to learn to use what they know in the varied contexts of
[their] practice (Ball & Bass, 2000, p. 95). Thus mathematics courses for PTs cannot lose sight of the domain of application of the targeted knowledge (i.e., the domain of mathematics teaching).

We consider next what might be essential elements of MKfT about the role of assumptions in mathematical activity. We begin by describing two elements we identified based on consideration of the role of assumptions in the discipline of mathematics (e.g., Fawcett, 1938; Kitcher, 1984) and mathematical analysis of classroom practice where the notion of assumptions received explicit instructional treatment (Fawcett, 1938; Jahnke & Wambach, 2013; Stylianides, 2016).

- **Element 1:** Understanding that a conclusion is dependent on the assumptions on which the argument that led to it was based.
- **Element 2:** Understanding that different legitimate assumptions can lead to different conclusions that, although on the surface may appear to be contradictory to each other, may nevertheless both be valid within the set of their underpinning assumptions.

These interrelated elements are central to mathematical work. The different sets of axioms in Euclidean and non-Euclidean geometries, including associated results, offer an illustration of both of these elements in the discipline of mathematics or in the upper secondary school (Fawcett, 1938).

Similar ideas are central also to the elementary school (Stylianides, 2016) and are consistent with recommendations in curriculum frameworks (e.g., NGA & CCSSO, 2010, p. 6). Furthermore, the two elements are essential for mathematical knowledge that is also pedagogically functional. For example, they can allow a teacher to recognize that, when two students offer inconsistent answers to a task, this does not necessarily mean that one of them is wrong; both students may have applied sound reasoning based on different assumptions about the conditions of the task. We capture this kind of pedagogical functionality of elements 1 and 2 under a third element of MKfT:

- **Element 3:** Ability to recognize possible ways in which elements 1 and 2 might apply in mathematics teaching.

Regarding how to promote PTs’ MKfT, in Stylianides and Stylianides (2014) we discussed and illustrated a special kind of mathematics tasks that we called pedagogy-related mathematics tasks. These tasks have two major features: (1) A mathematical focus, which relates to mathematical ideas that are important for teachers to know; and (2) A substantial pedagogical context, which is an integral part of the task and essential for its solution. Notwithstanding the importance of pedagogy-related mathematics tasks, there is also a need for the use of other kinds of tasks in mathematics courses for teachers. In this paper, we focus on a task sequence that illustrates another approach we followed to promote MKfT. Unlike pedagogy-related mathematics tasks where mathematics and pedagogy are intertwined in the same task, this task sequence illustrates an approach to promoting MKfT in which (1) initial work on a non-contextualized mathematics task can create a productive space for pedagogical reflection and (2) follow-up instruction can foster the intertwinement between mathematics and pedagogy. We elaborate on the task sequence in the Method section.

To conclude, in this paper we address the following research question: What task sequence can offer a productive learning environment for prospective elementary teachers to develop the three elements of MKfT that we described earlier about the role of assumptions in mathematical activity?
Method

Research context

This research derived from the last cycle of a 4-year design experiment (e.g., Cobb et al., 2003) in a semester-long mathematics course (3hrs per week) for prospective elementary teachers in the United States. The design experiment comprised five research cycles of implementation, analysis, and refinement of task sequences and associated implementation plans that aimed to promote PTs’ MKfT. The students were undergraduates who majored in different fields and were taking the course as a prerequisite for admission to the master’s level elementary teacher education program. The task sequence we focus on was implemented toward the end of the semester and was the only one that explicitly targeted PTs’ MKfT about the role of assumptions in mathematical activity. We introduced the task sequence in cycle 4 because we felt an explicit intervention was needed to adequately promote PTs’ MKfT of elements 1–3. Analysis of how the task sequence played out in cycle 4, alongside our developing understanding of how things “worked,” led to modifications of the task sequence, culminating in the form described below which took place in cycle 5.

Figure 1: The “Floors Problem” (derived from Ball, 1993) in part A of the task sequence

The task sequence

The task sequence comprised three parts. In part A we used the “Floors Problem” (Ball, 1993) in Figure 1. Two task features made it suitable for our goals to promote elements 1 and 2 of MKfT. First, the task conditions were ambiguous and thus subject to different legitimate assumptions; a major ambiguity concerned whether or not the person in the task had to travel directly to the second floor. Second, different assumptions about the task conditions could support different arguments for answers to the task that might appear to be contradictory but might actually be correct given their underpinning assumptions. In addition to promoting elements 1 and 2 of MKfT, we hypothesized
that PTs’ mathematical experience with the task in part A could offer a productive context for pedagogical reflection (cf. element 3). We capitalized on this potential of the task in parts B and C.

In part B we used two conceptual awareness pillars (or simply pillars; Stylianides & Stylianides, 2009) to which the PTs responded individually and in writing. (There was a third pillar whose discussion we omit due to space limitations and a lack of direct relevance to our focus.) The pillars are presented in the first column of Table 1 (see next section). With them we aimed to amplify PTs’ mathematical learning (see pillar 1 in relation to elements 1 and 2 of MKfT) and its intertwinement with pedagogical reflection (see pillar 2 in relation to element 3). As per the definition of pillars (Stylianides & Stylianides, 2009), the non-directive prompts in them could increase PTs’ awareness of key realizations they might have developed (possibly in tacit form) during their work on the task.

Finally, in part C we engaged PTs in small-group and whole-class discussion around the three prompts in Figure 2 that aimed to further support PTs’ reflective insights from part B and help them consider the applicability of those insights beyond the particular task. The prompts raised issues relating to elements 1–3 of MKfT. For example, in prompt 1 the first question related to elements 1 and 2, while the second question related to element 3. Each small group was asked to collectively produce a written response to each prompt prior to a whole-class discussion. Due to space constraints we report only findings from our analysis of the small groups’ written responses.

| 1. “Conclusions are ‘true’ only within the limits of the assumptions on which they are based.” How do you understand this statement? Do you think it is important for elementary school students to develop a sense of the role of assumptions in mathematics? Explain. |
| 2. “Teachers should always make sure that the mathematical tasks they give to their students have unambiguous conditions.” What do you think about this statement? Explain. |
| 3. There may be situations where teachers do not realize that a mathematical task they give to their students has ambiguous conditions. What might happen in these situations and how might teachers handle the situations? |

Figure 2: Discussion prompts used in part C of the task sequence

Data and analysis

The task sequence in research cycle 5 was implemented in two parallel (independent) classes of the course that were both taught by the second author. At this stage of our analysis we are using data from only one of the classes: videos and transcripts of the implementation of the task sequence in this class with 16 PTs attending on that day; these PTs’ written work including their individual responses to part B and their group responses to part C; and field notes from a research assistant documenting the work of one small group. Our data analysis was guided by elements 1–3 of MKfT that we aimed to promote. Specifically, we conducted qualitative content analysis of the transcripts and field notes in part A to examine whether and how the PTs developed understandings relating to elements 1 and 2, and also of PTs’ responses to parts B and C to identify themes in their responses and examine whether and how these themes corresponded to elements 1–3 of MKfT.
Implementation of the task sequence and discussion

Part A: implementation of the Floors Problem

Stylianides showed the problem statement and the building model, and explained the notation for negative numbers. He also established a common notation with the class about representing trips. After that, he asked the PTs to work on the problem first individually and then in groups of four. He also said he would not answer any clarifying questions about the problem, an intentional aspect of our instructional design. The discussion in the small group where the research assistant was taking field notes is indicative of the way the PTs engaged with the problem (all names are pseudonyms):

Amanda: So… can you pass the second floor and then go back to it? Or do you have to stop, because you’ve technically gotten there? So… you just have to look at how to get directly there? If not, it’s going to be infinity!

Beth: That’s what I did… the direct. I just counted how many up and how many down…

Monica: But that doesn’t say that you have to come in the entrance… So you can start anywhere?

At this point Stylianides passed by the small group and Monica asked him whether the trips had to start from the ground floor. Stylianides reminded her that he would rather not respond to clarifying questions and he moved on to a different group. The small group discussion continued as follows:

Victor: So… the solution of this problem depends on our assumption.

Amanda: Well, fine then. I say 15… because I’m assuming that you start on the ground floor and can’t pass [floor] 2 and can’t change direction more than once.

Victor: I say 25 because… [He was interrupted by the start of the whole-class discussion.]

As illustrated by this exchange, the decision not to respond to clarifying questions allowed for the notion of assumptions to emerge naturally in the discussion: had the instructor specified an interpretation, the PTs would not have considered alternative interpretations. The whole class discussion started with the small groups explaining their answers to the problem: 25, infinity, 15, and 51. Sherrill explained the answer of 25 by noting how each floor could constitute a separate starting point for a direct trip to the second floor. Sophie then tried to explain infinity as an answer:

Sophie: Well, we picked infinity because […] if you’re saying you can go up and down and up and down as many times as you wanted before you reach the second floor, I think that the question isn’t specific enough. Like they [Sherrill’s group] assumed you can only go up or down one time. […]

Stylianides: So you say [referring to Sophie] if we don’t assume that [what Sherrill’s group assumed] and [we assume] you’re allowed to travel up and down as many times as you want, then the answer would be infinity? [To the class:] What do you think about that? Is one of them wrong? Are both of them right? […]

Lindsey: I think […] they just made different rules, and like, thought processes. […] You could have a direct route and that’s it, no going back and forth… like, you could, when you were talking about going up and down and up and down and that’s not
really a direct route… So really, you could do anything that you wanted to, but it just depends on what the person… what the problem is looking for, I guess.

Sherrill: It’s up to the interpretation of the reader... Like I read it and I just assumed that it had to be a direct route, but it clearly doesn’t state that… […]

Infinity as an answer was discussed again later, after the class had considered also 15 and 51 as possible answers. Overall, the whole-class discussion mirrored the previous small-group discussion. Sophie, Lindsey, and Sherrill’s comments show an increased understanding of elements 1 and 2: the PTs acknowledged that the task allowed for different legitimate interpretations of its conditions and that their conclusions depended on their assumptions (element 1), while realizing that the different answers they came up with were all correct based on their underpinning assumptions (element 2).

Part B: PTs’ responses to the pillars

Analysis of PTs’ responses to the two pillars gave rise to the themes summarized in Table 1. Each response could receive multiple codes. The frequencies are offered to show how prominent each theme was among PTs’ responses, not for generalizability. Regarding pillar 1, PTs’ responses under themes 1–4 related to both elements 1 and 2 of MKfT. The responses below illustrate all themes:

Sherrill: I was surprised at the multiple assumptions made. I had not even considered the fact that answers other than 25 existed because of the way people interpreted the problem. I now realize how greatly making assumptions can alter mathematics. (themes 2, 4)

Lorri: [A]ll of our groups had different interpretations of how many ways there were […] Some of the other groups’ answers […] I could understand their rationales as to why their answer was correct. Our answers were not wrong under this ambiguous problem. (themes 1, 3)

<table>
<thead>
<tr>
<th>Pillars</th>
<th>Themes and frequencies (in parentheses)</th>
</tr>
</thead>
</table>
| **Pillar 1:** Is there anything that particularly stood out to you from our work on the “Floors Problem”? | 1. Multiple legitimate interpretations (8)  
2. Multiple assumptions (5)  
3. Multiple correct answers (4)  
4. Importance of assumptions (4)  
5. Other (2) |
| **Pillar 2:** The “Floors Problem” was purposefully designed to be ambiguous. Why might a teacher use a problem like that in his/her classroom? | a. To encourage sensitivity to language (7)  
b. To increase awareness of the role of assumptions (6)  
c. To enhance appreciation of different possible interpretations of the same (ambiguous) text (6)  
d. To enhance appreciation of the interdependency between different assumptions/interpretations and different answers and solution paths (5)  
e. To encourage discussion, explanation, or proof (5)  
f. Other (3) |

Table 1: Summary of results from PTs’ responses to the pillars in part B of the task sequence (n=16)
Regarding pillar 2, PTs’ responses under themes a–e showed ability to recognize how their mathematical insights from the problem could apply in teaching. Thus the responses offered evidence related to element 3 of MKfT. We offer two responses that illustrate some of the themes:

Lorri: A teacher could use this ambiguous problem to get their students to understand that sometimes their answers are not wrong and that there may be other answers to a problem. Students will be able to explore their different ways of interpretation and must be open to others’ interpretations […] They will understand that there will be different […] answers that will depend on the information given in the problem, which may be ambiguous. (themes a, c, d)

Helen: To learn about assumptions and understand not only the importance of specifics […] but also the freedom for one to think along the terms of their own assumptions. (themes a, b, c)

**Part C: responses of small groups to the discussion prompts**

Overall the PTs’ responses to part C were pedagogically sound and were informed by the powerful impact the Floors Problem had on their mathematical learning. Also, one can see parallels between PTs’ responses in part C and the part B pillars; these were supported by our instructional design.

**Prompt 1:** An illustrative explanation of the first question in prompt 1 was: “You have to start with a base and then make assumptions from that. So your conclusion can only be based on those assumptions. Therefore your conclusion can be only true or false for those assumptions.” Regarding the second question in prompt 1, all groups noted the importance of helping students develop a sense of the role of assumptions in mathematics. The groups justified their response with reference to the following: the importance of assumptions in the discipline; knowledge of assumptions can help students understand that different legitimate interpretations of a problem can lead to different valid conclusions; and knowledge of assumptions can highlight the need for students to explain their thinking. These justifications relate to element 3 and are underpinned by the understanding of elements 1 and 2 that was evidenced in PTs’ responses to the first question in prompt 1.

**Prompt 2:** All groups disagreed with the statement and highlighted, in a similar manner, that the phrasing of a task should align with the teacher’s goals. Here is an illustrative response: “If a teacher is giving a math test, or graded evaluation where they are looking for a specific answer then yes, the tasks should be unambiguous. However, if the teacher is trying to prove a point about assumptions or different approaches to the same problem, an ambiguous task may be beneficial.”

**Prompt 3:** Two major points emerged from the responses to prompt 3. The first point related to teachers being able to recognize that some students’ approaches to a task that appear as “faulty” may be in fact mathematically sound based on unforeseen (to the teacher) legitimate assumptions. The second point related to teachers asking students to explain their thinking to see whether the students indeed operated on different assumptions rather than just focus on the final answer. Again, these justifications relate to element 3 but are also based on understanding of elements 1 and 2.

**Conclusion**

In this paper we investigated how teacher education can promote prospective elementary teachers’ knowledge about the role of assumptions in mathematical activity, with attention to the design and implementation of a task sequence that aimed to support three elements of MKfT. We illustrated a task-based approach to promoting MKfT whereby a mathematics task, although not embedded in a
pedagogical context, can nevertheless create a productive space for pedagogical reflection through
the creation of a powerful mathematical experience for PTs. Analysis of data from the fifth research
cycle of a design experiment in a mathematics course for PTs provided evidence for the promise of
this approach and highlighted the important role of the teacher educator in implementing deliberate
(pre-planned) instructional moves to help amplify PTs’ mathematical learning and enhance the
pedagogical functionality of their acquired knowledge. Future research can investigate whether and
how the rich insights (both mathematical and pedagogical) that PTs may develop through the task
sequence about the role of assumptions in mathematical activity can inform their practice.

Introduction and methodology

Asymptotes and asymptotic behaviour play an important role in many traditional and modern mathematical disciplines and are supported by a rich and well-established abstract theory. Some basic aspects of these concepts can be utilized already in elementary mathematics as powerful tools in graphing and analyzing behaviour of elementary functions at infinity and near singularities and in graphing simple plane curves such as hyperbola. Therefore, this body of knowledge is a common part of upper secondary mathematics curricula worldwide. Here, we investigate its didactical transposition to the Croatian general upper secondary education. The survey is conducted within the theoretical framework of the Anthropological theory of the didactics (ATD), developed by Y. Chevallard (Chevallard, 1981, 2007). The main idea of the ATD is to determine a relation \( R(p,O) \) between a body of knowledge \( O \) and a person that occupies a position \( p \) in an institution \( I \). Accordingly, mathematical knowledge and activities are described in terms of a praxeology \([T, \tau, \theta, \Theta]\), where its practical component, praxis, is represented with a task \( T \) and a technique \( \tau \) and its discursive or theoretical component, logos, with a theory \( \Theta \) and a technology \( \theta \). Research within the ATD should include relevant data about the relation \( R(p,O) \) for all institutions \( I \) involved in the educational process i.e. the process of didactic transposition (Bosch, Chevallard & Gascón, 2005). Questioning and understanding conditions and constraints on the relation \( R(p,O) \) is necessary for setting up attainable, justified and significant educational interventions (Barbé, Bosch, Espinoza, & Gascón, 2005). Hence, as relevant for our setting, we analyzed and compared the relations \( R_B(p,O) \) and \( R_S(p,O) \), where \( O \) is a graphical representation of an elementary function and a hyperbola in a square coordinate system, together with corresponding techniques regarding asymptotes, while institutions considered are two actual Croatian mathematical gymnasium textbooks \( B \) and the cohort of 40 the final, fifth year mathematics education students \( S \) at the largest mathematical department in Croatia.

This is a part of a more comprehensive study regarding asymptotes and asymptotic behaviour in the Croatian pre-university education which also included the institution of academic mathematicians. The methodology included a praxeological analysis of the textbooks as representatives of the knowledge to be taught and three questionnaires with open-ended questions for the prospective mathematics teachers to provide an insight in related knowledge available to students as a potential taught knowledge. Based on this, a reference epistemological model (REM) is proposed and then verified and improved with scholarly knowledge gained from semi-structured interviews with two
academics. Here, we focus on textbook topics, tasks, techniques and discourses related to $O$ and on three particular tasks from the questionnaires administered: graphing and describing a simple rational function and a shifted exponential function from a real world problem, given by formulas, and graphing a hyperbola and its asymptotes.

Results and conclusions

The results of the textbook analysis show that graphing a function $f$ pointwise, that is, by plotting some corresponding points $(x, f(x))$ and connecting them by a smooth curve dominates all other available techniques for graphing functions given by formulae. A technique of graphing a function or a curve regarding its properties recognized from a corresponding algebraic expression (formula or equation) occurs only in relation to the tangent and cotangent function and to a hyperbola, while the tasks on graphing polynomials and rational functions appear only as common practical activities of utilizing derivatives (calculus). Finally, a technique of transforming a prototype graph of an elementary function to get a graph of its composition with a linear function (by translations and dilations) is rarely implemented. Although textbook praxeologies of graphing functions often elaborate function properties and flow, discursive accents are set on establishing a function’s domain, monotonicity and symmetry of its graph, neglecting its asymptotic behaviour. Asymptotes are seen relevant only for tangent and cotangent functions. Results of the questionnaire analysis completely reflect those of the textbooks. The students applied techniques and provided discourse to the same extent as it is given in the praxeological organization of the textbooks. Namely, their dominant techniques are drawing curves through their points and drawing graphs regarding function properties determined by using calculus, their chosen techniques are not the most efficient for the task in question, and asymptotic behaviour is available to them but not fully utilized in praxeologies relevant to graphing functions or curves. Considering this, it is our suggestion for the teaching practice and for an ongoing curricular reform in Croatia that: all relevant function properties should be emphasized when describing its behaviour; common properties of a function should be more related to its algebraic representation and utilized for its graphing; functions should be graphed by graph transformations, whenever fitted; and asymptotic behaviour should be more emphasized, adequately graphically represented and described by formal and informal mathematical discourse.

Using variation theory to explore the reteaching phase of Lesson Study

Thérèse Dooley and Tugba Aysel
Institute of Education, Dublin City University; therese.dooley@dcu.ie

Keywords: Variation theory, Lesson Study, task design, fractions.

Japanese Lesson Study is now internationally accepted as a powerful form of professional development, particularly in the field of mathematics. It involves a cycle in which teachers collaborate to plan, observe, analyze and refine actual classroom lessons (Lewis, Perry and Murata, 2006). Frequently the lesson is retaught, although rarely by the same teacher to the same students (Fernandez and Yoshida, 2004). Reteaching of a lesson allows teachers to see how small variations in, say, the presentation of a task can deepen learners’ understanding of mathematical concepts. This suggests that variation theory might be a useful lens for exploration of this phase of the Lesson Study cycle. From this theoretical perspective, learning is defined as “a change in the way something is seen, experienced or understood” (Runesson, 2005, p.70). Thus small changes in the design of a task can result in changes in what it is that students discern or notice. Watson and Mason (2006) refer to dimensions of possible variation (what is possible to vary) and a range of permissible change (perceived constraints on the extent and nature of change in any of the dimensions of variation): “Teachers can … aim to constrain the number and nature of the differences they present to learners and thus increase the likelihood that attention will be focused on mathematically crucial variables.” (p.102)

In this paper we report on a research project in which one primary and three post-primary teachers participated in Lesson Study in order to examine transition issues in mathematics. In particular, there is reference to the mathematical written work of two different groups of students who engaged with a similar task. The teachers had identified the topic of fractions as one that poses both teaching and learning challenges at primary and post-primary levels. They developed a research lesson and taught it first to a junior post-primary class (students aged 12-13 years) and later to senior primary class (students aged 11-12 years). The goals for both lessons were the same and centred around students’

1. development of confidence in comparison of fractions;
2. utilization of their own approaches to solve the problem;
3. discussion of their own ideas and opinions with each other; and
4. motivation to engage in further such mathematical tasks.

The particular task they chose (sourced from nrich.maths.org) concerns the identification of the greatest amount of chocolate in a room where there are three bars on one table, two on another and one on the last table. It is assumed that an unknown number of people will enter a room in turn and that each will decide which might be the best table at which to sit ‘at that moment’. Thus the first person should choose the table at which there are three bars. The comparison faced by the seventh person is mathematically more complex than that encountered by the first six people as, up to this point, comparison is between whole numbers and fractional amounts less than 1. For example, a choice that might have to be made by Person 6 is ½ or ⅓ or 1 bar of chocolate. However assuming
that Person 6 opts for the table at which there is one bar, the choice for Person 7 is $\frac{1}{2}$ or $\frac{2}{3}$ or $\frac{3}{4}$. While much planning time was spent anticipating such complexities and how pupils might deal with them, the teachers did not foresee that poor organisation of work by students would impinge on their solution processes. A change introduced in the second iteration of this lesson was that students would be encouraged to present their solutions in tabular form, and, in fact, on inspection of their written artifacts, most did so. However, while the use of this table facilitated fraction comparison (Goal 1), it did not encourage the exploration of various approaches (Goal 2) to the same extent. It appeared that this small variation in the task had considerable impact on students’ focus of attention.

Conclusions

A broader range of permissable change appears to have been conveyed in the post-primary than in the primary class due to the introduction of the tabular format in the second lesson. However, students perceived a narrower dimension of variation than was suggested by either teacher, evident in the frequency of use of decimals for recording in the post-primary class and use of fractions/tabular format for recording in the primary class. This may have been influenced by the teacher’s representation of the task on the whiteboard in each lesson and might be explained by its endurance (and thus propensity to be noticed) over the course of each lesson. Such representations seem to have a considerable impact on the (enacted) object of learning and deserve focused attention in the design and analysis of mathematical tasks. More generally, while other theories have explanatory power in the consideration of the different outcomes of two similar lessons, variation theory has a significant role to play.

Changes in the images and arguing from the mathematics textbooks for the secondary school in Argentina along 67 years

Viviana Carolina Llanos and María Rita Otero

Universidad Nacional del Centro de la Provincia de Buenos Aires (UNICEN). Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Argentina; vcllanos@exa.unicen.edu.ar rotero@exa.unicen.edu.ar

This work analyses the changes in the relationship between arguing and images from the mathematics textbooks for the secondary school in Argentina along 67 years. The textbooks have been published in the period 1940 thru 2007. The analysis is done by (N=137) textbooks based on three meta-categories in an inductive way. A factorial analysis of multiple correspondences was performed to find the main similarities and differences between the textbooks and to make a cluster analysis and one possible classification.

Keywords: Textbooks, mathematics education, secondary school.

Introduction and conception of arguing

In 1994 an educational reform was performed in Argentina. The syllabus was changed and the scholar textbooks were adapted to the new educational system. The main modifications were realized in the properties of the images more than in the content. The characteristics of the text books, the ideas about argumentation and the characteristics of the images in the books are analysed. This research adopts an idea of arguing that emphasizes the relevance of the divergences between different points of view and the epistemological function of arguing, proposed by Leitão (2007). Different from other theories as Schwarz, Hershkowitz & Prusak (2010), Driver, Newton & Osborne (2000); Leitão proposes that arguing has to be analysed based on three elements: “argument, argument against and response” in order to generate confrontation between argument and argument against, to achieve construction of knowledge and transformation of perspectives in the subject (response). These processes occur into face to face situations, or in negotiations of the different points of view with ourselves, in this case, when we are reading a textbook.

Methodology, categories of analysis and some results

A set of (N=137) mathematics textbooks is selected by means of purposive sampling techniques. The analysis was performed starting from a previous qualitative inductive categorization based on three meta-categories:

A- Characteristics of arguing. A1- Commencement of arguing: Questions or situation, which will be answered later; Definition, using to introduce knowledge; and Examples to formulate knowledge. A2- Type of arguing: Deductive formal, used deductive mathematics argument (definition, theorem, hypothesis, theory, demonstration, etc.); Deductive informal, they do not reach the formalism of the demonstrations; and Inductive that generalize knowledge from a single case. A3- Degree of arguing, cognitive conflict promoted by the text is analysed in three levels: High, books that generate explicitly confrontations, without solution in the text; Low, textbooks generate explicitly a cognitive conflict, solved later; and Absent, textbooks that inform without questioning.
B- Relationship between the images and arguing (Otero, Moreira and Greca, 2002): **B1-** Use of the image: Ornamental, images used with a decorative aim, not related to the content; and Argument, used as source of information, knowledge can be derivative. **B2-** Type of image: Mathematical representations, use mathematical systems of representation; and Non-mathematical representations, images not related with mathematical content. **B3-** Grammatical style of the images: Conceptual, represent relations and fixed characteristics between the represented elements; and Narrative, identify actions between objects that can represent a relation between them in the image. **B4-** Relationship with the “real world”: Naturalist, images referring to the empirical world, detailed and complex; and Abstract, not referring to the world that we experience.

C- Characteristics of the textbooks: **C1-** Date of publishing: Period 1, 1940 thru 1973, Period 2 1974 thru 1994 and Period 3, after the reform, until the year 2007. **C2-** Educational level: refers to the educational level the textbooks. Level 1, students between 12 and 14 years old; Level 2, students between 15 to 17 years old; and Level 3, older than 18 years old. **C3-** Mathematical traditions (Klimovsky & Boido, 2005): Computational, emphasis in the resolution of problems and calculation with numbers; Axiomatic, present the mathematics demonstrations steps; and Structuralist: books that search of regularities that meet the same conditions.

Using this categorization, a qualitative description is made, which originated a first analysis. Then, the categorization is transformed in a group of nominal variables and modalities using Exploratory Data Analysis (Lebart, Morineau, 2000). A Factorial Analysis of Multiple Correspondences allowed the selection of one possible classification in three classes. In addition, a test of randomness to analyse the reliability of the sample was performed using the statistical software SPAD.

The analysis explains changes in the images and arguing, given by: books that propose questions, or only definitions and examples, by the way to conceive and validate to mathematical knowledge, and mainly by the changes in the images and the relation between images and knowledge. The goal of most books seems to be informative. This explains the absence of questioning and discussing about several points of view, and the low level of arguing and conflict found within them.

Teacher’s pedagogical design capacity and mobilization of textbook

Ljerka Jukić Matić

Department of Mathematics, University of Osijek, ljukic@mathos.hr

Keywords: Textbook mobilization, pedagogical design capacity, mathematics teacher.

To investigate, understand and explain the relationship between teachers and curriculum resources, in our context a textbook, Remillard (2009) derived a model of the teacher-curriculum relationship, from earlier Brown’s (2009) Design for Capacity Enactment Framework. The center of the model represents the participatory teacher–curriculum relationship designating what the teacher and the curriculum bring to the teacher-curriculum interactions. In this model, teacher resources include concepts of pedagogical design capacity, human and social capital, and agency and status. Curriculum resources include several components: mathematical topics and tasks that are structured in deliberate ways, embedded supports for the teacher to guide pedagogical decision-making and presence of a pedagogical orientation or emphasis embedded in instructional strategies and lesson structures. In domain of teacher resources, an interesting and important characteristic is the pedagogical design capacity (PDC). PDC describes the capacity of teachers to perceive and mobilize existing resources to create productive instructional episodes (Brown 2009), which to some extent, depends on the used resource and on the ways of working with that resource (Gueudet, Pepin & Trouche, 2013).

In this study, we wanted to examine the relationship between the mathematics teacher and the textbook in the classroom. Therefore, we formed the following research questions: What characterizes the nature of the teacher–textbook relationship and why? What is the level of the teacher’s pedagogical design capacity?

Remillard (2009) suggested that individual PDC can be measured by examining dimensions of human and social capital, therefore in this study, two measures are used to examine the teacher’s level of PDC; the one proposed by Remillard (2009) and the one the one described by Leshota (2015). Leshota (2015) proposed that one possible way for measuring teacher's PDC is examining whether teachers make injections of mathematical content into the lesson, omissions of mathematical content from the textbook and mathematical errors. Using those criteria one could determine whether teacher has low or high PDC.

We observed four lessons in Mrs. D’s classroom and conducted an interview with the teacher. In terms of textbook content, Mrs. D offloaded, adapted and improvised in the lessons, but not to the same extent in every lesson. Those types of textbook mobilization were dynamically interchanging within a lesson. Mrs D. made several injections of content that are not in the curricular outlines or in the textbook for this grade level. She had no critical omissions in the lessons.

It seems that the teacher regards the textbook as a vital resource for the students’ learning, but not crucial for her teaching. The established relationship between the teacher and the textbook could be regarded as a two way process in which both participants communicate. The outcome of that process is a product that fits the students’ needs and the teacher’s goals. The teacher positioned herself as having instructional authority in the classroom, regardless of what her colleagues in the school do or think. Recognizing the textbook’s affordances and constraints allowed her to place
herself as an authority over the textbook. Mrs D. showed a high level of PDC in her teaching. She omitted content from the textbook, like activities or worked examples which were not crucial for learning mathematics. She injected content that is not usually introduced until the following grade because it was applicable to the topic being taught.

From our perspective, the term PDC seems to be more efficient when examining teaching expertise than Shulman's pedagogical content knowledge (PCK). In a way, PDC has more dynamic nature than PCK. Therefore, from the perspective of the textbook utilization, teachers’ development of PDC is an important and critical part of their interactions with the textbook. Our study showed that interplay between curricular knowledge, professional development, mathematical knowledge, knowledge of the textbook’s characteristics are important aspects in ability to craft pedagogical beneficial lessons. More studies on teachers’ PDC would be beneficial for new and inexperienced teachers.

How to design educational material for inclusive classes

Anna Noll, Jürgen Roth and Markus Scholz
University of Koblenz-Landau, Germany; noll@uni-landau.de

Keywords: Inclusion, symbols, easy-to-read, fractions.

Inclusion is based on international legitimate developments like the Salamanca statement, which emphasizes the right of education for all (UNESCO, 1994). Furthermore, several studies showed that coeducation can have a positive effect on the development of performance of pupils with and without special educational needs (Markussen, 2004). But to include all students regardless of their physical, intellectual, social or other abilities the educational framework conditions need to be adopted at first.

One important step into this direction consists in providing all pupils access to the assignments by enhancing their readability.

Theoretical background

Readability can be enhanced by linguistic simplifications like the application of the easy-to-read guidelines (Netzwerk Leichte Sprache, 2006). Easy-to-read language has been established to facilitate understanding in everyday life for people with disabilities. It is, for example, used for the simplification of manifestos in order to support participation in society. So far, these guidelines are not verified scientifically, but show several similarities to empirically based linguistic simplification rules, like the Hamburger Modell (Langer, Schulz von Thun, & Tausch, 2011). The authors state, among others, that only one statement should be made per sentence. Another possibility to facilitate the comprehension of assignments is the use of symbols. A symbol can be defined as a graphical image conveying a single idea or concept (Detheridge & Detheridge, 2002). Little empirical data about the use of symbols to foster the readability of texts exists (Jones, Long & Finley, 2007; Poncelas & Murphy, 2007). Nevertheless, a positive influence can be assumed, e.g. because of the multimedia principle (Mayer, 2009). It indicates that people learn better from words and pictures than from words alone. An explanation is given by the cognitive theory of multimedia learning (ibid.) which assumes that pictorial and verbal information are processed in two different channels in our brain. When words and pictures are presented, both channels are used and the cognitive load on the limited capacity of the working memory is reduced.

Methodology

Does the use of easy-to-read language and/or enriching text with symbols facilitate students’ performance in mathematical tasks? This research question shall be answered with the following methodology. The tasks of this study deal with introducing fractions. These are taught in activity-oriented manner with hands-on material. The tasks are divided into two complexes. The first complex aims at the conduction of more basic actions like counting. Then, the pupils receive an input about fractions by watching a video. The pupils use the information of the video for more complex mathematical considerations which are necessary in the second task complex. Thus, the pupils’ conceptualization of fractions is fostered, e.g. by the naming and comparison of fractions. In November and December 2016, a pre-study was conducted with 30 students in grade 5, 6 and 7. The sample consisted of pupils with learning difficulties and students without special educational needs. The students worked on the tasks individually and participated in a subsequent interview. Data was
also collected by use of eye tracking and thinking aloud. A first result of the pre-study is that the symbols are used by the students without explanation. This result can be exemplified by the following excerpt of the interview and the corresponding eye-tracking data. The different colors of the heatmap represent different durations of the fixations:

<table>
<thead>
<tr>
<th>Student: The little pictures helped me, because I could see how it works. Because sometimes I didn’t understand the text and then I watched the pictures and they helped me.</th>
</tr>
</thead>
</table>

![Heatmap showing eye-tracking data with different colors for durations of fixations.](image)

**Figure 1: Primary data insights**

Deeper qualitative analyses, which focus on how the symbols are used by the students as well as on the linguistic comprehensibility of the tasks, will follow. For the main study a posttest-only design, which includes two experimental as well as one control group, is planned. While experimental group 1 receives a linguistically and pictorially simplified version of the tasks, experimental group 2 works with a variation which is linguistically simplified only. The control group receives a not simplified version. After working with the exercises, the students’ knowledge about fractions will be measured. The participants’ reading ability and their IQ will be elevated beforehand. These control variables shall help to build comparable groups.

The application of the Universal Design for Learning framework to task design in order to support lower attaining children in the primary school mathematics classroom

Caitríona Wynne¹ and Lorraine Harbison²

¹Church of Ireland College of Education (a college of Dublin City University), Ireland; caitrionawy@gmail.com
²CASTeL, Institute of Education, Dublin City University, Ireland; lorraine.harbison@dcu.ie

Keywords: Universal task design, mathematics education, inclusion of lower attaining children.

Background to the study

It is a requirement that all schools in Ireland administer standardized attainment tests in mathematics when children are in 2nd Class (aged 7 – 8). On the basis of these results, children who are deemed to have underperformed nationally (Standard Score <90), are usually offered additional support by means of withdrawal from their mainstream classroom for mathematics lessons to work on a complementary program with the learning support teacher. Although it is argued that such provision is offered to less able children as they tend to simply ‘give up’ in classrooms in which they find the mathematical tasks too challenging, the concern is that that these children will fall further and further behind. It is the contention of the authors, that it is not the tasks per se that are too challenging for the children but rather the nature of the tasks, which all too often tend to emphasize traditional practices of rote procedure and drill.

In this study, the researcher, who was working as the learning support teacher, and the class teacher planned together to integrate children back into their classroom by co-designing mathematically rich tasks. Over a four week period, three children who had formerly been withdrawn from the classroom were put to the fore in the planning of the tasks. Particular consideration was given to their learning styles. The mathematical tasks were inspired by the three key principles of the educational framework, Universal Design for Learning (UDL), which constitute Multiple Means of Representation; Multiple Means of Action and Expression; and Multiple Means of Engagement (Rose & Meyer, 2000). The term ‘universal’ is particularly pertinent in the design of the tasks as they were developed in line with specific mathematical learning goals for ‘all’ learners from the beginning rather than implementing a standard ‘one size fits all’ set of tasks and differentiating the tasks to cater for the marginalized, less able children, at a later stage.

Therefore, in order to create learning tasks that will engage all children by design, this research sought to ascertain:

1. How can the principles of UDL be used to design mathematically rich tasks?
2. Do UDL informed tasks engage and support children of low-ability in mathematics?

Methodology

This case study took place over four weeks with one class of 32 children for 45 minutes per day. The children were aged between eight and nine years old.
It was a detailed body of work comprising collaborative universal lesson design on the topic of ‘Measurement’, implementation of lessons, critical analysis of tasks and peer review. Each lesson was assessed using an adapted scoring rubric developed by Spooner, Baker, Harris, Ahlgrim-Delzell and Browder (2007). Frequencies of different events were tabulated. Formal observational instruments were developed to recognize and discern certain types of behaviors such as children’s degrees of engagement. Observations were supplemented by photographs. Teachers’ daily reflections were analyzed using the analytic technique of pattern matching. A matrix of categories was developed and evidence placed within each classification. Information was put in chronological order. A follow up interview was held with the host teacher at the end of the intervention.

Results

The 14 lessons scored 82 points out of a maximum of 84 points on the adapted scoring rubric (Spooner et al., 2007) implying that a very high level of the UDL approach was used in the task design and implementation. Diversity was the starting point in planning the tasks, with lower ability children being accommodated within and enriching the regular class. The development of positive learning profiles for the three target children, such as, ‘needs assigned role during group tasks’, or, ‘needs to have basic equipment available such as a pencil and a ruler prior to task allocation’, helped to remove barriers to and enable participation in learning. UDL tasks offered the children various ways of acquiring information and knowledge; provided alternatives for demonstrating what they knew; tapped into children’s interests, gave appropriate challenges, and increased motivation. Multiple means of representation, action and expression, and engagement were used in task design. Video clips were used on five occasions, concrete materials on eight occasions, ICT (PowerPoints, images, interactive stylus and interactive tools) were used during eight lessons, a parallel ICT mathematics program was set as homework for the children on each of the 14 days and the local environment was used on seven occasions. ICT was also found to be a key component that engaged children who were previously observed to be challenged by mathematics.

Discussion and conclusion

This research revealed that tasks which take into consideration UDL instructional goals, assessments, methods and materials are usable and accessible from the outset rather than having to retrofit the tasks to children’s needs as an afterthought. Crucially, results from this study found that by intentionally creating flexible learning opportunities, less able children were engaged and understood difficult mathematical ideas when they were provided with UDL informed tasks.

TWG23: Implementation of research findings in mathematics education
Introduction to the papers of TWG23:

Implementation of research findings in mathematics education

Uffe Thomas Jankvist¹, Mario Sánchez Aguilar², Jonas Bergman Ärlebäck³ and Kjersti Wæge⁴

¹Aarhus University, Danish School of Education, Denmark; utj@edu.au.dk
²Instituto Politécnico Nacional, CICATA Legaria, Mexico; mosanchez@ipn.mx
³Linköping University, Department of Mathematics, Sweden; jonas.bergman.arleback@liu.se
⁴Norwegian Centre for Mathematics Education, Norwegian University of Science and Technology (NTNU), Norway; kjersti.wage@matematikksenteret.no

In this introduction, we briefly present selected theoretical constructs relevant for the Thematic Working Group 23 (TWG23). We first address the topic of “implementation research” by looking into other research fields and domains where this topic is well-developed. Drawing on a taxonomy of so-called “implementation science” in health-care, we attempt to categorize the papers and posters of TWG23 according to their “implementation research aim” (Nilsen, 2015). Using this taxonomy, we elaborate on future perspectives for the TWG by relating to ongoing discussions in mathematics education research.

Keywords: Research findings, research results, theory to practice, implementation research.

A need for creating a new CERME Thematic Working Group

With almost five decades of accumulated knowledge, research findings, theoretical frameworks and experiences, the field of mathematics education research now has quite a bit to offer to the ongoing teaching and learning of mathematics in primary, secondary and tertiary education. Regardless of the well-known long and winding “journey” that research results must travel before finding an actual foothold within practice, results from mathematics education research nowadays seem to be present to a much larger extent in practice than ever before – not to say that there is anything strange in this, but rather it is probably only natural given that the field has matured and become successively more and more established over the years.

Indeed, as researchers in mathematics education, we are frequently involved in putting previous empirical results and findings as well as theoretical constructs based on these to good use in mathematics classrooms, mathematics programs, mathematics teacher education, in-service teacher training, etc. In several countries there are ongoing developmental projects that rely heavily on previously documented research results. However, as researchers we often find ourselves in a peculiar situation when wanting to report on these activities, since such accounts do not necessarily fall under the usual paradigm of “research in mathematics education” and do not in a clear-cut manner qualify as either “empirical” or “theoretical research”. To assist in closing this “gap” the purpose of creating a new thematic working group focusing on aspects and issues related to the implementation of research results and findings, is to provide a venue for discussing, collecting and advance the “implementation research” aspects of our activities.
Implementation research and its aims

In relation to research on actual implementations, mathematics education may profit from other disciplines or areas, where research on implementations is further ahead. Healthcare is one such area, where since 2006 an entire journal has been devoted to “implementation science” (the name of the journal as well). Although the journal of course publishes several empirical studies related to various aspects of implementations, it occasionally also offers theoretical studies focusing on “implementation research” itself. One such theoretical contribution is the study by Nilsen (2015), who proposes a taxonomy consisting of five categories of theoretical approaches in order to make “sense of implementation theories, models and frameworks” (p. 1). Nilsen describes implementation science as “the scientific study of methods to promote the systematic uptake of research findings and other EBPs [evidence-based practices] into routine practice to improve the quality and effectiveness” (p. 2). Although Nilsen focuses on the case of health care, the definition seems adaptable and applicable also to the field of teaching and learning of mathematics. As part of the background for the taxonomy, Nilsen states that “Implementation science has progressed towards increased use of theoretical approaches to provide better understanding and explanation of how and why implementation succeeds or fails” (p. 1). According to Nilsen, the theoretical approaches used in implementation science have three overarching aims:

1. describing and/or guiding the process of translating research into practice (process models);
2. understanding and/or explaining what influences implementation outcomes (determinant frameworks, classic theories, implementation theories); and
3. evaluating implementation (evaluation frameworks).

The five categories of theoretical approaches consist of those provided in parentheses following the aims above. For aim 1, process models serve the purpose of breaking down the translation process into smaller steps, stages or phases. For aim 3, evaluation frameworks serve the purpose of assisting in evaluating the success – or lack thereof – of a given implementation. More interestingly, perhaps, are the theoretical approaches associated with aim 2. Determinant frameworks specify types of determinants that act as barriers and enablers that influence implementation outcomes, or even specify relationships between types of determinants. Classic theories are defined as those originating from fields external to implementation science, e.g. psychology, sociology or organizational theory that can be applied to understand or explain aspects of implementation. Finally, implementation theories are defined as those which have been developed from scratch within the field of implementation science.

Implementation research aims of the papers and posters in TWG23

TWG23 received 16 papers prior to the congress. At the congress 14 papers and 1 poster were presented. In the light of Nilsen’s three aims of implementation research (or science), most of the studies presented in TWG23 at CERME 10 in Dublin concerned aim 1, addressing aspects of how to adapt research results and findings to practices in schools or other learning situations. A few of the presented studies touch upon aim 3, i.e. evaluation frameworks. Although it is seldom the main focus of the studies presented, aspects related to aim 2 occasionally surface. We shall return to
potential reasons for this distribution, but first we will use Nilsen’s framework to categorize and briefly discuss the papers and posters in TWG23 presented at CERME 10.

In line with Nilsen’s aim 1 to guide the process of translating research into practice, Ärlebäck describes and discusses the framing of, and experiences from, a project that combines research, practice, and teachers’ professional development based on the tenets of the “Models and Modeling Perspective” on teaching and learning. Besides providing a general description of the methodological considerations in the project design, the paper describes how the accumulated results and experiences in the research literature on so-called model eliciting activities are used to inform the design, implementation and evaluation of activities aiming at introducing functions to grade 8 students. The focus of the paper is on the implementation, and aims to show how the teacher in question realized the offered perspective and tools in practice. The work presented by Aguilar, Castañeda and González-Polo aligns with aim 1 as it illustrates how research results generated in the field of mathematics education can be implemented in the design of mathematics textbook tasks. In particular, it is shown how research findings related to representation registers and to the conceptualization of the concept of function as a process are used in the design of textbook tasks for upper secondary level. The poster by Chandia and Montes matches with aim 1, since they report a professional development strategy for teachers focused on improving students’ and teachers’ problem solving skills. The professional development strategy by Chandia and Montes incorporates research results related to the creation of professional development systems in mathematics. Bulien presents theoretical and methodological arguments for the design and implementation of a research based course for pre-service teachers aimed at clarifying and strengthen the connection between didactical and mathematical theories to in-school teaching activities. Drawing on a design experiment methodology and the theory of communities of practice, Bulien elaborates on a “Mathematics Didactics Planning Tool” for teaching in different classroom situations. Thus, this study also relates more closely to Nilsen’s aim 1. Jankvist and Niss deal with the research-based design and implementation aspects of a so-called “detection test” in relation to upper secondary school students’ difficulties with mathematical conventions, concepts and concept formation, in particular those related to equation solving. In a similar manner, Ahl addresses the design of a detection test related to students’ difficulties with proportional reasoning. Hence, both these studies deal with Nilsen’s first aim, that is, translating carefully selected research results from mathematics education into suitable test items. Based on the answers of 405 Year 1 upper secondary school students, Jankvist and Niss also address aspects of evaluation (aim 3). Another research report that corresponds to aim 1 is the one by Kjeldsen and Blomhøj. In their work, research findings on students’ concept formation and the digital tutorial genre are brought to use in the teaching of a first year calculus course. They present and discuss a theory-based design and its implementation for students’ productions of video tutorials aimed at supporting their understanding of the limit concept. It could be said that this work is also related to the aim 3 delineated by Nilsen, since the study examines whether the designed learning environment supports the students’ formation of key concepts in calculus or not.

The paper by Valenta and Wæge touches on both aim 1 and aim 2 of Nilsen’s taxonomy. The paper describes a course aimed at supporting in-service teachers’ learning of ambitious mathematics teaching. The design of the course is based on a project called “Learning in, from, and for Teaching Practice Teacher Education Project” (aim 1). In addition, the particular question addressed in the
paper is coupled to aim 2, since it focuses on the learning potential in the interactions between in-service teachers and course instructors during the public rehearsals that are the key innovative feature of the designed course and manifested through cycles of enactment and investigation. The theoretical paper by Nilsson, Ryve and Larsson align with Nilsen’s second aim (understanding and/or explaining what influences implementation outcomes). They draw upon a systematic literature review on productive classroom practice to construct a framework for categorizing theories aiming at supporting teachers’ actions in mathematical classroom practices. They do so by relating to theories and literature on educational policy research, professional development research and implementation research. Related to a larger scale early intervention program, Lindenskov and Kirsted touch upon aspects of Nilsen’s aim 2. More precisely, they discuss teachers’ perception of “theory” and barriers these may lead to, when implementing research results in practice. In addition, they also address aspects of the translation of theoretical constructs to the teachers as well as the suitability of these constructs provided a given context of practice. The study reported by Tamborg, Allsopp, Fougt and Misfeldt clearly falls with Nilsen’s category of studies related to developing determinant frameworks (aim 2), since it investigates the role the local supervisor (enabler) in the implementation of a mathematics teacher training program.

Amit and Portnov-Neeman’s work can be related to the aims 1 and 3 proposed by Nilsen. They report on the implementation of a methodology used to teach reading and mathematics called “Explicit Teaching Method” focused on teaching students the “working backwards strategy” for solving non-routine mathematical problems; on the other hand, the effect of using the explicit teaching method as a means to learn the working backwards strategy is evaluated. Koichu and Keller position their paper as so-called design-based implementation research (DBIR) (see later). They present an evaluation framework (aim 3) to analyze and theorize their attempts in creating and sustaining online exploratory problem-solving discussion forums using the conceptual tools provided by Rogers’ “Theory of Diffusion of Innovation”. Ejersbo and Misfeldt report on a design-based research (DBR) project related to developing numeracy in grades K-3. This study too focuses specifically on evaluation aspects (aim 3), not least in terms of improving the design being implemented as well as the future of the project at the local school. Kuzle’s work somehow touches all three aims outlined by Nilsen. She reports on a collaborative project between educational researchers and practitioners with the goal of developing a problem-solving curriculum for grade 6 students using DBR. The curriculum was developed and implemented based on problem solving research and theory, and through the evaluation of its implementation objective and subjective factors that inhibited the full-implementation of the curriculum were identified.

Implementation of research findings in mathematics education

As seen above, a few aspects of aim 2 were touched upon in the papers and posters of TWG23, and some papers also considered aim 3. Still, aim 1 appears to be the dominant one among the reported studies. This, however, is not so strange since actual “implementation research” within the field of mathematics education must be regarded as a relatively new trend. This is of course due to the field of mathematics education itself not being much older than fifty years, but at the same time it is mature enough to have produced a sound basis of research results to actually be implemented into the practice of teaching and learning mathematics. Engaged in such implementation-oriented endeavors, researchers in mathematics education work systematically at different levels to establish
evidence-based solutions to the problems and challenges faced by practitioners and learners. Whether the research carried out is empirical or theoretical in nature, implementation of research findings and results is at the core of the research activities, either in the form of evaluating and furthering actual practices or materials etc., or to deepen our theoretical understanding to facilitate, guide and support various future implementations. Hence, and as already illustrated by the papers of TWG23, implementation of research findings and results in mathematics education can take many forms and expressions. Further examples from the literature are: in the design of experiments (e.g. Cobb, Confrey, diSessa, Lehrer & Schaublè, 2003) and mathematical tasks (e.g. Margolinas, 2013); as tools for professional development of in-service and pre-service mathematics teachers (e.g. Tsamir, 2008; Sánchez, 2011). The research findings and results that are implemented as part of systematic research are typically empirical results, theoretical results in terms of frameworks of different kinds, or some mixture of the two. Still, such findings and results usually fall within Nilsen’s first and third aims, whereas results directly concerning aim 2 are scarcely touched upon.

As seen from the presented research studies of TWG23, implementation of research findings may have connections with research areas already existing in the field of mathematics education. One such example, although not reported in TWG23 at CERME 10, is that of lesson study. In the lesson study approach, lessons are designed and analyzed as a means to improve mathematics teaching in the classroom, but also as a means for professional development of mathematics teachers. Another existing research area, represented in TWG23, is that of task design. Hence, from the presented papers, it is clear that “implementation research” encompasses different kinds and formats (textbooks, apps, software, etc.) of didactical designs and products, stretching from task design, over teaching modules, courses, to entire programs – on all educational levels. Yet an example is that of design-based research (DBR), where results might take the form of a teaching module that successively and iteratively have been envisioned, designed, applied, analyzed and redesigned. The result is the final design as well as measures of how successful the design has proven to be. However, to focus on the implementation aspect of DBR means to not only focus on the end product and its success in achieving what was set out to do, but also to seriously take into account the “design phase” of the design research cycle. That is, the phase where the researcher identifies a learning problem and then uses available research results to design a (preliminary) product or tool that can help students in overcoming this learning problem. A primary concern then becomes to focus precisely on the way research knowledge is applied to generate some type of educational product. Elements of these concerns are addressed by Fishman and colleagues (2013), who forefront the implementation aspects of DBR in a research approach they call design-based implementation research (DBIR) – a framework also used in a few of the papers presented in TWG23. In short, DBIR has:

“(1) a focus on persistent problems of practice from multiple stakeholders’ perspectives; (2) a commitment to iterative, collaborative design; (3) a concern with developing theory and knowledge related to both classroom learning and implementation through systematic inquiry; and (4) a concern with developing capacity for sustaining change in systems.” (Fishman and colleagues, 2013, pp. 136-137)

More generally, an important aspect when implementing research findings and results into practice is to focus on what Burton (2005) has called the methodology of the research conducted. Burton
argues that researchers in mathematics education in general pay little or no attention to explaining and motivating the rationale for the actual research design they apply to be able to draw the conclusions they report when writing up their research. This “craft knowledge” of the researcher is in a way silent. In Burton’s opinion, accounts of research is full of descriptions of how results were obtained (i.e. what the explicit methods applied were), whereas elaborations on why choices were made and decisions taken in order to arrive at conclusions are rarely found. The how-question concerns the methods used by the researcher to undertake his or her research, while the why-question focuses on the rationale for the research design, i.e. the methodology. That more emphasis should be put explicitly on the methodology has also been put forward by for example Wellington (2000), who describes methodology as “the activity or business of choosing, reflecting upon, evaluating and justifying the methods you use” (p. 22). He further argues that it is necessary to know the methodology of a piece of research to be able to impartially judge and assess it. TWG23 provides a venue and forum for researchers to discuss how to best put research results to use in practice alongside the accompanying rationale for why. In this sense, TWG23 has as one of its primary foci methodologies for initiating and institutionalizing research-based implementation designs. Over time, the activities of such a group could also make us wiser on the actual usefulness of our various research results, constructs, and frameworks.

**Perspectives for the TWG at future CERMEs**

Although the main focus of TWG23 seems currently to be on Nilsen’s first aim, and to some extent the third aim, in time the TWG may potentially contribute much more to the second aim: in identifying determinants across various countries; in identifying relevant classical theories external to mathematics education, which may help to understand or explain implementations; and last but not least in developing homegrown implementation theories of mathematics education. This was also reflected in the evaluation of the TWG, where the question was asked: What shall be TWG23’s contribution of knowledge to the field of mathematics education? The participants of the TWG collectively phrased the following “vision” for the group:

“We want to explore a wide variety of ‘good examples’ of implementing research findings and results (back) into practice in order to improve the teaching and learning of mathematics at all educational levels on a research-based foundation. Over time we may begin to look into the aspects of research on implementations, potential requirements for these to function, etc.”

Hence, for the future of TWG23, it may be envisioned that the TWG could come to consist of a core of researchers interested in these aspects (Nilsen’s second aim). But at the same time, a group like TWG23 is also a place for mathematics education researchers to go when wanting to report and discuss on any “intermediate” activities of either designing new research projects or developmental work, before the activities may result in more traditional research to be reported in other TWGs. In this sense, TWG23 also provides a forum for mathematics educators at CERME to “come and go” from one congress to another.

To put it a bit boldly, it is our hope that this TWG can assist in filling the “gap” of where to report on implementation activities in our research community, while at the same time act as a “bridge” between research and practice.

The aim of this paper is to illustrate how the research results generated in the field of mathematics education could be implemented in the design of mathematics textbooks tasks. First we present research findings related to the concept of function, particularly findings related to representation registers and to the conceptualization of function as a process. Next we illustrate with examples obtained from a high school textbook, how these research findings can be implemented in the design of mathematical tasks. We close the manuscript with a reflection on the implications for research that this kind of implementation may have.

Keywords: Textbook development, functions, task design, implementation of research findings.

Introduction

As noted in the call for papers for the Thematic Working Group 23, implementation research can encompass a wide range of different kinds of didactical designs on a broad range of formats. In this work we focus on the use of research findings in the design of mathematics textbooks. More particularly, we will address research findings related to the learning of the mathematical concept of function and its implementation in the design of tasks included in a mathematics textbook for upper secondary level.

Textbooks play an important role in the teaching and learning of mathematics. For example, textbooks can affect teaching strategies by conveying pedagogical messages to mathematics teachers (Fan & Kaeley, 2000); also, mathematics textbooks can contribute to the creation and strengthening of students’ misconceptions (Kajander & Lovric, 2009), and even the content selection and presentation of materials in a textbook appear to influence learners’ participation and success in mathematics (Macintyre & Hamilton, 2010). Due to the huge influence that textbooks can exert in the dynamics of the mathematics classroom, over time there has been a growing interest in developing new and high-quality textbooks, however as pointed out by Li, Zhang & Ma (2014), “there are a very limited number of studies available that examine and discuss textbook design and the process of textbook development” (p. 306). Even more rare are the studies considering the implementation of research results in the design and development of mathematics textbooks, which it is the main focus of this manuscript.

The aim of this paper is to illustrate how research results produced in the field of mathematics education can be implemented in the design and development of tasks for mathematics textbooks. To achieve this we identify some research findings related to the concept of function and illustrate how they were used in the development of tasks for a high school mathematics textbook that is currently in use in the Mexican education system.
On the concept of function and research findings associated with it

We have focused our attention on the concept of function because it is a fundamental concept in the mathematical knowledge and as such plays a major role in mathematics textbooks (Mesa, 2000), particularly in those of middle and upper level. Because of its status and importance in the corpus of mathematical knowledge, educational research around this concept has been developed for several years and its results could be useful in the process of designing textbooks. In the next section we mention some research findings associated with this concept that we ourselves have implemented in the design of mathematical tasks included in upper secondary level Mexican textbooks.

What do we mean by «research findings»?

The products or results generated by research in mathematics education can be varied and fluctuate in a range that goes from tangible products (such as textbooks, educational activities, software) to more abstract products (such as constructs and theories). When we use the term «research findings» in this work we refer to information that has been obtained or discovered through empirical research and that can be expressed through observations, identification of obstacles and students’ modes of thinking, didactical suggestions, etc.

We argue that this type of information may be applicable in designing mathematical tasks included in textbooks. Next we present some examples of research findings connected to the learning of the concept of function, whose implementation will be illustrated below.

What research says about the learning of the concept of function?

Different representations of the concept should be encouraged. Some students’ difficulties connected with the concept of function can be attributed to the procedural emphasis with which this concept is taught, and also to the lack of variety in the representation contexts in which this concept is illustrated and manipulated.

Research has shown that many students possess prototypical visions of the concept of function. For instance, they tend to assume that functions are linear or quadratic in cases where this assumption is unwarranted, so for example they tend to think that “u-shaped” graphs are parabolas (Schwarz & Hershkowitz, 1999); Carlson & Oehrtman (2005) suggest that this difficulty may be related to the fact that many teachers introduce the concept of function through prototypical examples, which often are linear or quadratic. Thus, they suggest that the concept of function instruction should include more opportunities to experience different types of functions emphasizing different contexts of representation.

This is in line with the observations of Duval (2000). He claims that the conceptual understanding of a mathematical object becomes more robust when there is coordination between representation registers. Each register highlights certain characteristics and properties of the mathematical object, and the interaction between these registers allows for a broader conceptual understanding, so it is important to promote tasks that favor the transit between such representation registers, particularly the transit in directions that are not usually addressed in school, such as transit from the graphical register towards the algebraic one.

A dynamic vision of function as a process should be promoted. A common practice in the teaching of mathematics is to represent functions as static objects, however it has been suggested that
students must possess dynamic interpretations of this concept in order to favor a conceptualization of function as a process (Carlson, Oehrtman & Engelke, 2010). For instance, Figure 1 represents the area under a curve defined by a function \( f(x) \), and it does not promote a dynamic conceptualization of the area function; to achieve such dynamic conceptualization the student should imagine that point \( b \) moves and in doing so the shaded area \( S \) increase or decrease its size.

![Figure 1: «Static» representation of an area under a curve](image)

This type of static conceptualizations is closely related to an action view of functions (Dubinsky & Harel, 1992):

An action conception of function would involve the ability to plug numbers into an algebraic expression and calculate. It is a static conception in that the subject will tend to think about it one step at a time (e.g., one evaluation of an expression). (p. 85)

However, an action view of functions may result in an impoverished conceptualization of the concept; for instance, students with an action view often think of a function graph as being only a curve, a fixed object in the plane, they do not think the graph as defining a general rule where a set of input values are mapped to a set of output values (Carlson & Oehrtman, 2005). It is desirable to move students from an action view of functions to a process view of functions:

A process conception of function involves a dynamic transformation of quantities according to some repeatable means that, given the same original quantity, will always produce the same transformed quantity. The subject is able to think about the transformation as a complete activity beginning with objects of some kind, doing something to these objects, and obtaining new objects as a result of what was done. (Dubinsky & Harel, 1992, p. 85)

Is difficult to achieve this transition from static to a dynamic view of functions, however it has been suggested that technological tools can help in this transition. For example Borba & Confrey (1996) have suggested an approach to the study of functions based on visualization and the use of software; the approach focuses on the relationship between graphs and tabular values, and on the relationship between graphs and algebraic representations. For instance students could be asked to use the software to graph and explore how the coefficients of a quadratic function relate to translations, stretches and reflections of its graph.
Examples of implementation of research findings in the design of mathematics textbooks tasks

As we have claimed before, we believe that research findings as those previously presented can be implemented in the design of tasks for mathematics textbooks. We are aware that there may be different types of «implementation of research findings»; although it is not our intention to discuss such distinction here, we do want to clarify that in this work the «implementation of research findings» is interpreted as taking results or suggestions produced through research, and to use them as a source of inspiration for the design of mathematical tasks. To illustrate this point, next we present examples of tasks that were designed taking into consideration the research findings previously discussed. These tasks are included in the text González-Polo & Castañeda (2014), which was developed by the second and the third authors of this article. This is a textbook for high school level that is currently in use in the Mexican educational system; high school in Mexico traditionally consists of three years of education divided into six semesters, and this book is used in the fourth semester. Its print run for 2015 was 10,000 copies. The tasks proposed in the textbook are unpublished, but some of them have been inspired by tasks used as tools in the development of research in mathematics education.

Tasks to study functions in different representation registers

As mentioned before, research suggests that the concept of function should be studied and manipulated in different representation registers, but also should be promoted the transit between such representation registers, especially in directions that are not habitually addressed in school.

To implement this research-based suggestion, we have designed activities that require the student to transit from a graphical representation register to an algebraic register, when the usual is to ask students to start from an algebraic expression to generate a table of values, and from this table trace the graph of the function. Figure 2 shows an example of this kind of task.

![Figure 2: Task that requires the student to transit from a graphical register to an algebraic register](image-url)

The English translation of the task instruction is as follows: «The graph in figure 1.66 belongs to a first degree polynomial function. Determine the new function obtained by rotating the graph 90º to the right leaving the coordinate (0, 0) as a fixed point». In this task the student must start working on a graphical register—rotating the graph 90º clockwise—and then determine the algebraic expression that defines the new function, which in this case would be $f(x) = -x$. 
Another example is shown in Figure 3. This is an activity in which the study of the concept of constant function in different representation registers is promoted, although contrary to usual, the student is required to transit from a numerical register—a table of values—to an algebraic register.

![Figure 3: Task that requires the student to transit from a numerical register to an algebraic register](image)

The English translation of the task instruction is the following:

«A buoy in the Pacific Ocean measures salinity (the amount of NaCl, sodium chloride). The measures are sent every hour via satellite to a meteorological database for analysis. Table 3.4 shows the information obtained during an interval of 14 hours.

a) Locate the coordinates on the plane and trace the resulting graph
b) Write the function that best fits the data graphed
c) Describe verbally the trend of the graph, i.e., how the data will behave in the next few hours?»

The interpolation requested in paragraphs b) is somewhat facilitated because the function that best fits the data provided is a constant function, which in this case could be the function \( f(x) = 35 \). It is important to note that the activity is complemented by the question: «What operation should you apply to vertically translate the graph of the constant function?». This question attempts to engage the student in a dynamic conceptualization of the constant function, that is, to be able to understand that the graph of a constant function \( f(x) = k \) will move vertically by adding another constant \( c \) obtaining thus the graph of the function \( f(x) = k + c \).

**Tasks to promote a process view of functions**

Inspired by the approach proposed by Borba & Confrey (1996) in which functions are studied with a strong emphasis on the visualization of their graphs, we have included tasks where students are asked to explore the graphical behavior of functions using software. It is assumed that these kinds of activities promote a dynamic conceptualization of functions where the graph is not interpreted as a fixed or static entity. An example of this type of task is shown in Figure 4.
Figure 4: Task requesting the student to use graphing software to explore the effect of parameters on the graph of a function

The task takes as its starting point the function \( f(x) = ax \) and the constant \( k \). Then the student is asked to use software to explore the effects that different integer values of the parameter \( k \) produces in the graph of the following functions:

\[
\begin{align*}
f_1(x) &= k \cdot ax \\
f_2(x) &= a^{k \cdot x} \\
f_3(x) &= a^{k+x} \\
f_4(x) &= a^x + k
\end{align*}
\]

Discussion

In this article we have tried to illustrate how some research findings related to the learning of the concept of function can be implemented in the design of tasks for mathematics textbooks. If one of our aims as mathematics educators is to bring products that are generated in our discipline closer to the school society (teachers, students, administrators, parents, etc.), then the textbooks are a privileged outlet for this purpose since it allows to bring research findings into the heart of formal mathematics instruction: the mathematics classroom.

Our enthusiasm as authors of textbooks and as researchers in mathematics education incline us to think that these tasks with a research-based design can be productive and beneficial for students’ mathematical learning, but what evidence is there to support these enthusiast assumptions? It would be necessary to develop studies from different perspectives that could allow us to understand how the textbook mathematical tasks are enacted in the classroom, and the type of conceptions and perspectives that they produce on students.
Regarding the actual design of the tasks, in her reflections on textbook design, Yerushalmy (2015) has suggested that the tasks appearing in textbooks—or more precisely the mathematical concepts involved in such tasks—can be organized around objects and operations that can mathematically and pedagogically support a variety of progressions and sequences. For example, in the case of functions, it can be considered an organizational map that clarifies the type of mathematical object involved in the task (like linear or quadratic functions), but also the type of operations required in the task such as represent, modify, transform, analyze, operate or compare, where each operation can take place in symbolic, graphic, or numeric representations (see figure 5).

![Figure 5: Example of an organizational map for the tasks included in a textbook. Taken from Yerushalmy (2015, p. 243)](image)

This type of organizational maps can make the design of tasks more transparent, that is, to render explicit the mathematical objects involved in the tasks as well as the operations that are performed on them. These maps can work as a framework that helps both textbook designers and users to identify gaps in the presentation of concepts, and produce a sequencing of tasks that addresses the largest possible number of operations and contexts of representation with the intention to provide students with a richer picture of the mathematical objects studied.

Finally, it is important to note that in addition to the textbook González-Polo & Castañeda (2014), there is a teacher’s guide explaining in more detail the theoretical background on which the design of the tasks is based, as well as their purpose. This kind of guide represents a fundamental support to achieve a classroom implementation of mathematical tasks that is faithful to the intentions of the task designers.

Designing a research-based test for eliciting students’ prior understanding on proportional reasoning

Linda Marie Ahl

Kriminalvården, Section for adult education, Sweden; linda.ahl2@kriminalvarden.se

Mathematics education in the Swedish prison education program is struggling with a high rate of students that fail to pass the basic mathematics courses. One of the main issues seems to be the challenge for the teachers to elicit students’ widespread prior mathematical knowledge. The consequence of this is that the teachers cannot meet the students’ educational needs with meaningful teaching activities. Focusing on the most pervasive mathematical idea in these courses, proportional reasoning, a test was designed that aimed to elicit students’ mathematical reasoning. This paper illustrates that by making use of accumulated and selected research results and findings, we can gain valuable information on students’ proportional reasoning competency. This information may be used as an access point for individualized instruction.

Keywords: Adults, individualized instruction, proportional reasoning, prison education.

Introduction

In the Swedish prison education program, only two out of ten students finish and pass their mathematics courses. This is disturbing in itself, but particularly so given the resources available. The teachers are university trained upper secondary school mathematics teachers, and the students sign up voluntarily and typically are highly motivated. Moreover, all courses are individually designed for each student, which should ensure good teaching and learning conditions. However, a challenge is that the student group shows significant variation in age, ethnicity, socioeconomic background, school background and life experience in general. For the basic mathematics, the mathematics in compulsory school and the first course in upper secondary school, there exists no such thing as one course design that suits all students’ different backgrounds. In 2015 the Swedish prison education program in mathematics had 728 students enrolled, spread across 47 prisons, and 80% of these were found in the basic mathematics courses.

A plausible reason for the low pass rate in the basic courses is that the teachers fail to make proper use of the individualization possibilities. A prerequisite for actual individualization is that teachers have the opportunity to find out students’ prior mathematical understanding and adapt the teaching accordingly. Realizing that this opportunity hinges on the teachers’ competencies, e.g., they need to put their didactic and pedagogical teaching competency to play (Niss & Højgaard, 2011). But teachers’ possibilities to individualize instruction might also depend on various forms of support. Inspired by Jankvist and Niss (2015), I report on a research-based effort to develop such support: a test for identifying beginner students’ prior mathematical understanding. The test needs to provide information on students prior understanding in two ways: vertically, in relation to progression throughout school years, and horizontally, throughout taught topics in compulsory school. Hence, a major design decision was to focus the content on proportional reasoning. As will be argued below, proportional reasoning permeates the basic mathematics courses in a systematic way, which means that probing students’ competencies in this area gives a good access point for individualized teaching. The foundation for the test is the accumulated and selected research results and findings related to proportional reasoning, since proportionality may be the most important, pervasive and powerful idea in elementary school mathematics (Behr, Harel, Post, & Lesh, 1992; Lamon, 2007).

Constructing such a test involves several design decisions involving the content and form of the test, as well as constructing, collecting and adapting test items that realize these design decisions. The

---

main question elaborated on in this paper is: How can research findings inform the development of a test that elicits students’ prior understanding on proportional reasoning so as to provide teachers with an access point for designing individualized teaching?

Theoretical underpinnings for the development of the test

Mathematical reasoning is one of eight competencies for identifying and analyzing students’ mathematical understanding, described in the Danish KOM-project (Niss & Højgaard, 2011). “The mathematical reasoning competency consists, first, of the ability to follow and assess mathematical reasoning, i.e., a chain of arguments put forward – orally or in writing – in support of a claim.” (Jankvist & Niss, 2015, p. 264). The kind of mathematical reasoning called proportional reasoning is a prerequisite for successful further studies in mathematics and science, since multiplicative relations underpin almost all number-related concepts studied in elementary school (Behr et al., 1992; Lamon, 2007). A proportion is defined as a statement of equity of two ratios a/b = c/d. Proportion can also be defined as a function with the isomorphic properties f(x+y) = f(x) + f(y) and f(ax) = af(x) (Vergnaud, 2009). A function, A(x,y), can also be linear with respect to several variables, (n-linear) functions. For example the area functions for a rectangle with sides x and y is bilinear (2-linear) since A(x,y) = xy and it is easy to check that this function is linear with respect to each of its variables when the other is considered constant.

Proportionality is a key concept in mathematics and science education from elementary school to university (Lamon, 2007). Despite the pervasive nature of proportional reasoning throughout the school years it is well known that children around the world have considerable difficulty in developing the mathematical competency to reason about fractions, percentages, ratio, proportion, scaling, rates, similarity, trigonometry, and rates of change (Behr, Harel, Post, & Lesh, 1992; Lamon, 2007). Typically, proportional reasoning problems come in the shape of a missing value problems or comparison problems (Lamon, 2007). In the former, a multiplicative relation is present where three elements are provided and the fourth is to be found. The latter asks the student to compare which ratio is the bigger or smaller.

From accumulated research, some key points for the developing of proportional reasoning and the building of multiplicative structures can be identified (c.f. Behr, Harel, Post, & Lesh, 1992; Fernández et al., 2012; Lamon, 2007; Shield & Dole, 2013; Van Dooren, De Bock, Vleugels, & Verschaffel, 2010; Vergnaud, 1983). Students need to:

1. Be able to distinguish additive from multiplicative reasoning and recognize when a multiplicative relation is present;
2. Be able to draw connections to the algebraic rules for fractions when working with part/part ratios, part/whole fractions and proportions, a:b = c:d;
3. Recognize and use a range of concrete representations for proportions, e.g., tables, graphs, formulas and drawing pictures;
4. Acknowledge the properties of geometrical objects in two- and three dimensions for calculation of scaling and similarity.

Key point 1. Research studies and findings show that the ability to distinguish additive from multiplicative comparisons constitute a major stumbling block for students (Van Dooren et al., 2005). Students need to be able to recognize that a proportional situation exists when the comparison is multiplicative (Shield & Dole, 2013). In Sweden, students get acquainted with additive strategies for reasoning about quantities in grades 4 to 6. For example, an increase in price by 10% can be calculated in two steps. First, calculate how much 10% is and then add this to the original price. A transition from an additive to multiplicative thinking approach is introduced in grades 7 to 9. The new price can now be approached in one multiplicative step: the original price multiplied by the factor 1.1, to find
the new price. Far from all students embrace this new idea of approaching percentage change. The additive approach works well for calculating a single increase or decrease, while they may lack motivation to change strategy. Fernández et al. (2012) found that the error of using additive strategies on proportional situations increased during primary school and decreased during secondary school. A desirable development in students’ reasoning would be that they, after being introduced to multiplicative reasoning, still hold on to their ability to use additive strategies when appropriate. However, research findings show that once students have been introduced to multiplicative strategies they tend to overuse this approach on everything that resembles a proportional situation (Van Dooren et al., 2005). Further, non-integer ratios cause more errors than integer ratios (Fernández et al., 2012; Gläser & Riegler, 2015), while the non-integer situations can be considered to require a more developed understanding of rational numbers.

Key point 2. Many situations require that students can relate to part/part ratios and part/whole fractions (Vergnaud, 1983). For example, if a company employs 11 women and 31 men, the part/whole fractions 11/42 and 31/42 represent the relation of women and men related to the whole. If asked to determine the company’s gender distribution, it is instead the part/part ratio 11:31 between women and men that is relevant. When a ratio connects two parts of the same whole, students may not adequately recognize the difference between part/part and part/whole relationships (Clark, Berenson, & Cavey, 2003). It is not easy for students to approach situations that require shifting from part/part to part/whole situations. Moreover, students need to connect mathematical ideas. Since ratios can be written in fraction form, they obey the same mathematical laws as fractions (Shield & Dole, 2002).

Key point 3. Another stumbling block for students is that they tend to apply linear proportional reasoning on scaling, without considering the nature of the item. Van Dooren et al. (2010) found that students tend to use linear proportional reasoning even when it is inappropriate e.g., in word problems where a real word context is required to solve the problem. For example: Farmer Gus needs 8 hours to fertilize a square pasture with sides of 200 meters. Approximately how much time will he need to fertilize a square pasture with sides of 600 meters? Recognizing this as a missing value problem i.e., three values given and one unknown, this problem will trigger a cross-multiplication type solution which gives the wrong answer of 24 hours. Since scale is one of the major themes that span mathematics, chemistry, physics, earth/space science and biology it is crucial for students to gain understanding of the concept of scale. Scale in one, two, and three dimensions is a central unifying concept that crosses the science domains, crucial for understanding science phenomena (Taylor & Jones, 2009).

Key point 4. Proportionalities can be represented in different ways, e.g., with words, pictures, algebraically, with graphs or tables. Shield and Dole (2013) enhance the use of a range of representations to promote students’ learning. If students are given the opportunity to work with graphs, tables and other diagrams that illustrate the proportional situation present in the mathematical task, their conceptual understanding is promoted (Vergnaud, 2009). Further, their ability to see connections between problems that are based on the same mathematical idea is enhanced, e.g. to see that missing value problems on similarity, proportional functions and speed problems can be illustrated with different representations but approached with the same mathematical idea.

Several concepts are in play when students reason with proportional quantities. The intertwined concepts required for the development of proportional reasoning makes up a conceptual field (Vergnaud, 2009). A conceptual field is a set of situations and concepts tied together. As the theory of conceptual fields show, together with other well-known theoretical frameworks for conceptual understanding, the meaning of a single concept does not come from one situation only (Sfard, 1991; Tall & Vinner, 1981; Vergnaud, 2009) but from a variety of situations demanding mathematical reasoning related to the concept in question. The conceptual field of intertwined concepts in play in
proportional reasoning cover at the least “linear and n-linear functions, vector spaces, dimensional analysis, fraction, ratio, rate, rational number, and multiplication and division” (Vergnaud, 1983, p. 141). It is the complexity of the concepts in play together with the pervasive nature of proportional reasoning from elementary school to university that makes proportional reasoning suitable for the design of the test.

Design of the test on proportional reasoning

An important design choice for the test was to use a multiple-choice design. Even though open response tests are a powerful method to elicit students’ understanding, the advantages of multiple-choice tests were in this case considered to be the best option. An open response test can be a negative experience for students with low prior understanding, since they may be unable to supply any answers. Since the students often have bad experiences from school mathematics, we want to avoid negative experiences in the beginning of a mathematics course. A multiple-choice test, on the other hand, is easy to take for the students. Even when they do not have the mathematical competencies to reason and solve an item, they can still provide an answer by intuition or chance. The test is designed to be followed up with student interviews. This is an important step since many students do not have Swedish as their mother tongue, which of course may cloud their interpretation of the items. Many of the students also have concentration difficulties, so a written test may not give a satisfactory picture of students’ prior understanding.

A downside of multiple-choice is the possibility to choose the right answer by chance. For this reason, a two-tier design was chosen (see examples below) yielding only 0.125 probability to pick both the right true or false value and the right claim. A pilot version of the test, consisting of 22 items, was tried out in April 2016. Feedback from the participants informed me that the test was too long and that some of the items were difficult to interpret. After revision and further testing, the resulting test consists of 16 proportional reasoning items. The final version of the test takes about 20 to 40 minutes to complete, without any time pressure.

The items in the test were chosen from published research papers, with the intention to draw on knowledge from the research field on proportional reasoning. The rationale for my choices is as follows: a) the items have already been proved to work well for giving information on students’ understanding, and b) extensive background information of the nature of the mathematical reasoning in play are provided as well as analyzes of students results. Referring to the key points presented in the theory section, the potential reasoning related to each item involves several concepts and abilities, yet the items can still be categorized as referring mainly to one or two of the four presented key points:

Key point 1. Students’ ability to distinguish additive from multiplicative reasoning and recognize when a multiplicative relation is present, and is always required for carrying out proportional reasoning, however mainly tested by items 1, 5, 6, 7, 11 and 16.

Key point 2. Students’ ability to draw connections to the algebraic rules for fractions when working on part/part ratios, part/whole fractions and proportions, a:b = c:d, is mainly tested by items 2, 4, 12, and 13.

Key point 3. Students’ ability to recognize and use a range of concrete representations for proportions, e.g., tables, graphs, formulas and drawing pictures is mainly tested by items 3, 8, 9 and 15.

Key point 4. Students’ ability to acknowledge the properties of geometrical objects in two- and three dimensions for calculation of scaling and similarity is mainly tested by items 8, 10, 13 and 14.

Several errors on items referring to the same key point indicate a lack of understanding that should be investigated further in the following student interview. The test items are also adapted to mirror the progression throughout the basic course. Items 1 and 4 refer to content taught in part two of the basic
course. Items 2, 3, 6 and 10 deal with content from part three and part four is reflected in items 7, 8, 9 and 11-16.

### Key points

- **Basic course**
  - Distinguish additive from multiplicative reasoning
  - Draw connections to the algebraic rules for fractions
  - Recognize and use a range of concrete representations
  - Acknowledge the properties of geometrical objects

Table 1. Schema over items in relation to key points and progression in the basic courses

The sources for the test items are: Hilton, Hilton, Dole, and Goos (2013); Fernadéz et al. (2012); Niss and Jankvist (2013a; 2013b); and Gläser and Riegler (2015). The items from Hilton et al. were already designed as two tier multiple test items. The other items were adapted from their original design to a multiple-choice design, using erroneous answer alternatives either reported in the original studies or answer alternatives recalled from my experience from teaching.

**Examples of test items**

In what follows, I will exemplify how research results on common difficulties on proportional reasoning are guiding the choice of the test items. To illustrate, items included to elicit students’ difficulties to discriminate additive from multiplicative situations and difficulties with scaling are displayed below.

Consider this item, adapted from Fernadez et al. (2012):

**Loading boxes:** Petra and Tina are loading boxes in a truck. They started together but Tina loads faster. When Petra has loaded 40 boxes, Tina has loaded 160 boxes. **When Petra has loaded 80 boxes, Tina has loaded 200 boxes.**

**True or False** because (choose the best reason)

a) Tina will always be 120 boxes ahead of Petra.
b) Petra loads faster than Tina.
c) Tina loads 4 times faster than Petra.
d) Tina loads with double speed.

This is a proportional situation where Tina is loading 4 times faster than Petra, so the claim “**When Petra has loaded 80 boxes, Tina has loaded 200 boxes.**” is false. Students should consider whether it is appropriate to use additive reasoning, that is, if Tina has still loaded 120 boxes more than Petra. If the students answer a) **Tina is always 120 boxes ahead of Petra**; further investigation of their reasoning strategies is required, though the answer indicates that there may be a lack of transition from additive to multiplicative thinking. This suspicion is further strengthened if the student is successful in items requiring additive reasoning, like in the item below, from Hilton, et al. (2013):
Running laps: Sara and Johan runs equally fast around a track. Johan starts first. When Johan has run 4 laps, Sara has run 2 laps. **When Sara has completed 6 laps, Johan has run 12 laps.**

**True or False** because (choose the best reason)

a) The further they run; the further Johan will get ahead Sara.

b) Johan is always 2 laps ahead of Sara.

c) Johan completes double the laps of Sara.

d) Sara has run 3 lots of 2 laps to make a total of 6 laps, so Johan must have run 3 lots of 4 laps to make a total of 12 laps.

This is an additive situation where Sara and Johan run at the same speed. Students should consider whether it is appropriate to use multiplicative reasoning, that is, if Johan runs 3 times faster than Sara. If the students answer d) Sara has run 3 lots of 2 laps to make a total of 6 laps, so Johan must have run 3 lots of 4 laps to make a total of 12 laps, further investigation of their reasoning strategies is required though the answer indicates that a difficulty to discriminate multiplicative from additive situations exists.

The two examples above illustrate how research findings on proportional reasoning have been used in the design of the test. By including items requiring multiplicative reasoning as well as items requiring additive reasoning you may elicit the students' ability to discern when a multiplicative situation is present.

The Dice- and the Circle item below are adapted from Niss and Jankvist (2013b), The Dice item is originally phrased: *A cube of wood with all edges 2 cm weighs 4.8 grams. What weighs a cube of wood, where all edges are 4 cm? Justify your answer.* [En terning af træ med alle kanter lik 2 cm vejer 4.8 gram. Hvad vejer en terning af træ, hvor alle kanterne er 4 cm? Begrund dit svar.] I added the claim: “**A wooden dice where all edges are 4 cm weight 19.2 g.**”, and the response alternatives.

**Dice:** A wooden dice where all edges are 2 cm weighs 4.8 g. **A wooden dice where all edges are 4 cm weight 19.2 g.**

**True or False** because (choose the best reason)

a) The weight increases 4 times if the edge doubles.

b) The weight increases 6 times if the edge doubles.

c) The weight increases 8 times if the edge doubles.

d) The weight doubles if the edge doubles.

**Circle:** Simon says that if you draw a new circle with half the diameter of another circle, the new circle will have half the perimeter and half the area of the other circle.

**True or False** because (choose the best reason)

a) The diameter is halved, the perimeter and area is halved.

b) The area will be ¼ and the perimeter ½ of the original.

c) You cannot know without knowing the length of the diameter in the new circle.

d) You cannot know without knowing the length of the diameter in the original circle.

Students may fail to interpret the effects on volume from a doubling of the edges, while further investigation on the students’ conceptualization of geometrical objects needs to be undertaken. To reason about the circle item, the students need to consider the conjunction that both the perimeter and the area are halved. Since (area scale) = (length scale)²; a halving of diameter will result in a ¼ size of area while the perimeter halves. An error on these items may indicate difficulties to acknowledge the properties of geometrical objects in two- and three dimensions for calculation of scaling and similarity.
Reflection

There are many reasons why educational research tends to be isolated from practice. Research results and findings need to undergo a number of transformations from theory to practice, before they can be adapted to teaching practice, as illustrated in the design of the discussed in this paper. The test was designed with considerations to a special prison context and early results from using the test shows that it provides valuable support for the teacher when eliciting students’ prior understanding of mathematics. Although, the test focuses on the mathematical reasoning competency it also informs us of students’ mathematical thinking competency, problem-handling competency and modeling competency since these competencies are intertwined and overlapping. Together these four competencies create one out of two overall competences associated with mathematics: The ability to ask and answer questions in and with mathematics (Niss & Højgaard, 2011). The other overall competence: The ability to deal with mathematical language and tools, covers the intertwined competencies representing competency, symbol and formalism competency, communication competency and aids and tools competency. The scope of the test does not cover the ability to deal with mathematical language and tools. These competencies are left to be tackled within the course design, as well as the further development of the students’ ability to ask and answer questions in and with mathematics.

A fundamental idea of educational research is that research findings should be put in play in teaching practice to help students to succeed with their studies in mathematics. I have discussed the design of a test for supporting teachers when pursuing the goal of finding an access point for individualized instruction. Through making use of accumulated and selected research results in the area of proportional reasoning in the design of the test, we gain a more thoughtful idea of the students’ prior understanding.

‘Explicit teaching’ as an effective method of acquiring problem solving strategies - the case of ‘working backwards’

Miriam Amit and Yelena Portnov-Neeman

Ben-Gurion University, Department of Science and Technology Education, Israel;

amit@bgu.ac.il ; yelenapo@post.bgu.ac.il

It has been shown that children who control strategies are better able to direct their own learning and knowledge. Seeking for an effective teaching method to achieve this goal, we experimented with the Explicit Teaching method vs. a traditional school one, using both to teach the Working Backwards Strategy. The study was conducted amongst 57 mathematically talented students participating in a unique mathematics program called Kidumatica. A mixed method analysis showed that Explicit Teaching produced better results regarding students' ability to use the strategy, though it did not affect the students' ability to recognize the strategy. This indicates that young students can understand when to use this powerful tool and, with further guidance, can also master their ability to use it.

Keywords: Explicit teaching, strategy, working backwards strategy

Introduction

Since Polya (1957), who claimed that students who control many strategies will become more effective and intelligent problem solvers, other researchers have advocated integrating problem solving strategies into school mathematics (English, 1993; Steiner, 2007), especially for talented students (Lee, 2014). The development and use of strategies is definitely not intuitive, and students need proper instruction, guidance and encouragement in order to systematically implement strategies in different domains - especially in problem solving (Tishmen, Perkins & Jay, 1996). Unfortunately, teachers face immense difficulties when it comes to teaching strategies in an effective way (Zbiek & Larson, 2015). This fact led us to look for an effective method to teach (talented) students some basic problem solving strategies. Based on interviews and talks with “professional mathematicians,” we decided on four such strategies: Trial and Error, Proof by Contradiction, Working Backwards, and Recursion, which were taught to students using the “Explicit Teaching method.” In this paper we focus on just one example, showing how Explicit Teaching can be used to teach students the "Working Backwards Strategy" for solving non-routine mathematical problems.

Explicit teaching method

Explicit Teaching is a systematic methodology that is currently used primarily to teach reading and mathematics. This method is described as “highly organized and structured, teacher-directed, and task-oriented” (Archer & Hughes, 2011). All stages of the learning process include mediation between the teacher and the learner, in which the teacher transmits an external understanding of certain information to the learner, who then processes that pre-determined understanding (Olson, 2003). Nevertheless, using Explicit Teaching does not predetermine or confine learners’ thinking; on the contrary, it can help them become more active solvers and foster independent thinking (Portnov-Neeman & Amit, 2015). The methodology consists of a five step model (Figure 1). The steps described below are performed sequentially by the instructor in order to efficiently pass on specific information to the learner with as little ambiguity and room for error as possible (Rosenshine, 1986).
**Orientation:** Each lesson begins with a clear instruction about the purpose of the lesson. Learners need to understand what they are going to learn and how it connects to previous lessons.

**Presentation:** The lesson material is divided into small units that fit the learners’ cognitive abilities. The teacher uses a model or schema to guide them through their problem-solving process.

**Structured Practice:** The instructor gives a direct and detailed explanation of the problem-solving using the model or schema that was presented in the previous step. During this phase, it is critical that the instructor asks learners questions and encourages class discussion in order to check and assess their understanding of the material and clarify any confusion.

**Guided Practice:** In this practice, the instructor addresses individuals’ questions and misconceptions one-on-one, and tailors responses to meet the individual needs of each learner. Students can work in small groups in order to develop their ideas together and help each other with the new material.

**Independent Practice:** In this step, learners are asked to complete an assignment on their own and without assistance. They are not expected to have a flawless understanding of the lesson, but they must understand the steps involved in the process. This step should continue until learners gain full independent proficiency with the materials.

---

**Figure 1: Model of Explicit Teaching**

**‘Working Backwards’**

‘Working Backwards’ is a useful and efficient strategy for solving problems in many aspects of our lives, in which an achievable outcome is known, but we have not yet determined the path towards achieving it (Newell & Simons, 1972; Portnov-Neeman & Amit, 2015). When dealing with word problems, for example, the information given in the problem can appear like a complex list of facts, so it is sometimes helpful to begin with the last detail given (Wright, 2010). The Working Backward strategy is illustrated in Figure 2 and explained step by step in detail below:

1) Read the problem from beginning to end and identify all its components and steps.

2) Check the final outcome of the problem.

3) From the final outcome, start reversing each mathematical operation in each step until you reach the beginning of the problem. For example, reverse the adding operation and replace with a subtraction operation.
4) After reversing every step, resolve the initial state of the problem.

5) Check the answer by starting from the initial state and working through the steps to see if the final outcome is achieved (Amit, Heifets & Samovol, 2007).

![Diagram of Working Backwards strategy](image)

**Figure 2: Model of the Working Backwards strategy (Amit, Heifets & Samovol, 2007)**

**Methodology**

The study presented here examined the effect of using the Explicit Teaching method to learn a new strategy, specifically the Working Backwards Strategy for mathematical problem solving. The research questions are: To what extent does Explicit Teaching affect:

a) The ability to recognize when the Working Backwards Strategy is needed for problem solving?

b) The ability to use and implement the Working Backwards Strategy?

**Context**

The study was conducted in the framework of "Kidumatica". Kidumatica - the math club for excellence and creativity - is an after school program for talented students in the 5th to 11th grades who are interested in mathematics, but require further tools to reach their full potential (Amit, 2009). Fifty-seven (N = 57) 6th grade students were divided in two groups: an Experimental Group (EG = 30 students) and a control group (CG = 27 students). Over a period of six months, these students learned different mathematical strategies, including the Working Backwards Strategy. The EG learned through the Explicit Teaching method, while the CG was taught using the traditional school one. None of the students in this study had been research subjects in previous studies involving the Working Backward Strategy, and none had learned the strategy before.
The ‘Explicit Teaching’ Group (Experimental Group)

Students in this group studied all the strategies by means of the Explicit Teaching method. Each strategy, including the Working Backwards Strategy, was taught for four weeks by one of the researchers, according to the model illustrated in Figure 1. The teacher had an integral part in the lessons. She clearly and explicitly outlined what the learning goals are for the student, and offered clear, unambiguous explanations of the skills, information and the problem solving process. As the lessons progressed, the teacher’s role reduced, until students were able to solve problems independently. It was like riding a bicycle, where the instructor gradually releases his hold of the bike and the child rides off by herself. The teacher showed the students the model of the strategy and explained the role of each step in the solution process. The following lessons were dedicated to structural, guided and independent practices. During the structured practice the teacher gave a direct and detailed explanation of the problem solution using the Working Backwards model (Figure 2). The teacher encouraged discourse between the students and asked questions to assess their understanding and clarify any confusion. In the guided practice, students worked in smaller groups or by themselves on different working backwards problems. The teacher walked around the students and addressed individuals’ questions. When the teacher felt confident enough of a student’s abilities, that student was allowed to start working individually and begin the independent practice step. At the independent practice stage, students were asked to complete several assignments using the working Backwards Strategy, and to solve complex problems on their own.

Traditional teaching control group

The control group studied the Working Backwards Strategy for the same period of time as the EG, but they studied the strategy in the traditional school method. This group differed from the EG in the following ways:

1. Lessons were mainly dedicated to students’ work. The teacher’s part was smaller than in the EG. Her role was to give short explanations about the lesson activities. She did not use the word “strategy” in her explanations, or explain that a special approach is needed for solving working backwards problems. Most of the lesson was dedicated to independent time, so that students would develop their own strategy toward those problems. It was important that students draw their own conclusions, create their own conceptual structures, and assimilate the information in the way that makes the most sense to them.

2. The teacher did not show the model of the strategy and did not name the strategy explicitly. Instead, students could develop their own model and meaningful name based on the teacher’s examples and their own experience.

3. The practice process in the CG was mainly independent, in contrast to the three levels of practice used in the EG. That led to less room for discussion and collaborative work between the students, unlike the EG, where time was allotted for these during the structured and guided practice.
Data collection and analysis

Data was collected via pre- and post-tests, students’ products, short interviews during and after the lessons, and teacher’s notes. The pre/post-tests were administrated to both groups before and after the learning program. Both tests included working backwards problems. This paper will discuss two problems from the pretest (problems 1 and 2 below), and two from the posttest (problems 3 and 4).

1. Card Problem: “Yael, Danny and Michael played cards. At the beginning of the game each one had a different amount of cards. Yael gave Danny 12 cards. Danny gave Michael 10 cards and Michael passed Yael 4 cards. At the end each one of them had 20 cards. How many cards did Yael, Danny and Michael have in the beginning?”

2. Mangoes Problem: “One night the King couldn't sleep, so he went down into the royal kitchen, where he found a bowl full of mangoes. Being hungry, he took 1/6 of the mangoes. Later that night, the Queen was hungry and couldn't sleep. She too found the mangoes and took 1/5 of what the King had left. Still later, the first Prince awoke, went to the kitchen, and ate 1/4 of the remaining mangoes. Even later, his brother, the second Prince, ate 1/3 of what was then left. Finally, the third Prince ate 1/2 of what was left, leaving only three mangoes for the servants. How many mangoes were originally in the bowl?”

3. Weight Problem: “Four students in the class weighed themselves. Cobi was 15 kilograms lighter than Adi. Gaby was twice as heavy as Cobi and Jenya was seven kilograms heavier than Gaby. If Jenya weighed 71 kilograms what was Adi’s weight?”

4. Baseball Problem: “The Wolverines baseball team opened a new box of baseballs for today’s game. They sent 1/3 of their baseballs to be rubbed with special mud to take the gloss off. They gave 15 baseballs to their star outfielder to autograph. The batboy took 20 baseballs for batting practice. They had only 15 baseballs left. How many baseballs were in the box at the start?”

At the end of each test, students were asked to write what method they had used to solve the problems. The purpose of the pre-test was to determine the homogeneity of the two groups. The post-test examined the effect of the teaching methods at the end of the learning process. A five point scale was used to rank students’ answers (5 points = full and correct answer, 0 points = no answer). For example, if students identified all the steps, calculated each one by doing the opposite mathematical calculation and wrote the final answer correctly, they received 5 points. Figure 3, for example, shows a five point solution for the “Weight Problem.” The problem has three steps: (1) Jenya was seven kilograms heavier than Gaby; (2) Gaby was twice as heavy as Cobi; (3) Cobi was 15 kilograms lighter than Adi. The student calculated the weight of each person by working backward through every step of the problem. Figure 4 shows an example of a 2 point solution. The student started with the last detail given and calculated Gaby’s weight correctly. However in the next two steps he did not reverse the mathematical operations and got an incorrect answer.
Findings

Findings from the pre-test showed that in both problems, there was no significant difference between the groups, which indicates that both groups had the same level of homogeneity. After six months of learning strategies, the average scores in the post-test for both problems were higher among the EG than the CG. In Table 1 we can see a significant difference in the post-test between the two groups in both problems. Figure 5 indicates that students’ ability to recognize the strategy improved after the learning process, but that both groups had similar results in the pre and post-test.

Table 1: Results from pre- and post-test in the EG and the CG
Our qualitative analysis of students' solutions revealed that the EG students reversed the mathematical operations much better and more easily than those in the CG, and were thus able to solve the problem correctly. Moreover, while the EG explicitly stated the name of the strategy they had used when asked, the CG students were very creative in naming the strategy, coining names such as, “going in through the back door”, “reverse manual” etc. Finally, the EG students used the model of Working Backwards Strategy in a very efficient way, sometimes adjusting the model to make it easier to use.

Discussion

Strategies are undoubtedly an important tool for goal-directed procedures in problem solving. Introducing them at a younger age can improve learners’ mathematical ability (Polya, 1957) as well as their understanding and thinking skills (English, 1993). To achieve this goal, it is important to use a specific teaching method (Tishmen, Perkins & Jay, 1996). In this study, that method is the Explicit Teaching method, through which we introduced the Working Backwards Strategy. The study examined the effect of this method on students' ability to recognize and solve working backwards problems. Fifty-seven sixth graders were divided into two groups, an experiment group (EG) that studied with the Explicit Teaching method and a control group (CG) that studied with a traditional school one. The strategy was unfamiliar to both groups and the findings from the pre-test showed that both groups had a similar starting point. At the end of the learning process, the group that studied explicitly showed higher results than the control group. The structured steps of the Explicit Teaching helped the students to have a better, clearer understanding of the strategy (Anhalt & Cortez, 2015). Qualitative analysis revealed that students who studied explicitly were more much resourceful in their solutions. They understood how the strategy works, adopted it and changed it to make it easier to solve. We believe that this ability developed due to the discourse and the collaborative work in the structured and guided practice. We saw how students’ understanding of the strategy and its use improved over time. They asked more questions, listened to other students’ answers and learned how to avoid misconceptions. In addition, the integral role of the teacher in this method helped students gradually to build their confidence. Thus, these students were more prepared to work on working backwards problems by themselves. Our previous study showed that teaching explicitly can help students become active learners and foster their independent thinking (Portnov-Neeman & Amit, 2015). The current study supports this conclusion, showing that Explicit Teaching did not limit students' thinking by fixing it on a particular process. On the contrary, students understood the core principle of the Working Backwards Strategy and then applied it creatively in whatever way seemed
best to them. Both groups showed improvement over time in their ability to recognize when and why the Working Backward Strategy is needed. The percentage of students that recognized the strategy before and after the learning process was similar. This is very encouraging, since it may indicate that the teaching method does not affect students' ability to recognize strategies. We can assume that with additional practice, all of the students could potentially master strategies and develop their understanding and their strategic approach to problem solving, but this has to be tested and researched. In this study, we experimented in ‘laboratory conditions’ with talented students, and found that the method works. Further research is needed to confirm its effectiveness outside of the Kidumatica Mathematics Club, in the ‘real world’ of education.

Conclusion

Mathematical strategies are complex concepts to learn and understand, and we as educators must search for the most effective way teach them. In this study, we used a systematic and structured methodology called Explicit Teaching, and found that students who studied with this method had higher scores than students who studied with a traditional school method. Introducing strategies like these to students is important, since they can help students evolve into better thinkers and develop their ability to solve problems. We believe that strategies can and should be introduced from a younger age so they can be developed over time. We have found that younger children are capable of acquiring the basic tools. Given time, they will be able to develop their tool kit of strategies further, and eventually master them all. It is our obligation as educators to teach our students how to use strategies correctly, and the sooner we do so the better.

Using a Models and Modeling Perspective (MMP) to frame and combine research, practice- and teachers’ professional development

Jonas Bergman Ärlebäck

1Linköping University, Department of Mathematics, Sweden; jonas.bergman.arleback@liu.se

This paper describes and discusses the framing of, and experiences from, a project that combine research, practice- and teachers’ professional development based on the tenets of the Models and Modeling Perspective on teaching and learning (MMP). Besides providing a general description of the methodological considerations in the project design, the paper describes how the accumulated results and experiences in the research literature on so-called model eliciting activities are used to inform the design, implementation and evaluation of activities aiming at introducing functions to grade 8 students. The focus of the paper is on the implantation and aim to showcase how the teacher in question realized the offered perspective and tools in practice.

Keywords: Practice development, teachers’ professional development, models and modeling perspective, model eliciting activities.

Introduction

Clarke, Keitel and Shimizu (2006) have shown that much of the teaching and learning of mathematics in many counties are centered around, and dominated by, a traditional use of textbooks. This practice seems to strengthen as the students progress though the educational system, as does the fact that many students lose their interest in, and motivation for, learning mathematics with increasing age. TIMSS 2007 for example shows that the attitudes towards mathematics in Sweden expressed by grade 4 students generally are much more positive compared to the attitudes among grade 8 students (Skolverket, 2008). This situation in combination with the declining results of Swedish students on the international assessments PISA and TIMSS, are reflected and frequent in the public debate as well as in many of the ongoing drives, projects and programmes trying to realize changes in schools. Learning mathematics is complex (Niss, 1999), and now more than ever is the role teachers play stressed for what mathematical understanding and knowledge the students develop in schools (Hattie, 2009; 2012).

However, the challenges that teachers meet in their everyday mathematics teaching are numerous and of various kind and nature. Students’ lack of interest in combination with too monotonous (and “traditional”) forms of teaching seems to be part of the reasons for the Swedish students’ declining performances as well as interest in mathematics. Often, a proposed strategy to reverse these trends is to try to change the prevailing norms in the classroom (Yackel & Cobb, 1996) by increasing student interaction and the overall student activity. Teachers are encouraged to try to vary their teaching, increase students’ activity levels and strive to make students ‘talk more mathematics’. But how is this going to work in practice in everyday teaching? How do we get students to ‘talk more math’ and to be more engaged and (inter-)active in the mathematics classrooms?

The concerns mentioned above are part of the motivation for the installment for a joint collaborative initiative between two municipalities and a university, from which this paper will discuss some aspects. The overarching question for the initiative is: How can we organize the mathematics
teaching so that students are given the opportunity to develop their conceptual, procedural/methodology and reasoning abilities in, for the students, interesting and engaging ways?

A project combining research, practice- and teachers’ professional development

As a response to the situation and challenges briefly outlined above, a collaboration between two municipalities and a university was initiated with the aim to establishing a long term and sustainable collaboration as well as to seek for ways to counterbalance the current trends. The initiative rest one three strands, namely to simultaneously (1) combine and produce research with (2) the development of teaching practices in schools and (3) to serve as professional development for the teachers in the municipalities. The project involves two researchers focusing on different grade levels: grades F to 6 (6- to 12-year-olds) and grades 7 to 12 (13- to 18-year-olds). The two researchers have autonomy in how they define, plan and conduct the work within the given boundaries defined by the university and the municipalities.

The project focusing on grades 7 to 12 runs a series of semi-parallel 1-year projects were the researcher in each project works together with 4-6 teachers from different schools and grades as partners (c.f. Jaworski, 1999) in, what ideally could be described as, a co-learning agreement (Wagner, 1997). Each project departs from the practices of the participating teachers and the possibilities and challenges they see in their everyday teaching. Based on the teachers’ experiences a discussion leads to the formulation, planning and implementation of a 1-year long project with specified aims and goals. The research carried out in the projects is centered around the participating teachers own everyday teaching, and their engagement in research and developing their own practices constitute the professional development for the teachers. Within the context of the initiative two key questions then become: How to coordinate the experiences and result from the individual projects? and How to communicate then? Note that these questions also are at the heart of mathematics education more generally (aka the accumulation of research and the dissemination of knowledge; a main topic for CERME 10’s TWG23). For the 1-year project discussed in this paper, the studied question was: How can we create and work with joint classroom activities that challenge all students regardless of their levels of mathematical understanding and capabilities?

The models and modeling perspective on teaching and learning

The models and modeling perspective on teaching and learning (Lesh & Doerr, 2003), MMP for short, sometimes given as an example of a so-called contextual perspective in the discussion on modeling (Kaiser & Sriraman, 2006), draws on and traces it’s lineages back to Vygotsky, Piaget and Dienes as well as influences from the American pragmatists’ tradition represented by Mead, Peirce and Dewey (Kaiser & Sriraman, 2006; Mousoulides, Sriraman, & Christou, 2007). The central notion in this perspective is that of models, which are conceptual systems used to make sense of situations and phenomena. Models are considered to be human constructs which are fundamentally social in nature and can be described as systems consisting of elements, relationships, operations, and rules that can be used to predict, explain or describe the behavior of some other system. In the MMP learning is equated with model development, in which the role of modeling activities is to support this development by engaging the students in purposefully developing, understanding, modifying, and using their models to make sense of different situations and contexts (Lesh & Doerr, 2003).
The adaptation of the MMP at the macro level for all grade 7-12 projects establishes a common perspective and vocabulary that facilitate communication within as well as between different projects and levels of stakeholders in the initiative. The inherent recursive complexity of the MMP (researchers developing models of teachers’ models for teaching and supporting students developing their models) connects the work and results from the different projects and levels. The inclusive and accessible notions models and model development (understood in a more mundane way) facilitates communication with teachers, high municipality officials and policymakers.

**Model eliciting activities**

*Model eliciting activities* (MEAs) are purposefully designed activities where students need to develop a model that can be used to describe, explain or predict the behavior of, for the students, meaningful contexts, phenomena and situations. Traditionally, much work within the MMP have been centered around so-called *model eliciting activities* (MEAs) developed by Lesh and colleagues (Lesh, Hoover, Hole, Kelly, & Post, 2000). Although originating in mathematics, MEAs have in the last 15 year been used to support and investigate the development of students’ models (conceptual systems) in a range of disciplines and contexts (Diefes-Dux, Hjalmarson, Zawojewski, & Bowman, 2006; Iversen & Larson, 2006; Yildirim, Shuman, & Besterfield-Sacre, 2010; Yoon, Dreyfus, & Thomas, 2010).

The research involving MEAs have resulted in six design principles for MEAs, which also to some extent capture the essence of the MMP: (a) *the reality principle* – the MEA connects to students’ previous experiences and is meaningful; (b) *the model construction principle* – the MEA induces a need for the students to develop a meaningful model; (c) *the self-evaluation principle* – the MEA permits the students to assess their work and models; (d) *the model documentation principle* – the situation and context in the MEA requires the students to externally express their thinking (models); (e) *the model generalization and sharable principle* – the elicited model in the MEA is sharable, generalizable and applicable to similar situations; and (f) *the simplicity principle* – the situation in, and formulation of, the MEA is as simple as possible (Lesh et al., 2000; Lesh & Doerr, 2003).

Teacher working with MEAs have proven to provide rice opportunities for professional change and development. Schorr and Lesh (2003) found that teachers working with MEAs in their classrooms

(a) changed their perception regarding the most important behaviors to observe when students engaged in problem activities; (b) changed their views on what they considered to be strengths and weaknesses of student responses; (c) changed their views on how to help students reflect on, and assess their own work; and (d) reconsidered their notions regarding the user of the assessment information gathers from these activities. (Schorr & Lesh, 2003, p. 157)

These experiences and results suggest that MEAs might provide a productive tool to address the question about how to create mathematics teaching that is challenging for all students. The teachers in the project found this a promising approach and especially expressed the following aspects of MEAs appealing: MEAs build on and respect what the students bring to the classroom in terms of prior knowledge in a fundamental way; MEAs focus on the students’ sense making of meaningful situations, representations and connections between representations; working with MEAs naturally includes a range of classroom organizations (working one-by-one, in pair, group or different whole class interactions); MEAs have the students work on explicitly formulating and expressing their
thinking using mathematics. In addition, the six design principles for MEAs come to play a few different roles: tools for design; tools for analyzing tasks; evaluative tools for students work in class; and tools for thinking about one’s own view of mathematics, teaching and learning.

The MEA and its’ implementation

We now end the paper by showcasing the result of one teacher’s implementation of an MEA given as an introduction to linear function in grade 8.

The context and the design of the MEA Candy time!

The teacher wanted to use an MEA to introduce linear functions in grade 8. Functions, and different representations of functions, are something that the students have been exposed to more or less consciously in different forms during the majority of their mathematical schooling. In other word, students already have ideas and models for what graphs and tables are and how and when to use them. So, rather than systematically treat these concepts in a traditional manner, the teacher wanted to challenge the students to use their previous experiences and to see and explore the connections between tables, graphs and diagrams by engaging in a more exploratory activity (aka an MEA).

The context of the problem was chosen by the teacher to be about buying candy. In Sweden, there is a often practiced tradition, that the children on Saturday do their weekly candy shopping, called lördagsgodis – “Saturday’s Candy.” Not seldom, the candy is bought in candy stores where you pick ’n’ mix candy after your own preferences and liking, and pay by the hectogram (100 grams) or the based on the actual number of pieces of candy you picked.

In the design of the MEA the teacher stressed four of the guiding principles as especially important for this particular purpose: (a) the reality principle: the choice of context and situations (the candy store) was made in order to be familiar to the students in that it should facilitate the students in making connections and interpretations between different representations; (b) the model construction principle: the intention with the activity Candy time! is for the students to build on their previous experiences and knowledge in order to connect and coordinate them further; (d) the model generalization and sharable principle: to promote that students share ideas as a means for furthering their models, the MEA was designed to have the students working along as well as in pairs or small groups, and engaged in whole class discussions. Note that the four principles not are independent, and that they contribute to make the students’ previous experience and knowledge the basis for the activity, to make students’ ideas and thoughts (models) visibility, and to facilitate that the students’ models are confronted with other students’ models so that they through discussion can refine and develop their ways of thinking.

Implementation

After the teacher started the lesson and introduced the first part of the activity, the students began to work individually on the first part of the task about the three stores A, B and C; see Figure 1 below. However, it only took seconds until the students spontaneously started discussing with each other about which store would given them the most candy for their money, and they spontaneous formed
pairs and small groups. The teacher observed the students’ work and listen to the students’ discussions while walking around in the classroom and making sure all students understood the task, but otherwise intentionally kept a low profile.

**Candy time!**

It’s Saturday and you’re thinking about which of the three stores A, B and C you’ll go to and spend 2,50 € so that you’ll get as much candy as possible. Compare all three stores and motivate your choice.

| Store A | You’ll pay 1 € for a bag of 32 pieces of candy. |

| Store B |
|------------------|------------------|
| **Pieces candy (#)** | **Price (€)** |
| 5 | 1,5 |
| 10 |  |
| 15 |  |

| Store C |

Figure 1: Part one of the activity *Candy time!*

The idea was that the students’ should use an experimental approach and try different ways and strategies to approach the problem. If the teacher noticed that some of the student got stuck she approached the student with encouragements like “Try to fill out the table for Store B!”, “What would it look like if one plotted the table-values for Store B in the same diagram displaying Store C’s pricing?”, or “What would Store A ‘look like’ in the Store C diagram?” When the majority of the students had decided in which Store to do their shopping of Saturday’s candy, the teacher focused and pulled the class together by asking “What would the graphs for Store A and Store B look like if you plotted them in the same diagram as the graph for Store C?”. When all the students had decided on which store gave them the most value for their money, the teacher, based on her observations in the classroom, chose a few of the students to orally present their solution for the whole class. The selected students showed, motivated and explained what method they used to approach and solve the problem. In the whole class discussion that followed the students’ presentations, the teacher, based on continuous inputs of the students, showed what the graphs for the different stores would look like if they were plotted in the same diagram.

The discussion continued in smaller groups were the students were engaged in thinking about and explaining: What use does one have of graphs and tables? What are the differences and similarities between the three stores? What factors other than the price can affect where one choose to buy one’s candy? Looking at the students’ answers, there is a tendency to consider graphs as suitable tools for comparing things (“when you want to compare something”, “you can see the differences in prices”) or to illustrate how something develops over time (“when you wanna show something along a timeline”). Tables on the other hand the students put forward as good tools for presenting different kinds of compiled data or results (“as for example results from sports”, “to present one’s findings”, “sport results, lengths, weight, sizes, ages, sexes, opinions”).
Regarding the differences and similarities between the stores the students mostly commented on directly observable features like “all are selling candy”, “the price goes up with the number [of pieces of candy you buy]”, “all have different pricing”. The selection of available candy in the different stores, both with respect to and quality and quantity, as well as to the geographical location of the store, were factors the students identified as things influencing where one buy one’s candy.

After the students had discussed and compared their answers for a couple of minutes, the teacher introduced part two of the Candy time! activity; see Figure 2 below:

Store D
– a new store – opens!!!!

You have previously meet Store A, B and C, but now there is a new store in town, Store D.
What is special with this new store? Will this new store offer any serious competition to the three already established stores (Stores A, B and C)?
Can you plot a graph representing yet another store? Write a few sentences explain your store’s price-fixing.

Figure 2: Part two of the activity Candy time!

While working on the second question in the second part of the activity, Will this new store [the Store D] offer any serious competition to the three already established stores (Stores A, B and C)?, the students concluded “well, it depends on how much you buy!”. Many of the students argued that Store D not would be any competition to the other stores if you as in the first part of the activity, only spent 2.50€. However, if you were spending a greater amount of money, then Store D should be the preferable choice. (“No, this [Store D] is more expensive that the others [Stores A-C]. But this [Store D] becomes more affordable if you buy a larger and larger amount”). The fact that the graph for Store D intersect the y-axis at y=10 some of the students interpreted as “you have to pay 1€ to enter the store, like an entrance fee” or that you pay for the box or bag you put the picked candy in: “Surely it’s some kind of fancy candy store where you have to pay for the boxing. That’s is probably one of the reasoning people will come [and shop in the store] – that it’s a fancy shop that is”.

The last task in the activity set lose the students’ creativity, drawing graphs describing other imaginary store’s pricing (see Figure 3). Most of the students draw in multiple stores and the most commonly pricing was a model giving the price proportional to the number of pieces of candy bought, as exemplified by Store H: “Every single piece of candy costs 0.10 € each”. One of the students wrote “In this store the only sell giant pieces of candy” (Store E) to explain the steepness of her graph. Store G was described by another student as “I’ve made a cheaper store - one where you’ll get one piece of candy for free!”, explaining the meaning of the graph intersecting the x-axis at x=1. Although the diagram only display the price for between zero and 11 pieces of candy, some of the students physically prolonged the lines representing the cost in Stores A – D and concluded that if you buy a large enough amount of candy, then Store D is the most price-worthy store. The
students also constructed stores that had price-fixing represented by a line with negative slope ("The price decreases, and after 11 pieces the candy becomes free", Store I), and stores with a flat rate price-fixing ("Take as much candy you want for 2,80 € ₲", Store F). After the lesson the teacher noticed and expressed her surprised over how much the students own examples of stores’ pricing showed and reveled about the students’ creativity and proficiency to interpret linear functions $y = kx + m$ with positive ($k > 0$), negative ($k < 0$) slope as well as zero slope ($k = 0$) in the given context of the activity.

The students’ worked on the second part of the activity till the lesson ended. The teacher then collected all the students’ written work, and followed up the activity the following lesson, after having read and summarized the students’ explanations, with a whole class discussion about the students’ conclusions, interpretations and price-fixing of their own stores. The teacher was surprised over the interest and engagement the students showed when working on the activity as well as over the wide range of solutions and explanations the students offered. The fact that the activity allowed for a variety of solutions resulted in almost all students wanting to share their solution and thinking at the whiteboard in the whole class discussion. In a few instances the students asked for how to name certain concepts such as origin and intersection point to be able explain their thinking more precise and clear to their peers. In other word, the students wanted to express themselves mathematically correct.

Providing a tool for lesson planning in pre-service teacher’s education  
Tone Bulien  
University of Stavanger, Faculty of Arts and Education, Norway; tone.bulien@uis.no

This paper discusses the theoretical and methodical arguments for the design and implementation of a research based course for pre-service teachers. The course program was carried out five times matching the methodology of design experiment and the theory of communities of practice. Students’ assignments in the course were designed to focus on planning teaching and to give the pre-service teachers experiences of how to use and connect didactical and mathematical theories to practical situations, and hence provide them with a tool for teaching in different classroom situations.

Keywords: Pre-service teacher education, implementation, design experiment, lesson planning, mathematics teaching and learning.

Introduction
The implantation of a new teacher-training program in Norway (Kunnskapsdepartementet, 2010) presented an opportunity to think about new ways of teaching a pre-service teacher course in mathematics within the program at a Norwegian university. Previous to this reform the corresponding course was organized more traditionally entailing plenary lectures, workshops and various student assignments in which the pre-service teacher students (PST) actively had to participate. However, feedback from the PSTs showed that they found it difficult to see the connection between the course work at the university and the in-school teaching practicing activities, especially with respect to the implementation of didactical theories in the everyday mathematics classroom practice (Bulien, 2008; Solstad, 2010). Therefore, the design and implementation of a revised course focused on and included activities that aimed to enhance and make the connection between theories of teaching and learning and the actual practice of teaching clear and explicit for the students. This paper discusses the central idea used to realize this connection in the redesign of the course, namely, to focus on lesson planning by adapting and introducing the so-called Mathematics Didactic Planning tool (MDP).

Besides presenting the MDP, the aim of this paper is to describe the research design and the theoretical background for the educational design experiment in which the MDP was developed, implemented and evaluated.

Introducing the MDP, the setting and background
The course that was subjected for redesign is a 30 credit compulsory course in the teaching and learning of mathematics given within a full time teacher education program for grades 1–7 (6–12 years old). The students take multiple courses simultaneously and the course in teaching and learning mathematics spans over a period of 2 years (7,5 credits each semester). Even though the program is a full time program, most of the students are not at campus all the time. Rather, the students travel and are physically present at joint seminars at the university for three separate weeks each semester. In each week, the students studied mathematics for 7 hours spread out over two days. The rest of the semester, the PSTs and teachers communicate via different media over the Internet.
In the first two semesters (credits 1-15) of the course in teaching and learning mathematics, the students focus on theories and frameworks related to the role of a mathematics teacher, teaching and learning mathematics, numeracy and early training of algebra (pre-algebra). This experience of different theoretical approaches to teaching and learning mathematics provided an advantage when they was introduced to the MDP in the third and fourth semester of their teacher-training program. During the second year of the course (credits 16-30) the PSTs worked through three MDPs, each organized in three different parts or phases named A1, A2 and A3, see Figure 1 (left).

![MDP model and course cycle of PST implementing MDP](image)

Figure 1: MDP model (left) and the course cycle of PST implementing MDP (right)

Phase A1 is about analysing textbooks and making a brief plan for teaching mathematics covering a whole school year. In phase A2, a much more detailed plan for teaching a lesson given a particular content is worked out. The last phase, A3, time is spend on reflecting back on the previous phases. The assignment students are obliged in phases A1 and A2 are written assignments carried out as group work, whereas the assignment in phase A3 is individual reflecting text.

In this second part of the compulsory course (semester three and four), the structure of the MDP was used as a frame to organize of both lectures and students’ assignments, and during the year the PSTs worked through three MDPs focusing on different mathematical topics as well as on different grades (1–7). The mathematical topics were geometry, measurement, statistics, probability and functions.

The introduction to the MDP model was given in the first seminar in the third semester at campus where the teacher and the PSTs together planned a fictitious lesson for teaching using the MDP framework. The following three MDPs were mainly supervised using Google Disk (GD) and through Internet seminars, but also in face-to-face seminars with the teacher when the students met at campus. Additionally didactical and mathematical theories were provided to the students through lectures, both at campus and in online video lessons made and hosted by the teacher. Having the PSTs iteratively working through three MDPs made it possible for the PSTs to familiarize themselves with the framework, and hence their need for support and guidance successively declined, aiming at the PSTs to be more and more independent. In other words, writing the assignments (A1,A2 and A3), the supervision in GD was more actively during the first MDP, less in the second and only by questions from the PSTs in the third (Bulien, 2013).
**Methodology**

The methodology of the project to implement the revised course on teaching and learning mathematics based on this new tool for teaching (the MDP) was founded on experiences from previous teaching similar courses; research about PSTs’ education experiences (e.g. Bulien, 2008; Solstad, 2010); and, students’ feedback on the content in similar and previous courses. Based on these, special emphasis in the revised course became the application of theory in practical teaching situations. In short, the aim of the project was to present a more visible connection between the theoretical work at campus and the practice at schools.

During the four-year teacher education program, the PSTs experience rather short periods of actually practicing teaching in schools, and each time they must focus on three or four different subjects which makes it difficult to go into depth on each subject during their practice time in the classroom (Solstad, 2010). Solstad (2010) found that PSTs’ ability to connect theory with practice increase the longer they attended the education program, but the students still wanted more supervision in implementing theory into their teaching practice. This increasing theoretical understanding might be a result of engaging in multiple cycles of supervised practice at schools and evaluated written assignments at the university, which suggests that a similar iterative learning model would be the preferred teaching and learning environment for the new course. However, closer collaboration and involvement with the actual teaching practices done in schools by the students was not feasible. Instead, a more active collaboration between the PST and the teacher in the spirit of communities of practice (Wenger, 1998) was integrated in the design of the course.

To guide and structure the overall re-design, implementation and evaluation of the new course, something that can be considered to be a classroom design experiment (Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003), a *design experiment* (Cobb et al., 2003) methodology was adapted.

Most classroom design experiments are conceptualized as cases of the process of supporting groups of students’ learning in a particular content domain. The theoretical intent, therefore, is to identify and account for successive patterns in student thinking by relating these patterns to the means by which their development was supported an organized. However, different classroom design experiments may set their focus on different constellations of issues (Cobb et al., 2003, p.11)

The theoretical intent of implementing the MDP was to focus on the PSTs’ development in lesson planning using didactical theories and mathematical knowledge, which could be evaluated in the assignments of each MDP and the PSTs’ reflection notes. The teaching and learning process involved in the implementation of the course was continually evaluated through out the five years based on the PSTs’ work and reflection as well as the teachers reflections notes and written logs. The course was modified and adjustments were made both during the semester and when before starting a new course for a new group of PSTs.

In the design and development of the MDP and the new course, Cobb et al. (2003) five crosscutting features of design experiments were used to structure and guide the work during the five-year period of this project.

First, design experiment involves both the *goal* and the *process* (Cobb et al., 2003). The goal was to educate prospective mathematics teachers so they could give their students a grounded mathematical
education based on mathematical knowledge and research about how to teach mathematics. The process, which should facilitate the goal, had two different parts. Initially the process was about developing a class of theories that supported the ideas of using the MDP as an artefact for the PSTs’ studies, and to get an overview of the implementation of the new ideas in the course. Next it was the process of defining the roles of the PSTs and of the teacher, in which the theory of communities of practice (Wenger, 1998) was introduced.

Since the collaboration between the PSTs and the teacher was supposed to be less like the usual teaching situation and more like an ongoing working together process, communities of practice was a suitable framing since “… the property of a kind of community created over time by the sustained pursuit of a shared enterprise” (Wenger, 1998, p.45). Further, Wenger claims that in educational design “Learners must be able to invest themselves in communities of practice in the process of approaching a subject matter” (Wenger, 1998, p.270). In this project the subject matter was the MDP that could be seen as a reification of a teaching and learning situation in the sense of “… giving form to our experience by producing objects that congeal this experience into “thingness”” (Wenger, 1998, p.58). For the MDP, the process was to present a learning trajectory to the PSTs that realized the possibility to adapt theoretical perspectives of teaching to classroom situations. A corollary to this involved a change in the teacher’s role from less lecturing to more supervising, which supports Wenger’s idea of self-investment.

Second, design experiment is about being innovative, and there should be a discontinuity between tradition and new ideas to test (Cobb et al., 2003). Expecting a more active contribution from the students and more supervision from the teacher changed the traditional lectures to seminars. In between seminars at campus, the supervision was implemented online using Google Disk (GD) and short video-films made by the university teacher. The focus for the supervision was to encourage the PSTs to evaluate didactical theories and mathematical knowledge and decide how to use them in teaching and learning situations.

Third, design experiment should involve both prospective and reflective situations (Cobb et al., 2003). In this project, the prospective aspect was manifested in the hypothesis or conjectures developed in terms of lesson plans in the written assignments in phases A1 and A2 of the MDP. In Phase A3 provided the possibility for reflection based on reflective knowledge and building on experience and research. Here, the MDP and the change of teaching and learning situations, build on previous teaching courses in mathematics and new ideas about learning, especially focused on social constructivism and the community of practice.

Fourth, design experiments include an iterative design. In this project, there are two levels of iteration (Cobb et al., 2003). A first is that the PSTs repeat the MDP three or four times during the course period, whereas the other is that the course itself was repeated five times with different students. The PSTs repeating the task hopefully provides better learning and the teacher had the possibility to adjust teaching according to the students’ needs for supervision. The iteration of the course focused on the design of both the MDP and the teaching on a meta-level.

Fifth, design experiment involves analysing and evaluating the course to search for potential new theories (Cobb et al., 2003). Each year the PSTs were asked to evaluate the course and their responses together with the exam results and logs written by the teachers during the year, were used to adjust
the plan for the course for the following year. Although analyses took place during the five years, a retrospective analysis is yet to be fulfilled. Since then the designed course with the MDP has been repeated five times, and it has additionally been used in other courses, might give broader information about the ability of the use of MDPs. This adoption into other courses and continued use lead one to assume that the analyses made after each year have given positive results, but there is still need for more thorough analyses to quantify the effects of the implementation of the MDPs and the changes in teaching. A retrospective analysis of all available written material collected during the five years is necessary and is currently in progress.

**Theoretical discussion of the MDP**

The Danish textbook for teacher education, Delta (Skott, Jess, & Hansen, 2008), was part of the syllabus for the course and in this book there is a presentation of Gomez cycle of didactic analysis (Gomez, 2002). Based on this work of Gomez an artefact for lesson planning named *The Mathematics Didactic planning tool* (MDP) was constructed by changing the original model to fit a Norwegian teaching and learning context informed by the work of Ball, Thames & Phelps (2008) and Niss and Højgaard (2011). Hence, the content of the MDP considered both mathematical, didactical and methodological theories that was based on the curriculum of the course, but focusing on different mathematical subjects for each assignment aiming at a (fictitious) classroom situation.

Gomez’ (2002) model for didactical analysis was inspired by the *teaching trajectory* of Simon (1995), which is a cyclic planning tool for mathematics teaching, and Shulman’s (1986) work on pedagogical content knowledge which later informed the development of *Mathematical content Knowledge for Teaching (MKT)* (Ball et al., 2008). MKT is divided into different theoretical issues like areas of *knowledge of content and curriculum, content and students, content and teaching, common content knowledge, specialized content knowledge*, and *horizon content knowledge* (Ball et al., 2008, p.403).

In the various parts of the MDP (Figure 1) these areas was conceptualized in terms of the *mathematical tasks for teaching* from Ball et al. (2008, p.400), such as for instance using *mathematical notation and language*, asking *productive mathematical questions*, and finding an example to make a specific mathematical point. Another theoretical framework used were the didactical and pedagogical competencies with specific regards to mathematics from the KOM-project (Niss & Højgaard, 2011). These are the eight mathematical competencies concerning mathematics as a discipline (chapter 4 and 5), and the six forms of specific competencies which a mathematics teacher should possess (chapter 6 and 7). The areas of knowledge concerns the students’ *competences of representing, symbol and formalism, communicating, aids and tools, mathematical thinking, problem-tackling, modelling, and reasoning*, and the teachers’ *competences of curriculum, teaching, revealing learning, and assessment* (Niss & Højgaard, 2011). In the following text these theoretical notions will briefly be discussed how to be used in the design of the different phases of the MDP; see Figure 1 for the presentation of the model.

A1 introduces and presents topic, grade and focus points from the National curriculum’s perspective. This provides the background for the PST choosing two or three textbooks, which the PST should analyse according to the mathematics topic and the focus points in the national curriculum. After which, they should make a short plan for teaching mathematics over a school year focusing on how to structure and organize given topics and argue for their choices. For instance, it would be wise to have worked with fractions and multiplication before an introduction to probability. A1 focus mainly
on theoretical aspects from *knowledge of content and curriculum* (Ball et al., 2008) and *the teacher competency of curriculum* (Niss & Højgaard, 2011).

A2 is the main part of the MDP where the PSTs works with their understanding of both knowledge about mathematics and didactical theories. It is important for the student to notice that the different parts of the plan (again see Figure 1) are meant to be understood and worked through in a hierarchical way. The theoretical aspects mainly focus on the MKT (Ball et al., 2008) and the competencies of teaching and learning (Niss & Højgaard, 2011), but of course additional theory is added when relevant.

The aim for this part is to formulate a plan for teaching the subject given, e.g. geometry, over a period of two to five lessons. In the first part (A2a), they present focus points and quality frameworks from the national curriculum to illustrate the frames and goals for the teaching and learning. Since the PSTs had no real class to teach, they had to make assumptions based on the information given in the national plans and other relevant sources such as e.g. textbooks. Analysis of mathematical content (A2b) illustrates “all” the mathematics that the PSTs knew about the subject given, including symbols, algorithms, different representations, modelling, etc. The goal of this part is to provoke the students to go deep into their own mathematical knowledge and analyse different aspects of mathematics without thinking about teaching or learning. In these analyses of mathematical content, the PSTs theoretical framework is knowledge about representing competency, symbol and formalism competency, communicating competency and aids and tools competency (Niss & Højgaard, 2011), which also illustrates general and special subject matter knowledge and horizon content knowledge (Ball et al., 2008).

Analysis of learning process (A2c) is about the students learning process in the specific subject given, e.g. geometry, not about general pedagogical learning theories. This part focuses on *knowledge of content and students* (Ball et al., 2008) for instance illustrated by knowledge about misconceptions, what could be difficult to understand and why, or how to support the learners that needed an extra challenge building on the mathematical issues discussed in A2b. Some of the same issues were the basis for the analysis of teaching (A2d), but this time the focus is teaching and to predicate how they can meet different situations that probably occur in teaching the mathematics subject given were, such as *asking productive mathematical questions* (Ball et al., 2008). This part is illustrating *knowledge of content and teaching* (Ball et al., 2008), and the teacher competencies about *teaching, revealing learning, and assessment* (Niss & Højgaard, 2011). Since the A2 is hierarchical built, the three analyses should be written in the way they are presented, the next building on the information given in the previous. A final and important task in A2 is to construct an open mathematics problem (A2e) with different levels of cognitive demands (Stein & Hiebert, 2009) which is based on knowledge gained from the three analyses. All the work is summed up in a schedule for the lesson(s) (A2f).

A3 is an individual written reflection assignment where the PSTs reflects on the decisions and analysis made in A1 and A2. Since A1 and A2 are carried out as group work, the final reflection gives each student the possibility to add his or her own perspectives on the process and the result of phases A1 and A2. The last phase, A3, has been a valuable resource for the on-going and continuing development and implementation of the MDP in the new course.
Final comments

Using different theoretical perspectives from previous research about teaching (Ball et al., 2008; Niss & Højgaard, 2011; Stein & Hiebert, 2009), the research design method for planning new teaching models (Cobb et al., 2003), and research-based models of lesson planning (Gomez, 2002), have been useful in designing and developing the new course in which the MDP serves as a backbone.

Although the PSTs’ practice in schools could not be integrated within the course, it could be argued that focusing on lesson planning by working with the MDP had a close connection to the practice of teaching mathematics, which was one intention of using lesson planning as a focal idea. Another was to elucidate the importance of theoretical argumentation when planning (and teaching) mathematics lessons and the intention of repeating the MDP several times became an important choice of performance since especially the complexity of A2 needed to be exercised several times. A profit of all the work was that all the MDPs together with the teachers’ comments were shared on a learning management system to be available for all the PSTs attending the course. When the PSTs finished the course, the students thus had a number of lesson plans ready to use (with adjustments) in their future career.

The empirical material available for analysing different aspects of the project is teachers’ logs, planning documents, students’ reflective papers from the course, students’ papers on didactical and mathematical analysis, and electronic records showing supervising dialogue during the writing of papers. The preliminary analysis of all the empirical material available, five years of teaching experience, and reading some of the PSTs’ final reflection notes indicates that the majority found the MDP challenging but educational, and that they experienced writing MDPs’ assignments to be valuable. Many argued that it would be too much work for planning lessons when working as a teacher, but that the experience of having done so during their education will influence their work as teachers.

There were a couple of practical changes made during the five years of study, such as to change the number of group members from groups up to 6, to working in pairs, and lowering the number of MDPs the students should work through from four in the first year to three the years following. Since the students only were on campus for a short time, much of the contact had to be via the Internet and became the common form of communication. Supervising the process of writing papers in this way had clear implications on the process. This is documented in several reflection notes where the PSTs explicitly wrote that they would not have gone so deep into the material if they had not been pushed by the supervisor.

In summing up, it seems like the MDP can be a good mediator for MKT and competencies. Further and more rigorous analysis of the empirical material will be valuable in documenting the proof of this indicative claim, and it should additionally provide more information and suggestions on how to enhance the MDP and the role of the supervisor.

This article is a description and discussion of a design research project in which we introduced a research idea about the influence of language on number concepts development into praxis on a school in grades K-3. Danish children have difficulties remembering the Danish number names because the Danish language resembles a primitive number concept in mathematical thinking. In the project, we renamed the numbers between 11-99 after the base-10 system. Our hypothesis was that this system would help Danish students to get a more secure concept about the base-10 system. The project lasted for three years ending in spring 2016. Our results were so convincing that the school decided to continue using the mathematical number names, and other schools that heard about the project seem to be interested in using the system as well. In other words, the project goes from being a top-down project to a bottom-up project.

Keywords: Design research, base-10 system, grades K-2, top-down and bottom-up project.

Introduction

In this article, we describe a design research project, which took place in a public school in the primary grades K-3. We started with a hypothesis, and then it moved on to a design and then contact with a public school. We ran the project for three years and then worked with the school on its continuation. The main concern of our paper is that of existing and anchoring projects that have proven successful and engaged (part of) the organization with which we have collaborated.

Our research idea was provoked by the fact that the Danish number names (Ejersbo & Misfeldt 2011; 2015) have an etymology and wording that are both peculiar and impractical. For example, in Danish, the number 73 is treoghhalvfjerds (three and half-four), the number 32 is toogtredive (two and thirty), and the number 16 is seksten (sixteen). These old roots are unknown to most students. Furthermore, the number names are abbreviated. In Danish, the number 70 or halvfjerds (half-four) was once named half-four-times-twenty (in Danish halvfjerdsindstyve), but the times-twenty (in Danish sindstyve) has been lost in the counting numbers but retained in the ordinal numbers (for further explanation, see Ejersbo and Misfeldt, 2011). Another concern is the irregularity of the number names between 10 and 20, where 11 and 12 have unique names while 13 to 19 each end with a ten. Also, the two-digit numbers from 13 to 99 have an inversion property (the ones are said before the tens), and the tens have names inspired by a 20-base system.

Even though Danish number names are particularly irregular, most European languages break away from the clear regularity of the base-10 place value system. So understanding the effects of such irregularities on mathematics teaching and learning is interesting. With that motivation, we developed a hypothesis of how speaking about numbers with specific regular words that resemble the base-10 system would be beneficial for learning about the numbers in an easier way. This hypothesis has been tested with a three-year long intervention at a school in the Copenhagen area.
The project has ended, and the intervention was to a large extent successful. The data about student learning confirms that the classes where the new words for numbers system was successfully implemented have very strong performances in the areas related to number sense and arithmetic. Therefore, some of the teachers and the school organization would like to continue the work. We consequently discuss the question of how to exit intervention projects while anchoring relevant practices from the intervention into the organization.

In the paper we explore how this initial hypothesis has been activated as a way of using language as a didactical tool in a design research project. We will describe the state of the art that allowed us to develop the project idea, and how the project proceeded. Then we will briefly state our results in terms of a more well developed and tested set of hypotheses. Finally, we will describe our exit strategy for leaving a better practice at the school and reaching out to other schools and teachers.

**Number concepts, base-10 and number names**

We know from the research literature that there are major differences in the kind of system and regularities a language uses to describe numbers. Most European countries have an irregular naming system for numbers between 11 and 20; both the German and Dutch systems feature an inversion property of the numbers between 13 and 99, similar to the Danish one. These inversion effects were studied by Moeller, Pixner, Zuber, Kaufman, and Nuerk (2011) for two-digit numbers, showing how inversion-related difficulties predict later arithmetic performance (for an overview, see Ejersbo and Misfeldt, 2011, 2015).

Different studies (Miura & Okamoto, 1989; Miura, Okamoto, Chungsoon, Steere, & Fayol, 1993; Miura, Okamoto, Vlahovic-Stetic, Kim, & Han, 1999) compared Japanese, Chinese, Korean, and English-speaking American first graders’ (6–7 years old on average) cognitive representations and understanding of place value. The findings confirmed that the Asian-language speakers showed a preference for using base-10 representations to construct numbers, whereas English speakers favored using a collection of units. Note that a significant difference between American and Asian number names appears between the numbers 11 and 19, exactly when the base-10 system starts to use two digits. In Miura and Okamoto’s (1989) study, children were asked to construct the numbers 11, 13, 28, 30, and 42 from sets of ten and unit wooden blocks. The results showed that 91% of the American first graders used unit blocks to represent the numbers on their first attempt. In contrast, about 80% of the Asian children used sets of ten blocks when representing the numbers on their initial attempt. These differences in cognitive representation were mainly ascribed to language (Miura et al., 1993).

Learning to count and understand the base-10 system are cognitive challenges involving many small steps. We have chosen to focus on oral counting, the cardinal principle of combining a name with a cardinal value, and the combination of words for a number, its cardinal value, and the digit sign.

Children typically learn the names of numbers as a long list of words and demonstrate knowledge of the stable order principle by almost always saying number words in a constant order while emphasizing the last number (Goswami, 2008). The names are developed as sounds connected to the number of objects in the sets.
The developmental shift to understanding the number name as a cardinal value requires a qualitative shift in children’s representation of numbers. The cardinal principle requires comprehension of the logic behind counting (Goswami, 2008) and the ability to judge the size of a set. It relies on a representation of quantitative information in which the coding of smaller quantities is different from that of larger quantities (Goswami, 2008). Children’s conceptual understanding of numeration depends on their ability to make a connection between a number name and its cardinal value, which they learn to do by grouping and quantifying sets of objects (Thomas, Mulligan, & Goldin, 2002).

Learning how to connect the number name, its cardinal value, and the digit sign is another challenge. As discussed, two different systems must be combined with different representations. Becoming an expert at combining these two systems means developing rapid access to an automatic use of written numbers and simultaneously being able to multitask to solve other problems in parallel. If the two systems are iconic and support each other, the child encounters less difficulty in learning this skill, as is the case for Japanese-speaking children. If the two systems are irregular and therefore conflict with each other, it is more problematic for the child to understand and remember the connection among the name, the cardinal value, and the sign. Duval (2006) described this situation as a conversion between registers and observed that the congruent conversions seem the easiest for students, meaning that the representation in the starting register is transparent to the target register. One obvious solution is, therefore, to use a fully regular approach to saying the names of the numbers, which means saying “one-ten and four” instead of fourteen and so on. It is possible and easy to create such a logical system for naming the numbers in Danish, and thus this became our main project idea.

This reasoning helped to form the project idea of using such logical number names as a didactical tool.

The design of a research idea

Occupied by these issues of why and how different languages influence number concepts and perhaps even the ability to learn simple arithmetic, we designed a three-year project to take place at a Danish public school in the suburbs of Copenhagen.

Using design research (Cobb & Gravemeijer, 2008), we formulated our hypotheses for empirical investigation. The hypotheses were grounded in our initial understanding of the difficulties that Danish children experience with the Danish number names. The research builds on the following two hypotheses:

1. Number names function as cognitive artifacts; hence, a concordance between spoken and written language is sensible.
2. Language constitutes concepts, which is why clear terminology seems effective in developing lucid concepts.

Project intervention

To address the question of the influence of number names on number concepts, we contacted a Danish public school that could be interested to run the project together with us. We already knew the school, which made the access easier. We were invited to a meeting with the leading team of the
school, including the headmaster, together with a small group of teachers from the school. We
presented our project, and the participants accepted it for one year as a start. An evaluation would
decide if it should continue additionally for two more years. We decided to involve all 10 classes—
three grade 2, three grade 1, four kindergarten classes—and 9 teachers in the primary section of the
school. The project combined the renaming of numbers with supporting the teachers in instructing
the students. In each class, 20–35% was children who had migrated from other countries, but all the
children spoke Danish, and all the teaching was in Danish. The entire research project was planned
to last for three years. The data consists of students’ performance in classroom observations, a
number understanding test, teachers’ portfolios, interviews with teachers and students, and notes
from collaboration with teachers. At the end of the projects, we used the national test for evaluating
the students’ competencies in Algebra and Numbers.

The first year

The cooperation with the teachers and the classes were only possible because of the positive attitude
from the headmaster of the school. She left it to us, the researchers and the teachers, to run the
project. But she and the leading team was helpful and showed interest the whole time.

An in-service course for the involved teachers was the first thing to arrange and run. At this course
many questions came up and were discussed. Should the teachers always rename both the names of
the numbers? How should the fractions be named? Would the student get to know the normal
Danish number names? We made a lot of decisions that day and agreed that the teachers should
write a log with further questions that we as researchers should answer, either by discussion or by
recording answers in the log.

The participants were now ready to start the next school year with the mathematical numbers.

Kindergarten: The Kindergarten (K) teachers were used to cooperating with each other and
continued this work with the mathematical numbers. We observed the classrooms regularly and had
follow-up meetings. The K teachers used both the mathematical number names and the normal
number names when they named a number, or the students read a number. They also arranged joint
counting for all using mathematical numbers, and they made materials for student use that helped
the students to be aware of the base-10 position system, and the students became very familiar with
the mathematical numbers. The parents were informed at a meeting with the kindergarten teachers
only; all in all, they implemented the mathematical numbers very easily.

Grade 1: The project proceeded differently in the first-grade classrooms. All these classes had new
teachers, which is normal for students in the first grade in Denmark. We were in a real-world
situation with all the mess that exists there. The three first-grade classes had three different teachers
who did not work together very often, and none of them continued the work done by the K class
teachers. So the routines disappeared. The big difference in practice between first grade and the K
class caused some chaos during the first two months. Furthermore, some of the first-grade teachers
left the school or their classes during that period. But new teachers came, and during November and
December the classes also worked regularly with the mathematical numbers. We were lucky that
one of the newcomers believed in the project idea and was very involved with it. He became a
teacher in two of the three first-grade classes, and his presence was a great benefit for the project.
**Grade 2:** We never observed any of these classes, but met with the teachers and discussed how they could implement the mathematical numbers in the best way. These students had already been in school for two years, and we decided that while we could not expect that they would naturally use the mathematical numbers, they should know them.

**Evaluation:** In the first year we were very busy collecting data, observing the seven classes, and trying to find the best ways to implement the mathematical numbers. The teachers’ log idea never caught on, so we solved any problems during our meetings with the teachers. At the end of the year, we tested all the students. The outcome of the test showed us that the student used both names for the numbers quite naturally. There was a slight tendency that the students were more secure from the spoken mathematical numbers to written numbers than from the spoken normal numbers to written numbers. In the K classes, we noticed that the students were much more secure in correctly recognizing and naming numbers between 10 and 20 than was normal for these classes.

During the year, we used the design research method as a way to evaluate the actual lesson related to how the whole project was running. We exchanged good ideas and noticed the progress and difficulties. We solved the difficulties in different ways and changed some of our means; but not our goal. We made a report of the first year with our results and data. It was positively received by the leading team, who decided to let the project continue for the next two years.

In our plan for the second year we decided not to observe in the K classes, but only meet with the K teachers. We would do a brief orientation for the new mathematics teachers in the four new first grades, and we would follow the second grades more intensively.

**The second year**

For each year, we expanded our research with new K classes and with that also thirds grades. The K teachers could more or less develop and repeat with their new students what they had done first year. The newcomers in the K teacher group were taught by especially one of the K teachers taking the major responsibility for informing the new teachers. As we discussed in our meetings with the teachers, the work in the K classes went very smoothly.

The four new first grades had new teachers, luckily only two teachers with two classes each. They did not know anything about the project before they chose to teach first-grade mathematics, but cooperated from the start. We met with them and introduced them to the project, and visited their classrooms several times during the year.

The three second grades were the most interesting, because the students were in their second year of the project. Their teachers were very engaged and consistent in the use of the mathematical numbers. Each time we observed the classroom we talked with the students and asked how they felt using two different names for one number. The answers were surprising:

- **Student 1:** It is fun, and we like to use the mathematical number names, because then we always are able to remember the names.
- **Student 2:** We also know the cardinal at once.
- **Student 3:** It is a help to remember the names of the normal number as well.
We were a little overwhelmed but agreed with the students that they should explain to their parents why we used the mathematical number names. We decided that no one could do it better than them.

At the end of the year, we used the same test we had used in the first year but only with the first and second grade. We noticed again that the students’ understanding of numbers was very good, both for the use of normal number names and for the mathematical number names.

Due to the time we had to do the project, and how it developed in the school, we decided to minimize the observation to only the three third-grade classes, but we still met with the teachers from second grade. We did not observe the first grades or meet with their teachers. We continued with the K teachers’ meetings.

The third year

We mostly concentrated our research on grade three and the kindergarten classes. The use of the mathematical number names seemed very natural for the students together with the normal number names, and they were bilingual in the numbers from 10–99. In third grade, the students were so familiar with the base-10 value system that they could transfer the knowledge to the decimal numbers, which meant that they easily answered questions correctly when asked to compare numbers like 0.4 and 0.25. In May 2016, the three classes had the national test in mathematics for third grade. Compared to the average of all the third graders in Denmark, one of the third-grade classes—the one that was observed most frequently—had an average score in Numbers and Algebra that was far above average. The other third-grade classes also showed a better result in Numbers and Algebra than the average third-graders.

The conclusion we draw was that the students using the new system showed a better understanding of the base-10 system. We saw these competencies, and met our goals, in all the classes which used the mathematical numbers. And because the national test investigates additional competencies in Numbers and Algebra, we dared to conclude that the students gained from using two names for the numbers.

During the following year, the school had a new headmaster and a new leading board, but because of the results, she decided to continue with the mathematical number names even though the research project stopped.

From Top-down to Bottom-up

With the decision that the school wanted to continue using the mathematical number names after our exit, we needed to design a plan for how it could be possible. Inspired by the research (Jarvis, 1999; Nielsen, 2001) we suggested the following plan:

1. All the teachers at the school should know that the project stopped as a research project, but that the project would continue as an intervention project with the teachers as the drivers.

2. One K teacher should be responsible for introducing the methods in the K classes for incoming teacher and for ideas to be exchanged among the K teachers.
3. A mathematics teacher should be responsible for orientation of the mathematics teachers in first grade each year and arrange a course at the beginning of the new school year, which everybody could join in.

4. There will still be access to the researchers for questions and other things; we are interested in the continuing process.

This plan was first discussed with the involved teachers who agreed to the work they should do, and then it was presented to the headmaster. She also agreed and was willing to find time for the teacher support.

We started the process with a course for mathematics teachers in the K-3 classes in August 2016. There were about 15 people at the course, which was organized and run by a K teacher, a mathematics teacher, and one of the researchers. At this course, we made a quick run through the ideas behind the project and how it had run in the previous three years. The teachers who had previously taught classes and been involved in the project exchanged ideas and views of the learning processes with the mathematical numbers. The K teacher told how she was at an in-service course for K teachers in the Copenhagen region and told about the project and how she and the math supervisor at the school videotaped how she used the mathematical number names in the K classes. The other participants at the in-service course showed a big interest in the project. A similar course will be held again, and the math supervisor has told us that there is already a big interest in this in-service course.

Discussion

This article is less concerned with the actual results of the investigations that we conducted in the school and more concerned with the transition from an intervention driven by research curiosity to an ongoing project driven by the school itself.

The project was large with many classes involved, and we must admit that it was a little too big for only two researchers on a very low budget. We shared the work, so at times only one of us made the observations, conducted the interviews, and participated in the meetings with the teachers. Everything was documented with taping, pictures, and materials that we analyzed together; we still have data waiting for deeper analysis.

In spite of the low budget and the few researchers, or maybe because of these limitations, we saw some teachers taking over the project in an especially engaged way. One teacher, in particular, took a lot of responsibility and during a period when other teachers were out sick, he taught all the three classes in third grade. Without him, we are not sure the project would have had the success it had. It would neither be possible to run such a project without the support and interest we had from the leading team including the head master, who played an important role.

Perspectives

As it looks now, we hope that the use of mathematics number names will spread to other schools and continue to develop. Even though we officially stopped the project at a meeting with all the
teachers at the school, we will continue with some kind of support if necessary. We will also stay in touch for our own sake.

Acknowledgment

We would like to thank Husum Skole, Copenhagen, for financial support together with the teachers, who worked for the project.

The notion and role of “detection tests”
in the Danish upper secondary “maths counsellor” programme

Uffe Thomas Jankvist1 and Mogens Niss2

1Aarhus University, Danish School of Education, Denmark; utj@edu.au.dk
2Roskilde University, IMFUFA, Denmark; mn@ruc.dk

This paper presents and discusses a specific aspect of the Danish “maths counsellor” programme for upper secondary school, namely that of detection tests. More precisely, the purpose and design of a detection test is presented, as is the prospective counsellors’ use of the test. In the description, emphasis is placed on the ways in which detection tests assist in informing the maths counsellors in their work with students experiencing learning difficulties in mathematics.

Keywords: Detection test, “maths counsellor”, learning difficulties.

Introduction

The words “test” and “testing” are omnipresent in educational research and practice in general and in mathematics education in particular. However, the actual notions covered by these terms are very diverse, as are their roles and uses. Basically, the terms mean “critical examination of a person’s or a thing’s qualities”. There is an abundance of different purposes, goals and objects of testing, as well as a multitude of different approaches to and instruments for testing. Without attempting to outline a comprehensive theory of test and testing, one distinction is worth introducing in the context of mathematics education, a distinction between direct and indirect testing. In direct testing, the test object directly epitomises the very purpose and goal of the testing. If your purpose is to find out whether a given person can actually drive a car, a direct test consists of taking the person to trial in real car driving. In indirect testing, the test object is devised as an indirect indicator of something that is not identical to the test object itself, because this “something” is either inaccessible in direct terms or too large or too complex to be fully represented by the test object. So the test object becomes a proxy for the underlying, but necessarily indirect, object of testing. Mathematical learning, understanding, reasoning, modelling, and problem solving are just a few examples of such underlying objects of testing, for which a wide variety of test objects are only more or less well-chosen proxies. Mathematics education research and practice make extensive use of indirect testing, alongside direct testing.

The key issue concerning indirect testing is what relationships can be established between respondents’ responses to the test object and the real underlying object of testing. The generic question is: What do responses to the test object tell us about the respondent’s qualities in relation to the real underlying object of testing. Since, in indirect testing, these objects are not identical it requires a non-trivial amount of clarification of concepts, of interpretation and analysis, and oftentimes of independent empirical research to account for the inferences that can be justifiedly drawn from responses to the test object onto the underlying object of testing. The “detection tests” in focus in this paper are instruments for indirect testing. So, the above-mentioned generic question has to be specified for our context. Our research question then is: In what respects and to what
extent does the detection test presented below allow for the detection of students with mathematics specific learning difficulties regarding mathematical concepts and concept formation?

Due to space limitations we are not able to fully answer this question here and to fully corroborate the answer. Instead, we confine ourselves to providing some key points in an answer, that is by describing the context in which the detection tests are used; by providing an overall description of what a detection test is; and finally by means of an illustrative and authentic example. It should be noted that although the actual content of the detection tests is based on research findings and issues considered in the mathematics education literature, the notion and role of “detection test” in the sense presented here have been introduced by us and thus have not been described previously.

The “maths counsellor” programme

This section is based on (Jankvist & Niss, 2016). The maths counsellor in-service teacher programme at Roskilde University (Jankvist & Niss, 2015) runs part time over three semesters (in total 30 ECTS – European Credit Transfer and Accumulation System), during which the upper secondary teachers – ideally – have a reduced teaching load at their schools. Each semester has an overarching theme: (1) concepts and concept formation in mathematics; (2) reasoning, proofs and proving; (3) models and modelling. These themes were chosen both because they are significant to upper secondary mathematics education in Denmark, as is spelled out in the national curriculum documents, and because they epitomise key aspects of the eight mathematical competencies in the Danish KOM-project (Niss & Højgaard, 2011), which constitutes the theoretical foundation of the maths counsellor programme. The teachers’ work in each semester is structured in terms of three different phases: (1) to identify (i.e., detect and select) students with genuine learning difficulties in mathematics; (2) to diagnose the learning difficulties of the student(s) identified; and finally (3) undertaking intervention according to the diagnosis arrived at with respect to the individual student.

At the very beginning of each semester, the teachers are equipped with a theme-specific detection test, consisting of questions and tasks for the students in relevant classes at their schools. As will be exemplified below, these tests are developed by us and are informed by research literature regarding the specific theme. The purpose of the test is to assist the teachers in detecting students with potential learning difficulties in mathematics. Usually, each teacher detects several such students, some of whom are selected for being offered maths counselling with the aim of rectifying or reducing the observed difficulties during the semester. This typically leads to the identification of 1-4 students per class in need of, and also interested in, receiving counselling. When speaking of mathematics specific learning difficulties, we rely on our previous definition given in (Jankvist & Niss, 2015, p. 260), i.e. “those seemingly unsurmountable obstacles and impediments – stumbling blocks – which some students encounter in their attempt to learn the subject. These stumbling blocks include, but are not limited to, a wide range of misconceptions, misinterpretations, misguided procedures, inadequate beliefs etc. with regard to established notions of mathematics. We do not include general learning disabilities, cognitive or affective disorders and the like.” The purpose of the counselling is not to motivate unmotivated students, but to assist those who work hard in mathematics on a daily basis but do not succeed.

In the diagnosing phase, the participating teachers – strongly assisted by the research literature they read as part of the programme (see Jankvist & Niss, 2015) – employ self-constructed tasks,
interviews, etc., to come to grips with the nature and origin of the students’ mathematics specific learning difficulties. Taking the diagnosis as the point of departure and with support from the research literature and supervision by us, the teachers design and implement an intervention scheme for the students selected. The intervention scheme also includes steps which enable the counsellors to “measure” in what respects and to what extent the intervention has worked as anticipated for the selected students. For each semester, groups of 2-3 teachers write up a report. After the completion of the third semester, all three reports are combined into one, along with an introductory chapter. This final report forms the basis for a final oral exam at the university. The teachers who pass receive a diploma as certified maths counsellor.

**What is a detection test – and what is it not?**

A detection test, as designed for the Danish “maths counsellor” programme, is a set of maths questions to be answered by upper secondary student classes (grades 10-12) within a time frame of 60-90 minutes without time pressure. The questions are short, both in their formulation and in the sense that they neither require lengthy procedures or computations nor longwinded explanations. Moreover, the questions do not involve conceptually complex or technically involved mathematics beyond standard upper secondary school mathematics. However, the questions are usually not routine questions either. On the contrary, many of them are deliberately posed in such a way that they break the “didactical contract” of upper secondary mathematics and require students to think and act independently. Danish upper secondary school takes three years and students usually enter at the age of 16 after having completed ten years of mandatory comprehensive primary and lower secondary schooling. Upper secondary students can choose to have mathematics for one, two or three years; three years being the advanced level. Danish upper secondary school covers three streams: general, technical, and business.

The primary purpose of a detection test is to be one among several instruments for detecting students possessing genuine learning difficulties in mathematics, within the relevant theme of the programme. So, the focus is not primarily on detecting the difficulties themselves – even though the tests do have something to offer to that end as well, because the questions in a detection test are composed such that wrong answers, individually or in combination with others, may suggest the potential presence of particular kinds of learning difficulties with a student giving these responses. As mentioned, a detection test is not meant to stand alone. When it comes to detecting students with learning difficulties, other sources of information, e.g. the teacher’s prior knowledge of the students have to be taken into account as well. More precisely, a detection test may be seen as having three different roles. Firstly, in cases when the test, within a certain area or theme, points out students who by the teacher/counsellor were already suspected to have difficulties within that area, the role of the detection test is to strengthen the teacher’s observations. Secondly, in cases when the test singles out students who were not already detected by the teacher, the test serves to amplify and sharpen the teacher’s attention and to supplement his or her own observations of the students. Thirdly, it is also a purpose of the detection test to provide an initial support in pointing out the specific sub-domains within the test’s theme, in which a detected student displays difficulties. Of course, students’ test responses may not only indicate difficulties within particular mathematical topics; students’ response patterns may also suggest overarching difficulties of a more principal or
general nature. Thus, this third role of a detection test then typically is to provide inspiration for the following “diagnosis” (cf. later sections).

It is important to keep in mind that a detection test is not meant to be a fair test of the students’ attainment levels in the subject of mathematics, neither when it comes to content knowledge, skills, and proficiency, nor when it comes to mathematical competence at large or to inventiveness or special mathematical talent. Due to the fact that detection tests are designed with a different purpose in mind, several important aspects of the usual handling of mathematics – e.g. familiarity with concepts and facts, computational skills, or proficiency in solving standard routine tasks – are not in focus of the tests. Similarly, the test cannot be used as a screening test in the usual sense, attempting to chart students’ possession of various mathematical competencies. However, employed on a larger population of students, e.g. a year group in a given school, the test may of course be used as a screening test for the potential presence of mathematics specific learning difficulties pertaining the theme of the test, within this population, but the test is still much more focused than a general screening test for attainment level or competencies.

Even though the test contributes to singling out students with potential learning difficulties, it cannot determine, in itself, whether a given student actually possesses such difficulties. It is certainly possible to encounter poorly performing students whose erroneous answers are not due to mathematics specific difficulties, but to ill-will and shoddy job, lack of accept of the didactical contract with or in the test (e.g. because the test is not supposed to influence teachers’ marks, or because the questions are of a different nature than usually encountered by the students), a bad day on the time of testing, or maybe to much more general learning difficulties (or disabilities) that manifest themselves in several subjects, not only in mathematics. To determine whether a student detected by the test actually possesses mathematics specific difficulties, supplementary means must be applied as well, not least the teacher’s knowledge of the student.

Beside the fact that the test, for a student who has been “detected” by it, may provide important indications for a subsequent diagnosis of mathematics specific difficulties, the test is not a diagnostic test. It requires an independent diagnostic process to uncover the specific nature of observed learning difficulties as well as the sources actually responsible for them. Oftentimes, preliminary hypotheses concerning the nature of the difficulties, and what may have caused them, must be supplemented with – or even replaced by – other hypotheses as the diagnosis proceeds. This may be due to much more deeply rooted difficulties than the ones observed at first, e.g. regarding more fundamental mathematical conceptions and beliefs than those in focus of the detection test.

An illustrative example of algebraic equations and equation solving

As mentioned above, in each semester of the programme the maths counsellors are equipped with a detection test related to the theme of the semester. Hence, detection test 1 concerns mathematical concepts and concept formation (we intent to discuss detection tests 2 and 3 in subsequent publications). This test consists of some 57 questions (and sub-questions) on selected topics relevant for Danish upper secondary school. These include: concepts of number (including fractions, decimals, negative numbers, irrational numbers); percent; algebraic expressions and transformations; equations (first and second degree, with different types of numbers as coefficients and solutions, and with the unknown on both sides of the equal sign); simple functions and aspects

Proceedings of CERME10

3828
of the coordinate system; and finally a selection of mathematical conventions such as: different symbolic notations for fractions; the equal sign; the inequality sign; minus and negative numbers. Out of the 57 questions (with sub-questions) around ten questions concern equations and equation solving. In the following we shall focus on examples of this.

As suggested by various researchers (see e.g. Kieran, 2007), students’ difficulties in solving algebraic equations are of two rather distinct kinds. The first kind is related to transformation of equations – and algebraic expressions – by means of permissible operations, eventually leading to solutions. This not only involves knowing and understanding the scope and legality of the operations at issue, it is also to do with the nature and structure of the number domains implicated, the meaning of the equal sign, and the arithmetic operations involved, etc. The second kind of difficulty is to do with what an equation actually is, and what it means for an object to be a solution to an equation. Detection test 1 includes the following questions, among others: [17] Are there any values of $a$ such that $a^2 = 2a$? [18] Are there any values of $b$ such that $4b = 4 + b$? [20] What is the solution(s) to the equation: $3x - x = 2x$? [25] Is $x = 0$ a solution to the equation: $3x - x = 2x$? [35a] Solve the equation: $3x + 20 = x + 64$. [36a] Solve the equation: $-6x = 24$. [37] For what $x$ do we have $38x + 72 = 38x$? Our purpose here is to illustrate two things: what the maths counsellor may learn from using the test on a larger population of students; and what the maths counsellor may learn about a single student from his or her answers to the test questions.

When a maths counsellor gives the detection test to a group of students, perhaps a larger cohort of students – say a class or a year group – certain patterns are likely to reveal themselves. For example questions 17 and 18 may tell us something about the students’ algebraic understanding, e.g. the students’ perception of how variables may and may not be denoted (anything other than $x$ is often rejected as a variable). Questions 35a and 36a address the first kind of difficulty of solving algebraic equations, namely the operational aspect in relation to the number domains involved. Question 35a is an example of what Filloy and Rojano (1989) call a “non-arithmetical equation”, referring to the fact that the unknown appears on both sides of the equal sign. Question 36a may give rise to difficulties due to the appearance of the negative coefficient and division by a negative number, but also the situation of having to accept a negative number as a solution. On the one hand, questions 17, 20, and 25 may tell us about the second kind of difficulty mentioned above, i.e. knowing what a solution to an equation means, as well as about the consequences of the fact that an equation may have infinitely many solutions. On the other hand, they may also tell us something about the students’ conception of equality in relation to equations and equation solving. From extensive experience, we know that Danish students have difficulties with equations that have either no solutions or any number as a solution. Question 37 addresses another aspect of the second kind of difficulty. Despite the fact that the vast majority of students are not able to correctly answer question 20, a large number of students will say that $0$ is indeed a solution to the same equation in question 25. More interesting, perhaps, are those students who are able to answer that all numbers satisfy the equation $3x - x = 2x$, but still answer “no” to $0$ being a solution. This may have to do with a belief that solutions are positive integers or be an aspect of more fundamental difficulties with $0$.

To illustrate what an overview of a large student population may reveal, we provide table 1, which displays a binary (“correct-incorrect”) coding of 676 Danish upper secondary students’ responses from 2012 and 2013 (from all three levels and streams). For the 405 1st year students participating in
the study we may confirm that questions 20 and 37 are indeed difficult ones, since 92.8% and 85.4%, respectively, cannot answer them correctly.

As an illustration of two maths counsellors’ use of the test in regard to equations and equation solving, we present the story of student Å (Christensen, 2016). Student Å followed the mathematics programme at intermediate level at a general upper secondary school. The two maths counsellors spotted student Å at the beginning of Year 1, and then worked with her for three consecutive semesters, while they themselves were enrolled in the maths counsellor programme. In relation to the above questions on equations, student Å answered incorrectly on both questions 17 and 18 (“no”), she left question 20 unanswered but answered question 25 incorrectly (“no”), and left questions 35, 36, and 37 unanswered. The two maths counsellors initially interpreted this as if she had difficulties with the transformation of algebraic equations and with algebraic expressions in general, since she also gave incorrect answers to: [6] What is \((a/b) \cdot (b/a)\)? (Where neither \(a\) nor \(b\) is 0.) (Å: “\(a^2/b^2\)”.) and [50] If \(a = b\) is then \(b = a\)? (Å: “no.”).

Table 1: Binary coding of 676 student answers to selected questions from detection test 1 (coding by Morten Elkjær Hansen as part of his master’s thesis at Aarhus University, 2016)

Based on interviews which confirmed that student Å most certainly had difficulties in solving algebraic equations, and handling algebraic expressions in general, the two maths counsellors designed a series of small interventions focusing on solving various equations, arithmetic as well as algebraic ones, etc. (Filloy & Rojano, 1989). Soon, however, the maths counsellors began to suspect that Å’s difficulties had indeed deeper roots. Student Å found that negative numbers as well as fractions were “ugly”, and on one occasion she uttered “0 that’s not a number!” Sometimes student Å had difficulty at distinguishing the operations of addition and multiplication. When trying to find the difference between two numbers, she counted on her fingers. When having to find how many times 8 divides 24, she answered “four” by counting “8, 12, 16, 24”, and even double checked the result by repeating the same count. Having to perform the division 24/6, she eventually gave up and replied “I don’t know when the numbers are so big.” It turned out that student Å had fundamental difficulties with the concept of number, including understanding of numbers, number domains and handling of numbers. She appeared only to be on safe ground when operating with small natural numbers, where calculations can be performed on her fingers. Student Å’s difficulties extended to her (in)ability to correctly apply basic mathematical terms. Thus, on a later occasion she used the term “diameter” (of a pizza) as just another unit along with centimeter and millimeter.
Upon revealing the depth of student Å’s difficulties and acknowledging these to be the cause of her symptomatic difficulties with equation solving, the obvious question becomes whether the detection test might have provided us with some indications of this. In hindsight, even if there were several questions that Å left unanswered, the ones she answered erroneously do seem to corroborate her subsequently revealed learning difficulties: [7] Is the number – a positive or negative or is it not possible to decide this? (Å: “negative”). [13] Which number is larger: 13/3 or 13/4? (Å: “13/4”). [15a] What is \( x + 0 \)? (Å: “0x”). [26] Round off 148.72 + 51.351 to an integer. (Å: “149 + 51 = 191”). [27] Which of the following fractions are equal: 1/4, 4/16, 4/12, 2/8? (Å: “4/12 and 2/8”). [52] If \( a < b \) is \( b > a \)? (Å: “no”). [53] Is \( (a - 1) / (b + 1) = (a / b) - 1 \)? (Å: "yes"). 55. Is \( (a + 3) / (a + 4) = 3/4 \)? (Å: "yes"). 56. Is \( (a - 1) / (b - 1) = a / b \)? (Å: "yes").

In total, the occurrence of the above erroneous answers, together with the responses to the previous questions on equations, indicates the presence of a manifest learning difficulty syndrome with student Å.

The revelation of mathematics specific learning difficulty “syndromes”

We now return to our research question, i.e. in what respect and to what extent do detection tests allow for the detection of students with mathematics specific learning difficulties – here exemplified by concepts and concept formation regarding equations and equation solving? As we saw in the case of student Å, she most certainly was detected to possess the potential learning difficulties as suggested by the test. Clearly, the counsellors’ first hypothesis concerning Å’s difficulties regarding concepts and concept formation was insufficient. However, we should keep in mind that this was the first time ever that these counsellors used the instrument of an indirect detection test. Once the maths counsellors become accustomed to the instrument and skilled in using it, they tell us that they are able to make much more accurate initial hypotheses – or even preliminary “diagnoses”. Indeed, having experienced a case like student Å, our two maths counsellors are able to make much more qualified initial hypotheses concerning students’ difficulties. Seeing the answers to the questions above on numbers, conventions, etc., these maths counsellors will no longer suspect a student “merely” to have difficulties with solving first degree equations; they will see this as a likely symptom of more deeply rooted and fundamental difficulties.

Indirect tests, such as the detection test outlined above, may mislead the interpreter of test outcomes in several ways. In the case of student Å we saw that the maths counsellors at first mistook the student’s apparent difficulties for her real, more fundamental difficulties. Another example, which we have also seen time and again, is where students are perfectly able to solve algebraic equations in an instrumental manner, but do not understand the relational aspects of the operations they perform or the very meaning of the solutions they arrive at (for references, see Jankvist & Niss, 2015). This is to say that if the aim is to “train monkeys” to find solutions to equations, then this is certainly possible. Our aim with the indirect detection test is to go deeper, since “our” object of learning is more complex than to mechanically obtain a solution. Our aim is to pave the way for drawing conclusions that are much broader than what the test questions ask, taken at face value, e.g. we insert “spot probes” into aspects of students’ mastery of numbers and algebraic expressions and attempt to come up with hypotheses concerning their concept of number in general: if a student comes up with this and that erroneous answer, (s)he most likely possesses such and such learning difficulties; or if, on the contrary, the student can give correct answers on this particular set of
questions, then it is fair to assume that (s)he has actually grasped, in a relational manner, something significant about the entities involved.

As illustrated above, an indirect test such as a detection test may function both on an individual student level and on larger populations. For example, in the case of student Å we noticed that she answered incorrectly to question 15 and question 50 (cf. above). This we interpret as an indication of student Å not believing 0 to be a number and possibly possessing misconceptions of equality. But how special are these misconceptions for a 1st year student like Å? The coding among the 405 1st year students displayed in table 1 revealed an error rate of 18.3 for question 15 and 13.6 for question 50. In addition, question 14, asking what $0 \cdot x$ is, which student Å answered correctly, has an error rate of 18.8 among the 405 1st year students. This is to say that if questions 14 and 15 are taken as markers of difficulties with the number 0, and if the population of the 405 students is representative, then it might be expected that more than one sixth of the students in a class at the beginning of Year 1 will have the number 0 as a “stumbling block” in some sense. The indirect detection test may suggest the presence of syndromes, on an individual level as well as on the level of populations.

Students’ video tutorials as a means for supporting and analysing their reflections on the limit concept

We discuss how a theory based design for students’ production of video-tutorials explaining problem solving activities in a first year calculus course can support the students’ conceptual learning. We focus on the limit concept and show how the production of tutorials can facilitate the students’ interactions and reflections and at the same time provide a rich source for analyzing their learning difficulties in relation to key concepts. The theory based design of students’ productions of tutorials and the following analyses can inform and support the development and implementation of the learning environment in order to facilitate better the students’ conceptual learning.

Keywords: Limit concept, calculus, student produced video-tutorials, student-student interactions, theories on the learning of mathematical concepts, learning environment.

Introduction and research questions

The many papers in the literature of mathematics education devoted to calculus signify the difficulties with the teaching and learning of calculus with the limit concept as one of the fundamental challenges (Rasmussen & Borba, 2014). In this paper we present and discuss a theory based design and its implementation for students’ productions of tutorials aimed at supporting the students’ learning of the limit concept. The research was related to a teaching experiment in a first year calculus course at Roskilde University, where the students produced tutorials with the app Explain Everything\(^1\) or similar apps. Building on theories explaining general learning difficulties with mathematical concepts such as the notion of students’ concepts images (Vinner & Dreyfus, 1989) and Sfard’s (1991) model for formation of mathematical concepts and the importance of communication in the learning of mathematics (Sfard, 2008) a didactic tutorial activity was designed. The purpose was to get the students to express their images of key mathematical concepts in dialogues with their fellow students and to support their concept formation process in particularly with respect to their use of symbolic representations and their reification of key concepts such as the derivative, integral and limit concepts as mathematical objects. The activity was designed and implemented as an assignment; namely to produce in small groups video tutorials explaining the group’s solution to selected exercises and the mathematical basis hereof, see figure 1. In the assignment specific requirements for the workflow of the students’ production were given in order to support the didactic purpose. The tutorials were used as a resource by the students at the course and in preparing for the final.

In the design and implementation of the experiment the basic idea was to use the digital tutorial genre to create a theory directed learning environment that encouraged the students to communicate with each other about mathematical theory, concepts and techniques. The tutorial genre mediated

\(^1\) The pedagogical set up was developed in collaboration with Maja Bødtcher-Hansen, University of Copenhagen.
student-student interactions and hereby supported students’ reflections on key mathematical concepts. The didactical assumption was that by focusing the students’ attention on the production of tutorials, aimed at supporting their fellow students’ learning, it would be possible to create situations where small groups of collaborating students would activate and express their own understandings and images of the mathematical concepts in focus. In addition, the digital tutorials could be (and was) used by students for their own retention of the problem solving techniques and their mathematical foundation – particular in preparing for the final. Furthermore, re-viewing and discussing the tutorials could support the students’ reflections on their conceptual learning or be used as a basis for common reflections.

With respect to the scope and focus of the working group Implementation of Research Findings in Mathematics Education (see the introduction to TWG23), the implementation aspect of this paper and further related work is the design and organization in the classroom of the digital tutorial in creating a learning environment in which research findings on students’ concept formation and the importance of communication are brought to use in the teaching of a first year calculus course. We are developing our practice of mathematics teaching through interplay with research – and in this process we are also engaged with research, so in the present paper, implementation of research results and research are intertwined.

We audio recorded the students’ reflections during their work with the tutorials. The transcripts of these records, the tutorials, the students’ performance at the course and observations during the course form the empirical basis for addressing our three didactical research questions (RQ):

1. In what sense and degree can a learning environment focusing on the students’ productions of tutorials and other digital products with subject matter content support the students’ formation of key concepts in calculus?

2. Which learning difficulties related to the key concepts in calculus can be revealed and theoretical explained through analyses of such student activities and products?

3. How can the findings from such analyses be used to further develop the learning environment and the way in which the students’ products are used in the calculus course?

In this paper we address the three RQs focusing on the limit concept.

The context of the experiment
The experiment was performed at the calculus course in the natural science bachelor program at Roskilde University. There were 32 first year students in the course, which was taught in English using a typical American calculus textbook (Adams & Essex, 2013). During the previous few years, it had become evident that the students’ had problems explaining and applying the concepts and methods of calculus in their subsequent courses. One possible explanation for the increasing difficulties for the students in developing their conceptual learning in the calculus course could be changes in their prerequisites concerning key mathematical methods and concepts from high school, which are fundamental for calculus such as algebra, variable, function and the limit concept. CAS and graphing software for calculators and computers are used intensively in mathematics teaching at high school in Denmark and students learn instrumented techniques to solve standard problems by means of such tools. Similar experiences are reported in other educational systems. Barbé et al.
(2005) have analyzed the situation in Spanish high schools, in particular the incoherence in the mathematical organizations of the theory of limits at high school level. Similar incoherencies have been found with other key elements of upper secondary level calculus in Denmark and American textbooks for first year calculus courses at the university level, due to the elimination of the topological parts of mathematical analysis (Winsløw 2015, pp. 200-203). In general, the extended use of it-instrumented techniques, in particular CAS-based techniques, poses challenges for the teaching of calculus in high school and at introductory courses at university entrance level. Gücler (2014, p.4) addresses the role of the teacher in students’ learning of the limit concept in such a teaching practice and pinpoints the importance of the teacher in challenging the students to consider limits both from a process and an object perspective in different mathematical contexts. In particular, the students need to communicate their conceptual understanding in order to really experience both of these perspectives and typically they will need specific support in order to grasp the idea of the limit of a function as a mathematical object.

Our approach to this challenge is to experiment with the learning environment so as to make the students produce and publish their own mathematical products in the form of tutorials in the digital genre through the use of various app’s and video-recordings with tablets. The students’ products combined oral and written explanations and presentations of their mathematical task and its content matter with visual and dynamical elements.

Implementation of the experiment: mediatized presentations and assessment

The students’ fabrications of the mediatized tutorials were connected to their usual homework of sets of traditional problems and exercises. During the course, the students handed in three sets of homework that each consisted of between 10 to 21 standard problems and exercises from the textbook. The students were allowed to discuss the solutions to the exercises with each other, but they handed in an individual presentation of solutions to the exercises. In order to participate in the final, a student had to have all three homework sets approved by the teacher. After the deadline for handing in a homework set, the exercises of the set were distributed between the students who in small groups produced a video tutorial of a solution to one of the exercises using the app Explain Everything or by other means. The video assignments were accompanied by a set of requirements for the product and a specific work flow which the students had to follow. The instructions given to the students can be seen in figure 1.

Each student also participated in a project work in which the students worked in groups with different subjects from the text book that were not covered in class. Each group wrote a technical report of two pages, which was supplemented by various video and/or other visual and oral digital products.

Finally, the assessment criteria were changed. The written test towards the end of the course was replaced by an oral test. The oral examination consisted of two elements: (1) a 12-15 minutes group presentation of the group’s project work. Every student was required to participate actively in the presentation of his/hers project work; (2) an individual examination of 8-10 minutes following the group presentation. After the presentation of the project work, the group left the examination room and hereafter each student was called back in for the individual examination. Each student drew by chance one of the three homework sets of exercises, and made a 5-6 minutes presentation of
selected parts of the subject matter covered by the exercises in the set. The presentation by the student was followed by 4-5 minutes of questioning in the remaining parts of the course and/or homework sets.

Figure 1: Assignment, product requirement and workflow for video production. ‘Tim’ in step 4 of the workflow refers to the teaching assistant. The students were requested to perform a quality test through his approval before they continued to step 5

The alignment of the requirements for the students’ work during the course and the final was an important aspect of the design of the new learning environment. The oral communication skills which were needed for the final were trained through the student-student interactions in the design phase of the video productions as well as in the actual fabrication of the videos of the homework exercises and the mediatized parts of the project work. The mediatized products of the project report were directly aligned with the first part of the final, and the video tutorials were directly aligned with the second part of the final. The bank of video tutorials of the total amount of exercises in the portfolio sets that were produced by the students during the course helped the students prepare for the second part of the oral examination. The students carefully designed tutorials that explained
clearly and in depth how to solve the exercises, because they were to be used by their fellow students in their preparation for the final.

Analyzing the students’ reflections on the limit concept

The students’ tutorials were examined during the course in order to identify those which were rich enough to be analyzed for answering RQ 2 with respect to the limit concept. Among them, a few were selected for discussions with the students in the classroom. Later, the material might be used for analyses that focus on other key concepts. Here, we illustrate with one case how we have analysed the students’ work with the tutorials for answering RQ 2 focusing on the limit concept. Guided by the theories, we looked for indicators of students’ image concept, of students revealing a conceptual understanding, and of students using a process oriented conception when we analysed the data. The data is transcripts of the audio recordings of one group of students while they produced their first tutorial of an exercise from the first homework set. The students’ video is also included in our analysis.

The students’ objective was to explain the limit concept using the exercise of finding the limit:

\[ \lim_{x \to 3} \frac{x^2 - 6x + 9}{x^2 - 9} \]

To begin with, the students observed that the limit cannot be found simply by inserting \( x = 3 \) in the expression, since the denominator is zero for \( x = 3 \). They mentioned the technique of factorization in order to handle this challenge. This technique is used in several examples in the text book. During their work, the students had software for graphical and CAS analysis at their disposal. However, before implementing this technique they began to reflect on the meaning of the limit concept. The students realized that the video should be aimed at “all the students that are struggling with calculus”, as student 2 phrased it. Accordingly, they took on the challenge of explaining the limit concept in their tutorial. Their dialogue went as follows:

S1: Wait a second and now I think I’m lost a little bit. What is this limit thing actually doing?
S2: We have to watch the limit, so we have to watch the value that our function is approaching, when it’s, when the axis approach … [S2 draws a graph of the function on the computer.]
S1: Ah, yeah so we can see here, that’s true. Okay trace, so we can see here, so we take x value 3, eeh.. to here, so it’s pretty close to 0.!
S1: Makes a lot of sense. We can also zoom in!
S1: I think you just say that a limit is a number that is (inaudible) by. We have a value that is approaching a number … right?
S2: A variable that is approaching a number?
S1: We have a function. We have variables in a function that is getting approached by a number. … It’s like we’re getting infinitely close, we’re getting infinitely close to a number in the function without reaching it. That’s a limit.

Here we see that there is a close interplay between, on the one hand, the students’ understanding of the particular problem in hand and their ideas and images for the limit concept in general, and on the
other hand, the challenge of producing an explanatory tutorial for their fellow students. The situation forces the students to activate and verbalize their images of the limit concept. It becomes clear for the students that their understanding is not sufficiently developed for explaining the limit concept clearly in their own words in the tutorial. In the process of writing the manuscript for their tutorial the students consulted the textbook of the definition of the limit concept. The dialogue continued as follows:

S1: Yeah, okay, but let’s first answer the first one. ... What’s an introduction to the topic. I think an introduction would just be like “A limit is an.”!

S2: Value that

S1: It’s actually like...

S2: A value or number, maybe a number. It’s a number that...

S1: Yeah it is a number that is getting approached, but is never reached!

S2: It can be reached, it can be reached. I just. You don’t have to say if it’s reached or defined or undefined, you just say that it’s a number that the function approaches as \( x \) approaches. As \( x \) gets closer and closer to the \( c \). [Referring to the notation in the textbook]

S1: But I mean it doesn’t reach the limit, that’s the idea.

S2: It has… it could. It can because you can write, because that’s only the...

S1: It’s still the number it’s going towards but...

S2: You can, you can say limit of \( x \) when \( x \) approaches 2, it’s (over) the limit.

S1: Yeah okay, but the limit is numbered, but it never reaches that number, that’s not the idea. The limit is just taking it to the limit.

S2: Okay!

The students are getting into a deep discussion of how to understand the limit concept. Student 1 is quite persistent in his process-based thinking of a limit, and he has difficulties with accepting that the limit of a function can actually be reached. Student 2, however, switches to a more object-based thinking in their discussion of how they should introduce the limit concept in their tutorial. In some of her utterances she is getting close to formulating the definition of a limit in her own words, and she seems to be aware of the fact that the value of the function can be forced arbitrary close to its limit in a certain point \( x = c \) by choosing \( x \) to be sufficiently close – but not equal – to \( c \).

After a while student 1 begins to switch into a more object-based thinking of limits. He says:

S1: A limit is a number that is being. A limit is a value, you have (on there), the \( y \) axis, when you’re approaching a number on the \( x \) axis…. But is it mathematically correct to say that? It’s like if you have a function, and you go towards the number.

In their tutorial the students explain in detail doing the algebraic manipulation by hand how to get to the identity: \[
\frac{x^2 - 6x + 9}{x^2 - 9} = \frac{(x-3)^2}{(x+3)(x-3)},
\] which for \( x \neq 3 \) is equal to \[
\frac{(x-3)}{(x+3)}.
\]

They explain in the tutorial how the limit of the given expression can be evaluated by substituting 3 for \( x \) in “the redefined function” and that this yields the result 0. The students also explain that the
given function is not continues for \( x \) equal to 3: “It has a hole in its graph for \( x \) equal to 3, while the redefined function is continues in this point and has the value 0”.

However, the crucial mathematical argument is not stated or explained explicitly in their tutorial; namely that since the two expressions are equivalent for all real value of \( x \neq 3 \), then

\[
\lim_{x \to 3} \frac{x^2 - 6x + 9}{x^2 - 9} = \lim_{x \to 3} \frac{x - 3}{x + 3}
\]

**Discussion and some initial conclusions**

Focusing on the limit concept, our findings in relation to the three RQs are:

Ad (1): The learning environment encourages the students to articulate and communicate their understanding of key concepts such as the limit concept in various situations and forms of representations. As illustrated in the analysis presented, in the process of producing the tutorial, the students engaged in dialogues about the limit concept using their own language. In their tutorial they used oral, written and visual forms of expressions in communicating their conceptual understanding and the techniques they used in solving their problem. The crucial didactical feature of the learning environment is the focus on the students’ productions of the tutorials aimed at their fellow students. Together with the prescribed work flow and the requirements specified in figure 1, the focus on the productions of the tutorials, encouraged and enabled the students to express and reflect on their own conceptual understanding. In general, from analyzing the students’ dialogues during their production of their tutorial it is evident that only when the students began to work on the video production they became fully aware of what their task really was about, how the technique they used could be explained, and why their results were correct.

Ad (2): From the analysis it is clear that the students found it very difficult to really understand and use the formal definition of the concept of a limit of a function from the text. Especially student 1 insisted on understanding the limit concept as a process or actually as two connected processes. He did not focus on the quality of the limit of a function, and he emphasized wrongly that the limit is a number which will not be reached by the function. This phenomenon can be understood by means of the concept of students’ concepts images (Vinner & Dreyfus, 1989). Their research explains and evidences that formal concept definition only become meaningful to students to the extent in which they are unfolded and concretized by personal experiences. The phenomenon can be further analyzed by means of the process – object duality of mathematical concepts (Sfard, 1991).

In the tutorial, the students explain how to use the technique of factorization to find the limit of the given function. They reached a new expression for the function, which is equivalent to the given expression for all real values of the independent variable \( x \) except for \( x=3 \). Only the new expression is defined for \( x=3 \) and can therefore be evaluated in \( x=3 \), which yields 0. However, in the tutorial, the students did not really explain why the limit for \( x \to 3 \) have to be the same for the two expressions since they are equal for all values of \( x \) except for \( x=3 \). Güçler (2013, 2014) found and analyzed similar difficulties in students’ learning of the limit concept.

Ad (3): In general, analyses of the students’ productions of the tutorials and the tutorials themselves allow pinpointing learning difficulties related to key concepts in calculus such as the limit concept, which are theoretically explainable. The analyses can provide ideas for variation of problems to be
dealt with in the tutorials in order to invoke and challenge the students’ different concept images of the key concepts in calculus. Such analyses can inform the development of the learning environment in order for the theories to be used in the practice of teaching for identifying and help overcoming students’ learning difficulties. Moreover, anchored to the students’ experiences with the tutorial, theories can help students develop a sound meta-learning related to the formation of mathematical concepts.

Also, the tutorials can be used in whole class teaching as a point of departure for discussing the relations between the techniques used to solve the different types of problems addressed and the mathematical theory explaining them and hereby contribute to the development of the mathematical organization in the calculus course.

Implementation enterprise through the lens of a theory of diffusion of innovations: A case of online problem-solving forums

Boris Koichu and Nelly Keller
1Weizmann Institute of Science, boris.koichu@weizmann.ac.il
2Technion – Israel Institute of Technology, nellyk@tx.technion.ac.il

The goal of this article is to present and theorize our more successful and less successful attempts to create and sustain problem-solving forums, in which exploratory discourse takes place. The main argument is that many implementation-related phenomena that we have encountered when working with seven high-school classes for one or two school years can be characterized and explained with the aid of conceptual tools provided by Rogers’ Theory of Diffusion of Innovation. The most successful process of forming an online forum in one of the classes is presented in some detail, and the parallel processes in the rest of the classes are presented in the form of an aggregated summary. Implications for future design-based implementation research are drawn.

Keywords: Problem solving, online forums in social networks, diffusion of innovations.

Introduction

This article presents an implementation aspect of a research project entitled “Heuristic and engagement aspects of learning through long-term collaborative mathematical problem solving”. The main research goal of the project (ongoing until September 2017) is to produce a model of learning through mathematical problem solving, which would be attentive to cognitive, socio-affective and contextual aspects of this activity. In particular, the model is supposed to attend to interactions between variations in heuristic behaviors (Koichu, Berman & Moore, 2006; Koichu, 2010) and socio-affective engagement structures (Goldin et al., 2011) activated when high-school students collaboratively cope with challenging mathematics problems for relatively long time.

An implementation aspect of the project consists of designing and sustaining a special learning environment, in which long-term problem solving might be investigated. The intended environment comprised of a particular combination of problem-solving lessons in a classroom and out-of-classroom work supported by online asynchronous discussion forums. Its design was strongly informed by past research on affordances of online learning environments. Past research tells us that students in online environments can actively participate in solving complex problems for 2-3 weeks almost without teacher interventions (Moss & Beatty, 2006) and that some of those students who tend to be silent in a classroom can actively participate in online discussions (Schwarz & Asterhan, 2011). In addition, there is evidence that online discussions enable students to meaningfully use their mathematical knowledge, enhance self-regulation skills and support knowledge construction (Nason & Woodruff, 2003; Tarja-Ritta & Järvelä, 2005; Stahl, 2009).

Schwarz and Asterhan (2011) attribute the benefits of online discussions to their unique traits, such as: fostering divergent rather than linear interactions, enabling flexible time schedules of

1 Selected findings of the project are reported in Lachmy & Koichu (2014), Koichu (2015ab), Keller and Koichu (in press).
participation in the discussions over relatively long periods of time, encouraging explicit and accurate expression of the ideas in writing. Koichu (2015ab) argues that many affordances of an online problem-solving forum stem from its fundamental characteristics of being a choice-affluent environment, that is, an environment, in which the students are empowered to make informed choices of: a challenge to be dealt with, a way of dealing with the challenge, a mode of interaction, an extent of collaboration, and an agent to learn from. In brief, past research on online collaborative problem solving presents many evidence-based cases of successfully working online forums.

However, little is known from the professional literature about how to put the forums into work and sustain them. Our experience in the aforementioned project taught us that this enterprise is truly challenging. The goal of this article is to make sense and theorize our more successful and less successful attempts to create and sustain problem-solving forums, in which exploratory rather than expository problem-solving discourse (this distinction is due to Stahl, 2009) takes place. The main argument is that many implementation-related phenomena that we have encountered when working with seven high-school classes (grades 10 and 11) can be characterized and explained with the aid of conceptual tools provided by Roger’s (2003) Theory of Diffusion of Innovation.

Conceptual framework

Approach: Design-Based Implementation Research (DBIR)

Werner (2004) refers to implementation research as the systematic study of the implementation of innovations. Fishman, Penuel, Allen, Cheng and Sabelli (2013) point out that this type of research encompasses studies of fidelity, of variations in implementations as well as studies of conditions under which programs can be implemented effectively. They further refer to implementation research and to design-based research as antecedents of a new, emerging research model, which they name Design-Based Implementation Research (DBIR). The core principles of DBIR are as follows:

1. a focus on persistent problems of practice from multiple stakeholders’ perspectives;
2. a commitment to iterative, collaborative design;
3. a concern with developing theory and knowledge related to both classroom learning and implementation through systematic inquiry; and
4. a concern with developing capacity for sustaining change in systems. (Fishman, Penuel, Allen, Cheng and Sabelli, 2013, pp. 136-137)

In addition, DBIR calls for breaking down barriers that isolate those who design and study innovations and those who study the diffusion of innovations. We find the DBIR concept and principles well-adjusted to the needs of our project.

Vocabulary: Selected elements of the theory of diffusion of innovations

The notion innovation is frequently used in the literature on implementation research as a self-explanatory one (Fishman et al., 2013). However, there exists a branch of the professional literature that explicitly focuses on innovations and the processes of their diffusion. In particular, Rodgers (2003) defines innovation as “an idea, practice, or object that is perceived as new by an individual or other unit of adoption. It matters little, so far as human behavior is concerned, whether or not an idea is ‘objectively’ new as measured by the lapse of time since its first use or discovery” (p. 11). In our case, the idea of stretching the boundaries of a classroom by means of an online problem-solving forum was an innovation because it was new to the students and the teachers.
Rodger’s (2003) theory of diffusion of innovations meticulously characterizes the innovation-decision process, in which individuals (or other decision-making units) decide whether to accept an innovation or not. In particular, Rodgers distinguishes five stages of the process: knowledge, persuasion, decision, implementation and confirmation. The stages are briefly presented below.

At the knowledge stage, potential innovation adopters are exposed to the innovation’s existence and obtain some information about how it functions. Sometimes individuals become aware of an innovation by accident, and sometimes they actively look for it in order to fulfill particular needs. It is also possible that the needs are formed as a result of one’s exposure to an innovation.

At the persuasion stage, an individual forms a favorable or unfavorable attitude towards an innovation. This stage presumes affective involvement with the innovation. In particular, the individuals may mentally apply the new idea to their present or anticipated future situation. They seek to answer such questions as “what are the innovation’s advantages and disadvantages in my situation?”, and seek the answer mostly from their near-peers, whose opinions based on their personal engagement with an innovation, are the most convincing. There is a discrepancy between forming a favorable attitude towards an innovation and an actual decision to adopt it. Adoption of an innovation can be influenced by a cue-to-action, an event that crystallizes an attitude into overt behavioral change.

At the decision stage, an individual adopts (i.e., makes full use) or rejects an innovation. Any decision is not final however. The rejection can occur even after a prior decision to adopt; in Rodgers’ terms, this phenomenon is called discontinuance. The theory distinguishes between active and passive rejection. The former type of rejection consists of considering adoption of the innovation and then deciding not to adopt it. The latter one consists of never “really” considering the use of the innovation. The decision stage frequently includes a small-scope trial. The actual sequencing of the three stages presented so far can alter. Namely, both knowledge–persuasion–decision and knowledge–decision–persuasion sequences are possible.

At the implementation stage, an individual puts an innovation into systematic use. Even though the decision has been made, the adopters may still feel a certain degree of uncertainty about the consequences of the innovation. In addition, problems of how exactly to use the innovation may emerge. Sometimes the adopters change or modify (in Rodgers’ terms, re-invent) the innovation at this stage. The implementation stage can be lengthy, but it ends when the idea that has once been innovative becomes institutionalized and regularized in the adopters’ normal functioning.

Finally, at the confirmation stage, an individual constantly seeks reinforcement for the decision to adopt or reject an innovation that has already been made. As a result of positive or negative messages about the innovation, the decision can be reversed. Rodgers points out that the change agents (i.e., those who influenced one’s decision to adopt an innovation) have responsibility of providing supportive messages to the individuals who have previously adopted the innovation.

**Methodological aspects of the project**

**Participants and the project’s activity**

Two experienced mathematics teachers and two of their 10th grade classes took part in the first year of the project (2013-2014); five more teachers and their corresponding five classes joined the
project during its second year (2014-2015). Each participating teacher acted in the project as a member of the research group and took part in the meetings of the group. In addition, each teacher worked in contact with an additional member of the group who was responsible for the technological support and documentation of the activity. Mathematics in all participating classes was studied for five hours a week, in accordance with the Israeli high-level curriculum (see Leikin & Berman, 2016, for details). For the concerns of this article, it is enough to mention that geometry was studied two hours a week and that its study included systematic work on proving tasks.

We planned that each participating in the project class would be engaged, at least three times during a school year, in the following activity. The students cope with a series of preparatory tasks during a 90-minute lesson and are offered an especially challenging geometry problem at the end of the lesson. They then engage, for 5-10 days, in solving the problem from home in a closed (that is, available only to the students of a participating class and the members of the research group) online forum. Different technological platforms, including Google+ and WhatsApp, were tried in different classes. When the problem is solved or, alternatively, when the students give up, a 90-minute lesson is conducted in the classroom in order to get closure. The lesson consists of whole-class and small-group discussions, during which the students share their experiences with the problem.

Documentation of the project

Forty-two meetings of the research group were audiotaped (about 100 hours) and, in addition, documented in the protocols of the meetings (more than 100 pages). The documents produced by the group and all relevant email exchange were stored. Every member of the group was required to keep a diary. The diaries were for writing anything their authors deemed important for the project, including their thoughts and feelings in relation to the project’s events. The diaries were stored in shared Google Drive of the group and were available for reading and commenting by the members. In addition, 14 lessons were videotaped, the content of the forums was stored (more than 3000 posts), interviews with students and teachers were conducted (about 15 interviews), and the students’ written feedback on different aspects of the project was collected.

The story of NK’s class, which is presented below in some detail, is produced using narrative inquiry methodological tradition. As Clandinin and Caine (2008) explain, “Narrative inquiry is marked by its emphasis on relational engagement between researcher and research participants” (p. 542). This approach was chosen because we (hereafter, BK and NK) had been active members of the processes under exploration; in particular, NK was a mathematics teacher of the class. An aggregated summary of the stories in the rest of the classes is produced using a general inductive approach (Thomas, 2006), which enables researchers “to condense extensive and varied raw text data into a brief summary format” (p. 238).

Findings

A (success) story of NK’s class

The main events at the knowledge phase of the project in NK’s class consisted of: (1) a conversation between NK and BK following BK’s observation of one of NK’s lessons; (2) a conversation between NK and her students. Because of the first conversation, NK decided to take part in the project mainly because the idea to stretch the boundaries of a classroom by means of an online forum resonated well with NK’s constant need to enrich her teaching repertoire in order to create
valuable learning opportunities for her students. In Rodgers’ terms, NK acted as a *venturesome innovator* who is able to cope with high degree of uncertainty about an innovation, and BK acted as a *change agent*. In her conversation with the students, NK acted as a *change agent*, and the students were potential innovation-adopters to be persuaded. NK argued that developing problem-solving skills was a strong benefit of participating in the project, and appealed to the students’ curiosity to try something new and be a part of an interesting initiative. The students’ reaction to the information about the project was favorable, though not exactly for the reasons that NK had presented.

The first mathematical problem of the project is presented in Figure 1. It is representative of most of the problems of the project. In particular, it looked similar to geometry problems the students were familiar with from classwork and homework. As such, the problem “invited” the students to approach it by means of mathematical ideas that worked well in the past. For instance, the students might think of including the angles, whose equality is to be proved, in a pair of triangles and attempt proving their congruence by finding some equal elements. However, such a general plan was insufficient; something else (e.g., a clever auxiliary construction) should have been invented.

**Nine-Square Problem:** There is a net of nine congruent squares (see the drawing). Prove that the two angles denoted in the drawing are equal.

![Figure 1: The first problem of the project](image)

When the problem was uploaded to the Google+ forum, three students worked on it. Their three-hour-long brainstorming session was unsuccessful. As a result, the forum was non-active during the next two days. The following day NK met the students at school and asked: “Why did you stop solving the problem? It is not too difficult”. The students showed NK their hand-made drafts as evidence that they had tried. NK asked the students to upload their drafts to the forum and continue solving the problem together. That evening eight students entered the forum, cooperated and eventually solved the problem. Two solutions to the problem by the active participants of the forum and an additional solution by a student who was a silent observer were presented at the mathematics lesson following the forum. The students’ voluntarily expressed their suggestions as to how to further run and improve the forum by the end of the lesson.

In Rodger’s terms, the first three students acted as *venturesome innovators*. Rodgers points out that this category of adopters is important for launching a new idea, but they have little influence on other individuals’ decision to adopt or reject the idea. The conversation between NK and the students in school was crucially important as a *cue-to-action* for eight students, who acted as *early adopters*. Rodgers characterized this category of individuals as *respectable*, that is, well-integrated members of a local community whose opinion about the innovation matters for the potential adopters. The mathematics lesson, in which these eight students shared their positive experience at the forum with the rest of the class, was another crucially important *cue-to-action*.

The next two problems of the project were approached on the forum by about the same group of students. The students learned to share their half-baked ideas, and even developed some rules related to publishing the full solutions at the forum. In brief, they agreed that a student who obtained
the full solution should not publish it early, in order to not “spoil the fun” for others. The forum was indeed exploratory rather expository in nature. Three months later, collaborative problem solving at the forum became a well-established practice for six students; most of their classmates joined the forum occasionally and constituted the *early majority*. It seems that each student has *decided* how and to which extend to use the forum. The *implementation* stage (three to eight month from the beginning of the project) was characterized by gradual two-directional diffusion of social and socio-mathematical norms developed in the forum and in the lessons. In particular, there were several forum-like lessons initiated by the students (see Keller & Koichu, in press, for details).

The evidence of *confirmation* of the students’ decision to adopt the innovation came from the following sequence of events. As mentioned, the Google+ forum flourished for several months, but it we have not yet mentioned that then it was deserted. NK inquired with the students about this fact and discovered that the activity moved from the Google+ to WhatsApp, a popular social network in Israel since about 2014. The students granted NK access to their WhatsApp forum, and we were happy to find there many autonomous problem-solving discussions of exploratory nature. The WhatsApp forum flourished in NK’s classroom until the students’ graduation in 2016.

**An aggregated summary of seven stories**

An aggregated summary of the conduct of the project in all participating classes, by Rodgers’ phases, is presented in Table 1.

<table>
<thead>
<tr>
<th></th>

</tbody>
</table>

**Table 1: The implemented stages of the project in seven classes**

The sign “++” in the table means that the stage is fully realized; “+” means that the stage is partially realized (e.g., the forum was active only as a trial or only few students were active); “-” means that there were no conditions for realizing the stage; “Active R” and “Passive R” stand for active and passive rejection, respectively. An empty cell means that the project did not arrive at that stage.

As Table 1 tells us, only NK’s class went through all five stages, up to the point when using the online forums for problem solving stopped being an innovation and became a routine. Implementation of the project’s idea at the scope comparative to NK’ class occurred in one other class, and partial implementation – in three classes. In two classes the project did not reach the implementation stage, despite of much effort made by the teachers and the research team.

**Concluding remarks**

Recalling Tolstoy’s seminal assertion, *happy families are all alike; every unhappy family is unhappy in its own way*, we can argue that there is a unique story behind each cell of Table 1.
Unfortunately, we cannot tell these stories here due to the space constraints. In brief, sometimes school conditions or classroom norms were inappropriate for realizing the project’s idea, sometimes a particular cue-to-action event did not happen at the right time or was not appropriately designed, and sometimes our decisions and actions as a research group were far from being optimal. We have also observed, more than once, the phenomena of discontinuance and of passive rejection for which we do not have convincing explanations, despite the extended data set in our possession.

We intend to continue the aforementioned project, and one of the lessons learned so far is that the DBIR concept and theories like the Rodgers’ theory of diffusion of innovation should be taken seriously. Either detailed or aggregative analysis of implementation of the project idea is helpful for us as a tool for refining the roadmap of the project. In addition, we now better understand that creating conditions for implementation of an innovative pedagogical idea in a school reality should be given full attention prior to delving into a pursuit for “traditional” research questions, such as questions on cognition and affect in mathematical problem solving that have been the main research questions of the project. Based on the accumulated experience, we call for reporting and analysing not only those cases where an innovative idea is being fully implemented, but also those case where the implementation was partial or did not occur as planned. We conclude by suggesting that systematic attention to implementation issues, by means of DBIR, may have not only practical, but also fundamental theoretical significance in mathematics education.

Acknowledgment

The research project is partially supported by the Israel Science Foundation (Grant No. 1593/13; PI Koichu). We are grateful to all the participants in the project, and especially to the teachers who cooperated with us and devoted much time, thought and effort to making the project work.

From theory through collaboration into practice: Designing a problem-solving curriculum for grade 6 students

Ana Kuzle

University of Potsdam, Germany; kuzle@uni-potsdam.de

Teachers are continuously confronted with instructional endorsements, such as the inclusion of problem solving in school mathematics. However, adoption of problem solving is still not a reality. One reason for it is the lack of practical teaching materials based on research findings to achieve the goals stated in the standards. In the context of this reform agenda, collaborative work between educational researchers and practitioners in a real setting working on issues of everyday practice is crucial in order to overcome the gap between theory and practice. In this paper, I focus on such theory based problem solving curriculum for grade 6 students that was developed using design-based research. At the end, I discuss factors inhibiting the implementation of the curriculum.

Keywords: Word problems, material development, mathematics activities, problem solving.

Introduction

The (inter-)national educational standards (e.g., KMK, 2003; NCTM, 2000) have strongly endorsed the inclusion of problem solving in school mathematics. Empirical studies, however, portray a different picture. Students are often unable to solve problem tasks (e.g., Schoenfeld, 1985). In addition, quality analyses in the German school system contend to a poor problem solving culture. As reported in Kuzle and Gebel (2016), problem solving tasks got rarely introduced. When this was the case, they were primarily done by the teachers; mostly routine tasks dominated the lessons, and problem solving strategies were explicitly applied in one third of examples only. The biggest problem reported by the school’s teachers was the lack of practical teaching resources to achieve the goals stated in the standards (Kuzle & Gebel, 2016). In the context of this reform agenda, the development of materials for students and teachers is of great importance for overcoming the gap between theory and practice (Jahn, 2014). One urban school recognized this deficit and set as a goal promoting problem solving instruction centered around curriculum material, developed through collaborative work between educational researchers and practitioners.

Here I report on a small part of SymPa1-project (Systematical and material based development of problem solving competence) focusing on collaboration between practitioners and researchers with the goal of developing a problem solving curriculum for grade 6 students using design-based research (DBR). The guiding question is: What factors inhibit implementation of research-based problem solving curriculum in practice? In the following sections I outline relevant theoretical and methodological underpinnings used to design a problem solving curriculum, before showing how these got implemented, and report on its evaluation (initial DBR-cycle). As a result of evaluation, I discuss the curricular redesign that might allow more effective implementation in practice.

---

1 SymPa stands for „Systematischer und materialgestützter Problemlösekompetenzaufbau“. Inga Gebel (researcher) and Christian Conradi (practitioner) initiated and participated in the project likewise.
Theoretical foundation guiding the design process

Plethora of research on problem solving undergoing since the 1970s identified several pivotal areas for a problem solving curriculum. I outline here only a small portion of this research that was crucial for the project based on German standards’ conception of problem solving (KMK, 2003).

Problem solving competence

Problem solving competence relates to cognitive (here heuristic), motivational and volitional knowledge, skills and actions of an individual required for independent and effective dealing with mathematical problems (Bruder, 2002; Kuzle & Gebel, 2016). Accordingly, students should a) learn approaches (heuristics) for solving mathematical problems and how to apply them appropriately in a given situation, b) develop reflectivity for own actions, and c) develop willingness to work hard (cf. Bruder, 2002; KMK, 2003). As problem solving competence encompasses so many different facets, problem solving curriculum should account for the following research areas: (a) teaching approaches and concepts on problem solving, (b) theories of self-regulated learning and self-regulation in problem solving, and (c) theories of motivation which are outlined below.

Teaching approaches and concepts on problem solving in combination with self-regulation

There are at least seven practices for problem solving curriculum that researchers (e.g., Kilpatrick, 1985; Pólya, 1945/1973; Schoenfeld, 1985) have claimed to be important for helping students grow in their problem solving ability: (1) osmosis (give lots of problems), (2) give “good” problems, (3) memorization (teach specific or general heuristic strategies (heurisms)), (4) imitation (model problem solving), (5) cooperation (limit teacher input by having students work in small groups), (6) reflection (promote metacognition by asking metacognitive questions or encouraging students to be reflective), and (7) highlight multiple solutions. In the recent years, Bruder (2002) developed a problem solving teaching concept focusing around Lompscher’s (1975) idea of “flexibility of thought”. Flexibility of thought is expressed by one’ ability to

1. reduce a problem to its essentials or to visualize it by using visual and structuring aids, such as informative figures, tables, solution graphs or equations (reduction).
2. reverse trains of thought or reproduce these in reverse, such as by working backwards (reversibility).
3. simultaneously mind several aspects of a given problem or to easily recognize any dependences and vary them in a targeted manner (e.g., by composing and decomposing geometric figures and objects, by working systematically) (minding of aspects).
4. change assumptions, criteria or aspects in order to find a solution, such as by working forwards and backwards simultaneously or by analyzing different cases. Such ability prevents “getting stuck” and allows new approaches and insights (change of aspects).
5. transfer an acquired procedure into another context or into a very different one by using analogies for instance (transferring).

These typical manifestations of mental agility can be related to analyses of heuristic approaches by Pólya (1945/1973). Untrained problem solvers, however, are often unable to access the above outlined flexibility qualities consciously. Moreover, not only the knowledge of different heuristics (flexibility of thought) is needed when problem solving, but also self-regulatory abilities which evolve gradually through a 5-phase model (Zimmerman, 2002). Problem solving can be trained by
learning heuristics corresponding to these aspects of intellectual flexibility in combination with self-regulation, which according to Bruder (2002) and Bruder and Collet (2011) develops through the following five-phase concept:

1. Intuitive familiarization: This phase builds on Pólya’s (1945/1973) model, in which a teacher serves as a role model when introducing a problem to students. Thus, the teacher moderates behaviors typical for the problem by engaging in self-questioning pertaining to different phases of the problem solving process (before, during, and after). For example questions such as, “What is the problem asking for?” “What information am I given?” “Is there anything I don’t understand?” “Am I headed in the right direction?” may help guide the students (Kuzle & Bruder, 2016). At this point the heurism in focus is not specified.

2. Explicit strategy acquisition: During this phase the students get explicitly introduced to the heurism in focus on the basis of a reflection from the first phase. Here the particularities of the heurism get discussed and it gets a name (exemplification). Here prototypical problems get used for introducing a heurism in focus, so that the students can more easily recognize its main ideas and more easily remember their specific steps for future problem solving.

3. Productive practice phase: During this phase the students practice solving the problems using the heurism in focus. Here is important that the problems do not reproduce type problems, but rather expand the possibilities from the first two phases. In addition, differentiation should be a guiding concept during this phase, so that students can choose at what cognitive level they want to work and adapt the observed learning behavior.

4. Context expansion: In this phase the students should practice the use of heurism in focus independent of a mathematical context. In that way, the students learn to flexibly, unconsciously and independently of a context use the heurism in focus.

5. Awareness of own problem solving model: The aim of the teaching concept is that the problem solving model of the students gets expanded, so that they are in a position to solve problems better using different heurisms. Awareness of own problem solving model can be induced by having students reflect on and document their problem solving process.

Lastly, students’ willingness to work hard is a major factor for the successful problem solving process. Without an effort from the learners, there will be no successful learning. For that reason, the criteria such as, understandable and clear problem, age-appropriate choice of context, and visible competence growth (Bruder, 2002) are crucial when designing problem solving curriculum.

To summarize: the problem solving curriculum was developed around the operationalization of the terminology “problem solving competence”. This included the teaching concept of problem solving by Bruder (2002) in combination with Zimmerman’s (2002) self-regulation model taking into consideration the criteria for motivating tasks (Bruder, 2002).

**Curriculum development**

The problem solving curriculum was developed in collaboration between the two researchers (author and young researcher) and one practitioner (teacher from the project school). More concretely, the researcher team developed the curriculum based on the outlined theories and school’s contextual factors (see below), which were discussed up-front. Curriculum materials (e.g., problems, textual parts, figures, colors) were either separately developed by the researcher team and
discussed afterwards with the teacher or the entire team met together and developed them. The final decision about the problem solving curriculum (e.g., content, problems) was met by the teacher.

**Enactment**

For the design of curriculum contextual factors played a great role, in which theoretical ideas had to be operationalized. Students of 6th grade were chosen to participate in the project lasting one school quarter (ca. 16 lessons, 1 lesson = 45 min). The implementation of the curriculum took place during two parallel phases (see Table 1). During the first DBR-cycle 13 students participated. Teacher A initiated the project, had previous experience in problem solving (e.g., attended professional development courses on problem solving, read literature on it, and implemented problem solving tasks occasionally in his teaching practices). The second DBR-cycle started parallel to the first DBR-cycle, and was led by another mathematics teacher. In total 12 students participated. Teacher B had practically no experience with problem solving or teaching problem solving.

</tr>
</tbody>
</table>

Table 1: Parallel enactment cycles

With respect to heurisms, focus laid on those heurisms prescribed by the school’s own curriculum, namely heuristic auxiliary tools (informative figure, table, solution graph), heuristic strategies (working systematically, working forwards, working backwards), and heuristic principles (composing and decomposing). Thus, all flexibility qualities were addressed. With respect to mathematical content, problems covered the content areas of 5th and 6th grade mathematics (operations with natural numbers and fractions, combinatorics, geometric and numeric patterns, measurement pertaining to 2- and 3-dimensional figures). Based on the project time frame, each heurism was covered within two lessons, but followed the above underlined problem solving concept. For one exemplarily operationalization with references to theoretical base see Figure 1.

During the implementation phase data collection took place on three different levels: student level, teacher level and classroom level. With respect to the student level, data from student textbooks (intermediate reflections, final reflection) and their workbooks (student productions) was collected. With respect to the teacher level, data from continuous communication with the teachers (e-mail, telephone calls), teacher textbook and semi-structured interview at the end of the project was collected. Concretely, continuous communication allowed the researcher team to support the teachers during the implementation phase with respect to pedagogical and/or methodological questions (e.g., discussion of different solutions, cooperative methods), by answering questions of content nature (e.g., questions about particular heurism), and through flexible and stepwise redesign of the curriculum after each lesson. Lastly, with respect to the classroom level, observations allowed for analysis of student-teacher interaction, and students’ interaction with the curriculum.
Qualitative-content analysis was used to analyze the collected qualitative data as outlined in Patton (2002). This method is particularly suitable for research activities, in which the knowledge is low and a study has more of an exploratory character. Thereby, the aim was to systematically analyze the
qualitative data and produce a category system by focusing on factors inhibiting the implementation of the curriculum. The deductive analysis was performed based on the theoretical foundation, which was then refined in the inductive analysis by emerging issues and additional codes. The situations were interpreted as inhibiting when they allowed for a limited implementation of the curriculum only as reported explicitly by teachers and students and/or was observed by reviewing the collected data. As a result four categories were produced (see Table 2, for more detail see Kuzle & Gebel, 2016). The category system was then used to interpret the results of the study with respect to the research question. All data got analyzed by the two researchers independently.

Table 2: Four content categories inhibiting implementation of the problem solving curriculum

Table 2 shows that also school and personal influences, which were not part of the design process, influence the extent to which the curriculum gets implemented. Thus, teachers also inhibit successful implementation of the curriculum, despite being part of the design process. I focus on this category by giving different subcategory examples since this factor was most surprising.

Figure 2 shows student’s work solving one problem where the heuristic auxiliary tool of informative figure was to be used. Instead of representing a graphical illustration of the situation to be resolved from which the solution can be “read” (informative figure), it represents a sorting of information. Hence, the student work is a reflection of teacher’s B lack of knowledge of problem solving, despite this problem being discussed in the teacher manual, which she glanced only once (professionalism). This was seen in all students’ notes. Moreover, the analysis of students’ workbooks revealed that teacher B avoided introducing problem solving terminology and allowed students to solve problems as they wished (teacher attitude). She explained that she did not want to burden them with formal terminology and constraint their problem solving process.
Also teacher B criticized heavily the name of the figures in the curriculum (Profi, Probi), which was reflected in students’ final reflection, where they urged for the change of figure names. Thus, teacher’s negative attitude about a design element transferred negatively onto the students. Such behavior was not observed with the students led by teacher A, who questioned the chosen names, but never criticized them during his instruction. Teacher B in comparison to teacher A was not part of the design team, but was assigned to implement the curriculum due to organizational school context. The case of teacher B shows that negative attitude and lack of professional behavior inhibited successful implementation of the curriculum. Hence, teacher as an inhibiting factor should not be neglected during the design and implementation process.

Conclusion

Problem solving must gain more importance in school mathematics. Although several teaching concepts and practices are known (e.g., Bruder, 2002; Kilpatrick, 1985; Pólya, 1945/1973; Schoenfeld, 1985), these get rarely implemented. Moreover, curriculum based on existing and empirically tested problem solving pedagogies is non-existent. To overcome this gap SymPa-project was grounded. Teachers participating in the project reported improvement in students’ problem solving competences with respect to deliberate and mindful use of different heurisms when problem solving. In addition, the teachers not participating in the project, reported students using these heurisms in regular mathematics classes. Hence, it was possible to develop curriculum that met the local demands with the aim of supporting a systematical development of problem solving competence. However, different objective and subjective factors inhibited full-implementation of the curriculum. With respect to the former (language, level of performance, learning pedagogies), changes done in the re-design phase of the DBR-cycle will shed light to which extent these were enough for successful implementation in the upcoming phases of enactment. With respect to the latter (school and personal influences), it became clear that the curriculum alone does not guarantee the implementation of the teaching concept. Substantial knowledge base of the content and pedagogical ideas seem necessary to teach in accordance with the theoretical foundation. Confidence and experience in teaching problem solving played a crucial role likewise. Likewise school organizational factors should not be ignored. Since the teachers were assigned to teach the problem solving lessons and received no compensation for the participating in the project, a lack of motivation may develop, which influences the willingness to teach, the lesson quality and with it the students’ acceptance of the curriculum.

In this paper I demonstrated that DBR-paradigm allows creating novel teaching environments in which theory and practice were not detached from one another, but rather complemented each other. Here the efforts were made to design, use and do research on problem solving curriculum in a real
setting. This promoted adoption of the innovation – problem solving curriculum – which became an official part of that school’s curriculum. Moreover, close collaboration during the design and enactment phase, and the re-design of the materials by the researchers as a result of teachers’ feedback allowed them to develop a sense of ownership for the designed curriculum. Future work should use similar methodologies to ensure implementation of research into practice, adoption of research into practice, which would then allow research on implementation projects. These components may build a fundamental step to overcome the gap between theory and practice.

Theoretical constructs for early intervention programs in mathematics: Who cares? – A Danish example

Lena Lindenskov & Katrine Kirsted
Aarhus University, Danish School of Education (DPU), Denmark
lenali@edu.au.dk, kaki@edu.au.dk

“There is nothing so practical as a good theory”. The statement from Kurt Lewin is frequently cited, also in mathematics education. The statement invites for and requires close cooperation between different agents, whatever their specific relation to practice and theory is. It is not a straightforward endeavour. One reason is that the term theory as well as the term practice may very well be given different meanings by different agents. This variation is, in our view, to be considered in “implementation research” and Lewin’s statement ought to be qualified by two questions: “Who cares about a good theory?” and “What makes a good theory good for whom?”

This paper explores the variation of how theory is perceived by mathematics teachers and by mathematics researchers involved in a developmental project on early intervention in mathematics education in Denmark. The paper exemplifies how agents’ different work conditions and work requirements seem to constitute qualitatively different needs for theoretical constructs, despite some common interests.

Keywords: Early intervention programs, teaching principles, theoretical constructs.

Background for the early mathematics intervention project

We noticed a long tradition of integrating early mathematics intervention programs into compulsory education practice like, e.g. Mathematics Recovery (MR) (Wright, 2006; Wright et al, 2007) and Extending Mathematical Understanding Intervention Program (EMU) (Gervasoni, 2016), in Australia, Ireland, the UK and the USA. A similar tradition exists in Denmark for early reading intervention programs, as such programs are implemented at a regular basis in all schools in Denmark. Either as part of a municipal policy or a matter of choice, schools launched early (from the first grade) intervention processes in reading to support individual children, who show signs of reading difficulties.

At the ministry level in Denmark concerns were raised about pupils failing at mathematics in the National Official Guidelines in the 2003 National Mathematics Curriculum from the Ministry of Education (UVM, 2003). In 2004 the need to support failing pupils in mathematics in the first school years was emphasised (Mortimore et al.) and the national official guidelines to the revised 2009 national curriculum (UVM, 2009) described, for the first time, the issues in detail. Still, no intentions of integrating programs for early mathematics intervention into compulsory education practice were seen in Denmark until recently (Lindenskov, 2007).

In 2009 the material Early Intervention in Mathematics [Danish: Tidlig Indsats i Matematik, TIM], written to primary school mathematics teachers was published and used in some places. Just before, in 2007 local politicians and school authorities in the municipality of Frederiksberg in the capital area, decided to give priority to mathematics teaching and learning in their 9 public schools in the period 2007-2013. Priority was given to a development project on early mathematics intervention
for their 9 schools in collaboration with the researchers Lena Lindenskov and Peter Weng. It soon became clear that the existing intervention framework and written materials solely focused on numbers and arithmetic, which were insufficient to comply with the Danish Mathematics Education Philosophy and Curriculum. Also, approaches in the existing intervention framework and written materials were insufficiently inquiry and problem based to correspond with the curriculum. Finally, teachers’ freedom and responsibility to adapt materials to their own students were too limited in the existing frameworks and materials.

With this background a research-based developmental project with four design cycles was prepared in order to develop a Danish program for early intervention in mathematics that would fit into the Danish Mathematics Education Philosophy and Curriculum. The private Danish fund Egmont showed interest in a Danish early mathematics intervention program (personal communication), and together Egmont, Frederiksberg Municipality and Aarhus University assured the budget for this project. The project was named Early Mathematics Intervention at Frederiksberg with the Danish abbreviation TMF [Danish: Tidlig Matematikindsats Frederiksberg].

Perceptions of what is good theory – by mathematics school teachers

Our research question is, *what is a good theory for whom - teachers as well as for researchers?* Our analyses draw on our communication with the 18 teachers involved in the design cycles of the project. In the following these teachers are called pilot teachers. All pilot teachers were chosen by their school principal as among the most qualified and motivated mathematics teachers at the school. Some also were ‘Mathematics Counsellors’ with a one-year diploma course.

It is the use of theoretical constructs in the four cycles, which is analysed in the following. We analyse interactions between teachers and researchers. The data come from written materials and recorded minutes and notes from seminars¹, training sessions, coaching sessions and e-mails.

Generally, Danish teachers have a relatively high self-confidence and a strong wish to influence. It is shown, for instance, that Danish teachers, more than British teachers, prioritise their students’ personal development and see their students’ mathematical development as a means for personal development (Kelly, Pratt, Dorf & Hohmann, 2013). Because of the way the 18 pilot teachers were chosen by their principals, we anticipated that the teachers would be involved, to a high degree, in the project’s four design cycles. The specific choice of mathematical and other aspects for the framework and written materials for the early intervention was actually made in dialectic processes involving the researchers and the 18 pilot teachers. Further descriptions of the cycles are found in Lindenskov & Weng (2014).

---

¹ Mathematics Recovery Programme (MR) is a source of inspiration for the developmental project, see Wright et al., 2007. This is why we included a teacher seminar with Ms. Noreen O'Loughlin from Mary Immaculate College, University of Limerick focusing both on some hypotheses and issues in MR and on specific concerns at Frederiksberg.
The framework and materials developed through four design cycles

(1) From January 2009 to September 2009, Weng and Lindenskov developed the first draft material, based on theory, empirical results and their knowledge about mathematics in life and in primary and lower secondary schools in Denmark. They initially doubted whether the teachers would find it relevant to study the rationales and theory behind the choice of mathematical areas, materials and evaluating and teaching principles. That is why only a few theoretical constructs and justifications were in the first draft communicated to the teachers.

But, as the structure and each part of the draft material were critically explored and discussed during the teacher training sessions from 14 - 18 September 2009, this expectation of the teachers’ perceptions of their needs for theory was wrong. The teachers endorsed the underlying ideas, but actually asked for further explanation of rationales and theoretical constructs. The teachers also asked for an extensive introduction to the program as such. The time teachers were expected to use in the development processes did not include reading articles, so the researchers presented articles orally and provided printed extracts or copies of some articles as handouts. The main printed materials were newly developed diagnostic test materials and the problem solving materials to be used with their students, plus general introduction and justification for the choice of mathematical areas and instruction approach.

At the end of the week, the teachers suggested that measurement as a mathematical area and the use of measurements in other mathematical areas should be expanded in the next draft.

(2) Lindenskov and Weng developed a second draft of material based on the pilot teacher feedback and feedback from the research assistant. This meant that for more mathematics areas further justification for and explanation of rationales and theoretical constructs were included. The second draft was sent to each school October 2009 for experimenting. Each pilot teacher tried out specific parts of the material in the fall of 2009. The distribution of the parts to each school was decided through discussions among all pilot teachers. Each pilot teacher was requested to try out two or three activities with as many pupils as possible. The age of the pupils was not important. If possible, more material was to be attempted. The pilot teachers were given a specific task in order to evaluate the materials: they were asked to document in as much detail as possible - by writing in premade tables - how each mathematics task and each mathematics and attitude question led to pupil-teacher conversations which could indicate the pupil’s thinking. The experiments were concluded with a seminar on 3 December 2009, where each pilot teacher presented results. Anything that had particularly surprised the teachers was also presented and some common concerns were then discussed. It was put forward that the pages with descriptions of justifications and theoretical constructs were helpful, ‘or else we do not know why the chosen mathematical areas, concepts and competences are important to focus on.’

(3) Based on these results Weng and Lindenskov developed the third draft material and introduced it at a seminar on 28 January 2010. Justifications and theory were included for all mathematical areas. In the following months, each pilot teacher tried out parts of the material with a number of pupils. This time all the pupils were in the second grade. The aim was to allow the pilot teacher to experience the structure of the material and to practice pupil-teacher conversation. Peter Weng
visited and coached every teacher once and the teachers were invited to contact the researchers at any time during the pilot study.

At a midway seminar on 9 March 2010, the teachers described their general impression as positive and generally considered the material adequate. Several pilot teachers said they found it motivating to work with the material together with the pupils and that they had heard from the pupils’ ordinary mathematics teachers that the intervention seemed to have a positive impact on the pupils’ learning process.

The individual schools’ prioritization of subjects was also discussed: how to decide between pupils’ participation in a class excursion or a TMF session?

At the seminar a representative from the Egmont Foundation was present, as the Foundation had decided to fund the project. In the developmental project, the choice of pupils was left to the schools and the criteria differed between schools. The Egmont representative was particularly interested in the discussions on ethical issues: Whether pupils with very weak home support should be chosen over pupils with better support from home, who would probably benefit more? It is well known from research that socioeconomic factors are important for pupils’ learning and development. Maybe particular pupils need this intervention the most, but are they really the ones chosen?

Issues regarding the scope and range of the material were discussed, for instance how to prioritise between presentations of many mathematical aspects or assuring success in fewer mathematical areas. The risk that the material put severe strain on teachers, especially when they were unfamiliar with it, was also discussed. To illustrate this discussion, we have listed three pilot teacher transcripts and one researcher transcript below:

**Teacher 1:** I feel pinned down by the material. I feel like, ‘Now I must do this, then I must do that,’ and you have to look for concrete material yourself. It is very restraining. While I look for extra material, I give the pupils small tasks on the computer to work with, OK.

**Teacher 2:** The material could be constraining. But the material is important as a database of ideas. The material gives me ideas. It supports my own inspiration process and it helps me to include everything in my practice.

**Teacher 3:** The material is useful, when I prepare the intervention sessions.

**Researcher Weng:**

Try to think about the material as something that provides you with opportunities and inspiration. We invite you to a flexible adaptation to specific pupils.

(According to the minutes, authors’translation)

The final seminar on 27 May 2010 discussed organisational and psychological issues in detail. The teachers wanted organisational and psychological aspects of individual pupils’ learning and instruction to be emphasised as equally as the mathematical aspects.
Also the teachers again asked for more geometry and measurement in future versions, as well as a compiled list of recommended materials, but they did not mention any further need for justification and theory. (According to the minutes, authors’ translation)

(4) The fourth draft was developed by 12 August 2010 and was to be used from 2010 onwards in the regular TMF for individual second grade pupils in all of Frederiksberg’s public schools. The research assistant, Tina Kjær, examined the material and ensured that the teachers’ suggestions were taken into account. Strongly supported by the pilot teachers’ feedback, organisational and psychological aspects of individual pupils’ learning and instruction were included as just as important as mathematical aspects.

**Example of how researchers’ theoretical understanding is communicated to teachers**

As an example of how the researchers communicated their theoretical understanding underpinning the developmental project to the pilot teachers, we have chosen the mathematics area “Basic Strategies for Numbers in Addition and Subtraction”. The table below shows in the left column four of the theoretical constructs chosen by the researchers to underpin the project. The right column shows how the constructs were being communicated and discussed between researchers and teachers. The right column consists of citations from the final written materials, which was published in 2013 and meant to be studied and discussed among teachers involved in intervention projects.

</tbody>
</table>

**Conclusion**

This paper has shed light on what is a good theory for whom - teachers as well as researchers, how to explain theory and justifications to the pilot teachers in a meaningful way and how to develop material in collaboration between researchers and teachers? During the four development phases the pilot teachers endorsed the underlying ideas of the intervention project and asked for the rationale behind every included aspect to be explicitly communicated. They encouraged more extensive introduction and to expand the included measurement aspects into two measurement aspects.

The teachers explicitly endorsed the theoretical construct and justifications in the material, as they said it helped them to acknowledge many opportunities to help the pupils and to identify pupils’ potentials and motivation while exploring and developing their mathematical needs. The teachers appreciated that the material gave a firm frame and at the same time invited and inspired the teachers to adapt and further expand the materials to the specific learning situations with the pupils. The teachers recommended the material to be expanded with more mathematical concepts and competences, which are considered relevant in the Nordic contexts (Dalvang & Lunde, 2006; Niss & Højgaard, 2011) and by the teachers as potentially troublesome for the weaker pupils, and to expand the materials on measurements and part-whole.
The teachers asked for further ideas and materials which could be used as they were or could be adapted in order to fit their own pupils’ needs and motivations. The teachers did not suggest more clarified theoretical constructs and justifications underpinning the program than were communicated to them already.

For the educational researcher the task was to find and select theoretical constructs to underpin the intervention and communicate these to the teachers, as it is further described in Lindenskov et al (2016). It could not be communicated as in scientific journals, but as justified practical advices. Both theorists and practitioners care for theory, but in very different ways.

Characterizing theories aimed at supporting teachers’ mathematical classroom practices

Per Nilsson¹, Andreas Ryve² and Maria Larsson³

¹Örebro University, School of Science and Technology, Örebro, Sweden; per.nilsson@oru.se

In this paper we draw upon examples from a recently published systematic literature review (Ryve et al., 2015) on productive classroom practice to contribute to the research on the nature of theories for action in mathematics education. By relating the results from the review to theories and literature on educational policy research, professional development research and implementation research we construct a framework for categorizing theories aiming at supporting teachers’ actions in mathematical classroom practices.

Keywords: Theoretical frameworks, theories for actions, mathematical classroom practice.

Introduction

The development of frameworks and theories¹ that aim at guiding the actions of teachers have rendered much recent attention in educational research (e.g., McKenney & Reeves, 2012; Ruthven, Laborde, Leach, & Tiberghien, 2009). Within research areas such as curriculum material (Davis & Krajcik, 2005), planning and implementing whole-class discussions of cognitively demanding tasks (Smith & Stein, 2011), professional developments programs (Borko, 2004; Desimone, 2009), and improvement of mathematical instructions at scale (Cobb & Jackson, 2012) cumulative work has been conducted to establish theories for action. Further, frameworks for supporting teachers’ actions and thinking such as curriculum materials, theories and models have been put forward as essential components of effective professional development (Cobb & Jackson, 2012) and for establishing productive mathematical classroom practices (Franke, Kazemi, & Battey, 2007). However, we need to know more about how theories should be designed to facilitate implementation; to be used and do real work in supporting and constructing teachers’ actions (McKenney & Reeves, 2012). In this paper we relate result from a recently published systematic literature review (Ryve et al., 2015) on productive classroom practice to literature on educational policy, professional development and implementation research in order to construct a framework for understanding and facilitating the implementation of theories and research results aiming at supporting teachers’ mathematical classroom practices.

Relevant research

The approach of the present study is based on the assumption that ‘theory matters’ for teachers, to enhance their ability to develop rich mathematical classroom practice (Charalambous & Hill, 2012).

¹ There are many ways to denote theories serving the purpose of guiding actions and this is further discussed below.
For instance, by adopting and making use of theoretical tools teachers are supposed to enhance their ability to establish productive routines in their classroom practice (Franke et al., 2007), develop and continuously adjust a learning trajectory and the means to support that trajectory (Cobb, Confrey, Lehrer, & Schauble, 2003), become more sensitive to notice instructional opportunities in the moment and be methodical without being mechanical. However, Burkhardt and Schoenfeld (2003) argue that most theories that have been applied to education are quite broad, lacking the specificity that helps teachers to guide and understand the design and analysis of learning activities. Cobb et al. (2003) adhere to this view, claiming “General philosophical orientations to educational matters – such as constructivism – are important to educational practice, but they often fail to provide detailed guidance in organizing instruction” (p. 10). So, there is this dilemma; theoretical constructs are supposed to enhance teachers’ capacity to teach but, to do such work, theories need to be of a certain kind.

Perspectives on theories

diSessa and Cobb (2004) detail the nature of different theories relevant for research in mathematics education. They distinguish between grand theories, orienting frameworks, frameworks for action, domain-specific instructional theories and ontological innovations. Skinner’s behaviourist theory provides an example of a grand theory. Even if grand theories have a prominent position in educational research, they appear to be too general to provide guidance for explaining and supporting the learning of mathematics. Orienting frameworks, such as constructivism (Von Glasersfeld, 1995) or communities of practice (Lave & Wenger, 1991), provide general support for specifying issues of learning, teaching and instructional design whereas frameworks for actions concern analytical constructs of a more or less general prescriptive character (diSessa & Cobb, 2004). Domain-specific instructional theories are also of a prescriptive nature as they are typically specific to a domain or even learning trajectory of certain content and the means by which this trajectory can be supported. An ontological innovation is descriptive in nature. It is about developing analytical categories by which aspect of a phenomenon can be discerned. The framework of Socio-mathematical norms (Yackel & Cobb, 1996) exemplifies an ontological innovation.

diSessa and Cobb’s (2004) categorization not only labels the nature of different frameworks, it also points to the descriptive, explanatory, predictive and prescriptive purposes of different theories. Firstly, theories could be used to describe the world and many theories and frameworks within mathematics education serve such a purpose. The contribution to research in engaging in describing or characterizing objects or processes as certain phenomena could be understood in terms of new or unconventional lenses for viewing the world. Secondly, a further purpose of theories is to explain relations between phenomena and as mentioned above this purpose is often stressed as absolutely central for theories. A prerequisite for explaining those relations is to explicitly characterize each phenomenon. Therefore, theories used for explanatory purposes build upon or encompasses descriptive theoretical contributions. Thirdly, in a similar vein predictive theories necessitate explanations and clear descriptions of phenomena. Predictions include foreseeing effects of certain actions under certain conditions. Finally, prescriptive theories are used to identify and articulate productive ways to make decisions and performing actions. This kind of theory integrates descriptive, explanatory and predictive knowledge to guide actors in constructing and establishing
interventions. Within design research prescriptive theories are often denoted design principles but neither the term nor the nature of those design principles are settled (Ruthven et al., 2009).

Theories for action

In this paper we are particularly interested in theories for actions and what McKenney and Reeves (2012) denote the prescriptive role of theories. Both the characteristics of theories of actions and prescriptive theories and ways of denoting them are not settled in educational research as indicated above (cf. McKenney & Reeves, 2012). As becomes apparent in (Ruthven et al., 2009), the relation between the terms used to denote theories for action is not just connected to neutral ways of denoting the same phenomenon but instead accentuates particular features and characteristics of such prescriptive theories. For instance, Ruthven et al. (2009) shortly muse about the relation between the design tools they introduce and design principles. They suggest that the conceptual set up of grand theories, intermediate frameworks and design tools introduced in Ruthven et al. (2009) stresses theoretical underpinnings for sensitizing researchers to critical issues while design principles from US often prescribe certain course of actions and are typically more loosely anchored in theoretical perspectives. One may ask, should theories for actions prescribe and sensitize teacher? In general, the development and understanding of design principles is weakly developed and in summarizing the most urgent issues for educational design research McKenney and Reeves (2012) suggest “a worthy challenge facing educational design researchers is to further the development of predictive and prescriptive theories” (p. 212). We want to add to this research.

Method

The design was framed by a ten-step process for systematic literature reviews (Gough, Oliver, & Thomas, 2013): (1) Need, (2) Review questions, (3) Scope, (4) Search, (5) Screen, (6) Code, (7) Map, (8) Appraise, (9) Synthesize, and (10) Communicate. In the project we engaged in processes 1-7 and 10. Our review questions were: (a) What characterizes research on classroom teaching practices, teaching approaches and teaching methods in mathematics? (b) What characterizes research on teachers’ instructional strategies used to establish classroom practices in mathematics? and (c) What does research tell about teaching for the learning of mathematical competencies?

We searched in title, keywords and abstract in Web of Science. Search strings were iteratively developed while reading some abstracts. In total, we had 622 hits that we screened for relevance according to our scope defined by our inclusion criteria. The screening was made in two steps based on: (1) title, keywords, and journal name, and (2) abstracts. Uncertain cases were discussed and decided upon collectively among the three researchers. After the two screening steps, 242 articles remained potentially relevant for the scope of the review. Simultaneously as the screening of

2 We searched Web of Science Core Collection as a way to focus on high-quality journal articles. We limited our search to the year span 2008-2014 and to the document types “article” and “review”.

3 See Appendix A in Ryve et al. (2015) for the exact search strings.

4 For an article to be included in the review, the article must be: (1) about mathematics teaching/learning/education, (2) related to compulsory school (grade 1-9), and (3) about the teacher's role.
abstracts, the articles that remained relevant were coded on Object of study, Method, Number of participants, Context, Results, and Implications for practice. When needed, we also read other parts of the articles apart from the abstract. 201 articles remained relevant for the review based on the inclusion criteria. The next step of the mapping was to structure and characterize trends and interests within the discourse of research in mathematics education that focus on teaching methods, classroom practice and teacher’s role in classroom practice. Therefore, we looked closer at the abstracts of the 201 articles, categorizing them in relation to object of study. See Ryve et al. (2015) for detailed descriptions of steps and rationales in the processes.

Figure 1. Categories and analytical relationships of the mapping

Of the 201 articles, we found 168 to be structured according to an analytical relationship between an outcome variable and a design variable. In the remaining 33, the object of study did not follow such a structure. The design variables we distinguished are gathered in the left column of the matrix (Figure 1), while the outcome variables we found are categorized in the top row of the matrix. In elaborating on the mapping we intend not to go through the entire mapping. We highlight and provide examples on some specific findings, which we then follow up on in the discussion. In the discussion we construct a new framework, to be used for categorizing theories to be implemented in mathematics classroom practices. On this account, and due to space limitation, we are not backing up all claims and findings by references from the mapping.

Elaborating on theories within the mapping

Student knowledge

Our review reveals a clear bias towards research that focuses students' product knowledge. Mathematical products relate to conventions, symbol systems, concepts and calculation techniques of mathematics. Looking at studies that emphasized a product view of mathematics and those emphasizing a process view we also notice a methodological difference. In the product view knowledge is expressed in the language of mathematical products and students understanding are profiled and ordered in accordance to the mathematics itself. Connected to such a conceptualization of knowledge, students’ performances are often measured by standardized tests (Desimone, Smith,
& Phillips, 2013). In the process view, qualities and progressions are not explicitly elaborated on. These frameworks are descriptive in nature, specifying a set of analytical categories, which is used to sensitizing (Ruthven et al., 2009) the analyst on some certain characteristics of, for instance, students’ ability to communicate and reason in and with mathematics.

*Interactional strategies*

Studies belonging to this category explicitly refer to teachers’ moves and actions. The teacher takes an active role in these studies; how he/she acts in interaction with the students, is central to the investigation. The focus is on how teachers communicate and engage with their students, and what role the communication and engagement play in students’ learning of mathematics. It could be about, for instance, how a teacher uses gestures and questions (Shein, 2012) and follow up on students’ ideas in order to develop the mathematical classroom practice (Akkus, 2013).

*Teaching approaches*

Teaching approaches refer to studies taking a broad perspective on classroom teaching in mathematics. The teachers’ actions and interactional behavior are not the main object of investigation. The teacher may be important, but it is the more general and overall structures of teaching that are the object of study. In our review we found different examples of teaching approaches, such as technology-based teaching, mathematical games, problem-based teaching, and contrasting ways of using textbooks in mathematics teaching.

*Learning material (task design)*

Some studies focus on how a specific artifact or design principle can support or challenge students’ learning in mathematics. In these studies, the teacher takes a passive role. Focus is on the students' interaction with the learning material and the role of the teacher is basically to execute the lesson. Studies belonging to this category may investigate the role of visualization or simulation in the learning of mathematics (David & Tomaz, 2012). In this group we also include issues of task design; types and sequences of tasks (Hattikudur & Alibali, 2010) and instructions for solving mathematics tasks (Orosco, 2014).

*Background variables*

Several studies did not connect classroom practice and students’ learning to any didactical design variable. These were studies giving accounts of personal attributes such as teachers’ beliefs, attitudes and knowledge in order to explain classroom practice and students’ performance.

*Characterization*

In 33 articles of the articles, the object of study did not follow the structure of an analytical relationship between two didactical variables. In this group of studies, to describe a certain practice or teaching approach is the focus in itself. The goal is to provide descriptive accounts of analytical categories of a teaching/learning phenomenon, which can be used to sensitizing researchers and teachers to critical issues of the phenomenon in question (Ruthven et al., 2009). It may concern the characterization of curriculum material (Sherin & Drake, 2009), the orchestration of math-talk with interactive whiteboards (Beauchamp, Kennewell, Tanner, & Jones, 2010), mapping the mathematics in classroom discourse (Herbel-Eisenmann & Otten, 2011), or profiling students’ understanding or strategies of specific subject matter content (Wagner & Davis, 2010).
Discussion

By relating the results of our mapping to literature on educational policy, professional development and implementation research we construct a framework for understanding and facilitating the implementation of theories and research results aiming at supporting teachers’ mathematical classroom practices.

In studying the papers it is apparent that teachers are ascribed different roles in different research studies. While quite a few studies within the category of learning material position teachers as administrators of tasks and computer programs other studies highlight the role of expert and orchestrator of classroom practices. Within the latter categories of articles, the role of teachers is central in asking questions, explaining content and acting formatively to support and challenge students’ mathematical thinking. In understanding the implementation of theories and results aimed at improving classroom practices and students’ mathematical learning it seems essential to consider how theories construct the role of teachers in classrooms.

Ruthven et al. (2009) notice the distinction between theories that prescribe teachers’ actions and theories that aims at sensitizing teachers to essential aspects of classroom practices. In a similar vein, while some theories and studies in our review are clearly prescriptive towards teachers (e.g., theories belonging to Instructional strategies and Learning material) and what they should do in classroom practices, others aims at sensitizing and empowering teachers (theories belonging to the Characterization category). We are not normative about these different ways and suggest that both could be productive for different teachers in different context. Further, we hypothesize that these two strands are correlated with research methodologies in that many studies within mathematics education taking an educational design perspective aims at empowering teachers while studies taking a stricter experimental approach prescribe and praise clear prescriptive instructions. However, to what extent and in which ways theories prescribe or sensitize teachers seem relevant to consider for anybody collaborating with teachers.

Cobb and Jackson (2012) stress that tools and frameworks within educational policies play a prominent role. When it comes to designing and using tools Cobb and Jackson suggest that it is important that the tools can be used by agents immediately in that they are easy to access, but at the same time harmonize with the planned reorganization of the practices. In addition, in developing frameworks, theories and tools it is essential to consider the amount and type of learning that are required for teachers to develop in order to use them in an appropriate and reliable way. Of course, such using requires good mathematical knowledge for teaching (Ball, Thames, & Phelps, 2008). However, there is also reason to believe that certain types of frameworks are easier then other to use and apply in a mathematical teaching practice. For instance, in our survey we notice how the product perspective dominates research focusing on student knowledge. That the product perspective has a long tradition in the field is probably the major reason for this. However, taking a closer look to the mapping we can also understand this dominance as if there is a higher degree of transparency in how to use product knowledge theories compared to process-knowledge theories. From this we learn that, in implementing theories to school practice, we need to consider how user-friendly, accessible and transparent different types of theories are to teachers. In other words, we need taking into account to what extent and which kind of teacher learning is necessary for productively implementing theories or frameworks to mathematical classroom practices?
Desimone’s (2009) put forward *coherence* as a critical feature of professional development programs. The concept of coherence refers to the relation between the PDP and teachers’ knowledge and beliefs. This raises questions about the extent to which theories should be coherent with teachers’ knowledge and beliefs. In other words, should theories strengthen teachers’ knowledge and beliefs or should it challenge their knowledge and beliefs? Should theories aim at strengthening classroom practice or should theories aim at reorganizing classroom practices (Cobb & Jackson, 2012)? The reorganization of practice could include working with new types of mathematical problems, new roles for students and teachers, and the establishment of new classrooms. Hence, in examining and choosing theories, frameworks and models, mathematics educational researchers working with teachers should consider whether the aim is to **strengthen or reorganize ongoing practices** and, consequently, consider how frameworks are supportive for such endeavors.

To conclude, as a complement to categorize theories for actions in terms of content areas we suggest it is productive for researchers working with teachers to consider theories in terms of: the positioning of teachers in classroom practices; the positioning of the teacher as a receiver of the theory; the amount and type of teachers’ learning required; and if theories primarily function to strengthen or to reorganize practices.

In this paper we investigate the role of the local supervisor when implementing a mathematics teacher training program based on Action Learning (Misfeldt et al. 2014, Plauborg et al. 2007). Using data from interviews of teachers, local supervisors and school managers we examine the arising expectations on the local supervisor and how these expectations influence the program’s ability to support teachers in their professional development. We do so by using Clarke’s (2009) Situational Analysis and Arcform notation (Allsopp 2013) to map the actors’ relation to the supervisor. We see that the local supervisor is caught in a tension between expectations from the Action Learning method and the school managers. This hinders schools in anchoring Action Learning as a teacher training method and thereby benefitting its full potential.

Keywords: Teacher training, Action Learning, theory and practice, Arcform.

Implementing teacher capacity building through collaboration

A crucial aspect of a number of initiatives to improve mathematics education is the ability for teachers to collaboratively question and improve their own teaching (Stigler 1998), sometimes involving resource persons such as researchers or teacher educators. For such in-service training or capacity building to be efficient and scalable it is important that they are anchored in the school organization and not solely dependent on enthusiasts. Initiatives like Lesson Studies and development of own practice (alone or in collaboration with researchers), are examples that requires systemic and organizational attention (Lewis, Perry & Murata 2006). Systematic approaches often mean that teachers take on certain roles in relation to each other’s practice in order to maintain initiatives. Such structures and roles that connect in-service training to practice and build directly on the school organization and culture are important. Research has found that it is very difficult to make sustainable changes with teacher training initiatives (Shear, Gallagher & Patell, 2011; Henriksen et. al 2011), and Maurer (2010) has estimated that 70% of teacher training projects fail in changing teachers’ practices within the given time frame of the project. This is a major challenge to the mainstream implementation of research findings in mathematics education. According to research literature the difficulties with changing teacher practice through in service training are associated with a lack of connection between training programs and teachers’ existing practices (Fixsen et. al. 2005) as well as with the fact that teacher training programs often lack a focus on establishing active, collegial relations among teachers, which are crucial in order to build sustainable development (Hargreaves 2000, Sølberg, Bundsgaard & Højgaard 2013). When trying to address these concerns certain employees often take on certain roles towards their colleagues in the sense that they advocate for, manage and nurture certain projects. In this paper we explore this challenge by investigating a case where the distance between training activities and day-to-day teaching is very small and where the collegial relations are supported in a direct fashion. We do so by describing an Action Learning case as it has been implemented in a Danish municipality.
Context

In 2012 a municipality in Denmark launched a teachers training program aimed at developing teaching practices and enabling schools in the municipality to develop teacher competencies independently from external resources. The training program involved every school in the municipality and a total of 3500 participating teachers. The program consisted of a combination of a summer university in which teachers where given thematic lectures on a variety of subject-specific and pedagogical topics (implemented at 80% of the schools) and a method called Action Learning (implemented at approximately 20 % of the schools). Action Learning is a teacher-training program developed as an alternative to traditional course based in-service training. It draws on inspiration from Action Research in that it is based on an assumption that solutions to practical problems require practical understandings, which must be gained through iterative attempts to solve the actual problem (Plauborg et. al. 2007). The “action” in Action Learning refers to a pedagogical or didactical intervention that address real classroom issues as the individual teacher experiences them. While the “problem” is defined by the individual teacher the intervention is developed collaboratively by a group of teachers engaging in a so-called “team-conversation”. Local supervisors from each school were designated the responsibility to facilitate professional discussions among the teachers in the team conversations. The local supervisors were teachers from the school who had a mathematics supervisor education, and who provided didactical support on a daily basis. The local supervisors also had the responsibility of anchoring the collaborations among the teachers at the schools to enable their ongoing professional development. The characteristics of Action Learning therefore seem to counter many of the challenges identified in the research literature about teacher training programs; active collegial teams are established, the team conversations are facilitated by the local supervisor in order to maintain an academic focus in the conversations and the starting point is the teachers’ existing practices. In this context these initiatives however relied heavily on the local supervisors who were designated a key part in facilitating the team conversations and in anchoring team collaboration at the schools. In our research we therefore investigate the expectations arising to the local supervisors in the implementation of Action Learning and their possibilities meet these expectations (for further information about the program see the full evaluation report (Misfeldt et al. 2014).

Method

Our research draws on interviews of key actors in the training program from two schools, namely the participating teachers, local supervisors and school managers. We interviewed 6 teachers, 2 local supervisors and 2 school leaders coming from 2 different schools. Our interviews explored the actors’ experiences of the training program and their understandings of the role of the local supervisor in the program. We also collected documents and literature that describes the Action Learning Method and documents from the municipality describing how Action Learning was to be carried out. All of these sources were considered with the goal of identifying how the role of the supervisor was perceived. We analyzed this data by using Clarke’s Situational Analysis (Clarke 2009). Situational Analysis is rooted in Grounded Theory, but modified according to postmodern assumptions that “boundaries are open and porous; negotiations are fluid and usually ongoing” (Clarke 2009). There is no a priori assumption that human actors are of greater importance than either non-human or discursive actors (Clarke 2009), which allows us to view the Action Learning
concept as an actor in itself. In Situational Analysis, Situational Maps provide a methodological approach to organize and visualize empirical data by foregrounding situations (Clarke 2009). We initially processed our data by using a sub type of Clarke's Situational Maps: Relational maps (den Outer 2013). Like other situational maps these aim at foregrounding situations rather than individual actors or their actions by mapping all actors (human as well as non-human and discursive) that occur in any situation, but go further than this by showing relations between actors. Relational maps use a type of network notation where actors are represented by labeled nodes and relations are represented by un-labeled lines drawn between the actors/nodes.

We drew our relational maps while reading our transcribed interviews and other relevant documents. We began by listing the relevant actors that appeared in our data and their relation to each other. We produced many versions of some maps, modifying them as some actors and relations grew in prominence in our analysis. The messy nature in our data was easily overviewed with the simple structure of relational maps and thus they played an important part in opening up our data and thereby prompted our analyses. However, beyond a certain point they seemed to counteract rather than support overview. Clarke stresses that though situational maps are useful tools for beginning analyses, they are not necessarily an appropriate end-product of analysis (Clarke 2003, 563). We experienced two related problems: Firstly, it was difficult to draw some types of relations between actors and secondly they became difficult to understand/interpret, especially when returning to the analyses after several weeks. To overcome this limitation of our relational maps, we chose to visualize the situations through Arcform notation (Allsopp 2013). Like relational maps, Arcform maps do not visualize our data, but rather the results of our ongoing analysis. Arcform maps differ from most relational maps, but resemble many network notations by supporting direction and labels on relations (arcs). Thus relations like “local supervisors coach teachers” are clearly visible as an arc labeled “coach” pointing from an actor node labeled “local supervisors” to another actor node labeled “teachers”. However, Arcform also differs from most other network notations by allowing arcs to point from or to other arcs. In this way more complex relations like “teachers see local supervisors as coaches” can be drawn as shown in Figure 2.

Figure 1. The sentence “Teachers see local supervisors as coaches” expressed in Arcform.
Results

As our analysis progressed it became clear that the actors in our data articulated their relation to the local supervisor quite differently, and that they had different conceptions of the main job of the supervisors in the action learning project. Though these actors were all engaged in the same project at the same school, their ways of participating and their relation to the supervisor was rather different and seemed at first glance to be related to their role in the school outside the project. Besides being a part of a project, the actors were respectively also teachers, supervisors and school managers, and this fact seemed to be of importance. Our maps also revealed that this meant that the actors had different expectations on the supervisor and that these expectations could intersect with problematic consequences. In order to refine our analysis of these preliminary results we decided to use a notion of cultural logics developed by Nielsen (2012), which we will introduce below.

In a study on teachers’ learning from collaboration in teams, Nielsen develops a view of teacher collaborations as having a dynamic stability (Nielsen 2012). It is dynamic because it involves numerous ongoing activities that are oriented towards one or more objectives. It is stable because it involves a perceived regularity in actors’ actions suggesting a stable understanding underlying these activities. Such logics effect peoples’ objectives and can be difficult for externals to change, because they reflect the every-day phenomena which are experienced as urgent by the actors involved. For example, although teachers most likely find the learning processes of students an important objective to orient their collaboration towards, so too may they find the practicalities that make a well-settled lesson (Nielsen 2012). In situations where there are multiple cultural logics we can expect actors sometimes to be caught in a tension between these logics.

The notion of cultural logics is highly useful in our context as the Action Learning training program is a project in which several actors’, who occupy diverse positions, participate. Viewed this way the role of the supervisor is at risk of being caught in a tension between multiple cultural logics. As the local supervisor is a key actor in implementing and anchoring the Action Learning method, such tensions and their implications are of particular interest in this study. We identified three dominant logics. We refer to these as the workplace logic, the curriculum logic and the project logic. The cultural logics are characterized by situations in which certain aspects of the training program are foregrounded over others which translate into a set of expectations on the local supervisor. In brief the logics translate in to the following expectations:

- In the **workplace logic** the supervisors are expected to manage the project and to avoid delays in the project.
- In the **curriculum logic** the supervisors are expected to be willing and able to guide the teachers academically in their professional development.
- In the **project logic** the supervisors are expected to initiate and support the teachers’ professional development in a coaching-manner where an equal relation between supervisor and teacher is crucial.

The map below illustrates how the role of the supervisor is formed by the different cultural logics.
Figure 2. An Arcform map showing how two actors (school managers and teachers) see local supervisors as three different roles (project managers, academic beacons and (equal) coaches) with three different cultural logics (workplace logic, curriculum logic and project logic).

The goal in the project logic are progress and development of the school, while the curriculum logic foregrounds the quality of teaching. Though these logics can be complementary, our mapping revealed that the supervisors are faced with a tension due to a collision between the project logic and the workplace logic. In the following two sections we will therefore further describe the dynamic stabilities of the two latter cultural logics and unfold the tension emerging from here.

The project logic

The project logic concerns the cultural logic of the Action Learning training program as it occurs in documents describing the Action Learning concept and the expectations to the role of the supervisors emerging from it. In the Action Learning concept, the primary priority is the competence development of the teachers participating. In this, the supervisors are first and foremost expected to have the will to develop the school and the teachers and to do so as an equal coach rather than as a managerial authority. The supervisor is expected to initiate the Action Learning collaboration and to support the teachers in their development - not to lead/manage them. This is crucial as it is an acknowledgement that it is the teachers themselves who are experts on their own practices – the role of the local supervisor is therefore to facilitate conversations that creates the best setting for this knowledge to be shared (Plauborg et. al. 2007). The statement below from a local supervisor illustrates her view of the Action Learning project suggesting that she embraces the project logic and that she is capable of seeing the potentials in the method.

Local supervisor:  

(…) there were some 3rd grade teachers who said: “We have already tried this method. Why do we have to go through it again?” And my argument was that even though we have tried the method before, it is not implemented at our school. We don’t use it as a method as things are now.
The statement indicates that the supervisor views competence development as ongoing and Action Learning as a way to enable such ongoing developments. She therefore argues to her colleagues that Action Learning is not a syllabus which you only have to read once and then move on – rather, Action learning is a concept that involves specific ways of collaborating which are not implemented at the school. The statement thereby demonstrates a will to develop the school that resonates with the expectations embedded in the Action Learning concept. It also tells us that the supervisor has the skill needed to spot and to articulate that the crux is to integrate Action Learning as a way of collaborating.

The workplace logic

The workplace logic concerns the main objective of the training program from the school managers’ view and their expectations to the local supervisors’ role in the project. From the interviews with school managers the training program appears as a project among many other projects in which the main priority is to safely navigate the school through it and to avoid any delays. Though the school managers presumably also have an interest in developing the competencies of their teacher staff, safely getting through the project appears as the dominant cultural logic. Interviews with school managers show that this logic translates into an expectation that the local supervisors will be managers of the project due to high trust of the professionalism of the supervisors. The statement below from a school manager illustrates how the supervisor is referred to through the workplace logic.

School manager: I highly trust my supervisor’s skills. Our supervisor is very professional and she is currently going through a pre-leader course. (...) and I thought that she therefore was better qualified to manage the project than I was.

In what appear as an acknowledgement of a supervisor’s skills, this supervisor is given the responsibility to manage the project. At this particular school a group of teachers refused to participate in the training program due to short notice and discomfort about having to be observed as a part of the project. As the school managers had distributed the responsibility to manage the project, this became an issue for the local supervisor to handle. Consequently, the supervisor was obliged to “persuade”, as she puts it, another group of teachers to participate in the project.

Local Supervisor: I didn’t lure them but... I just told them that it wasn’t optional. They just had to do it, you know.

As the responsibility of managing the project was designated to the supervisor through the workplace logic, these project management issues become a task for the supervisor to handle. This implies that the supervisor is required to draw on a formal leadership mandate by reminding the teachers that participation in the project is mandatory. As the supervisor describes in the following excerpt, this incident resulted in an uncertainty among the teachers about the role of the supervisor:

Local Supervisor: I think that this made it very unclear for the teachers what my part in this project was. Am I here to check if they are doing a bad job? Will I go to my manager and say: “That teacher does a bad job. She is really bad at teaching math”. Or whatever it might be.

The supervisor’s task of managing the project is not necessarily problematic in itself. But as a group of teachers refuse to participate in the training program, this is an issue that becomes a task for the supervisor to handle. In order to handle this issue, the supervisor is obliged to find another group of
teachers that are willing to participate. As no other teachers were willing to participate in the project the local supervisor was obliged to emphasize to a specific group of teachers that they were obliged to participate as this was necessary for the Action Learning project to carry on.

Implementing research findings in practice – emerging problems and prospects

Our analyses have identified three cultural logics, two of which we have unfolded above. Each of these cultural logics produces a certain set of expectation to the supervisor in terms of how he or she adequately should participate in the project. What becomes evident from our analyses is that the local supervisors are met by mutually exclusive expectations as a consequence of these logics; the project logic expects the supervisor to support the teachers as an equal peer whereas the workplace logic expects the supervisor to manage the project as a superior. This has at least two consequences. Firstly, the supervisor’s delegated management role triggers an uncertainty among the teachers of the intentions of the supervisor and raises the questions of whose errands he or she is running. Is the supervisor’s main task to support the teachers in their professional development or to monitor their work on behalf of the management? This uncertainty makes it difficult to draw on the supervisor as an equal facilitator. A key component in the Action Learning concept is the joint observations of each teacher’s practice, which subsequently are meant to be the starting point for a conversation aiming to develop the teachers’ understandings of their own practices. Such an uncertainty among the teachers in respect of the supervisor’s role represents a substantial barrier in creating a safe environment in which the teachers can learn from their own practices. Secondly, the coexisting logics cause a tension on the supervisor as he or she is expected to fill many roles at the same time. Each of the cultural logics influence the actors’ expectations to the role of the supervisor according to their own dynamic stability, thus tying the supervisor to different, incompatible priorities at the same time. As the potential for anchoring the Action Learning concept is closely connected to the role of the supervisor, there seem to be little chance that the supervisors are capable to do so under such difficult circumstances.

Our analysis also points to more general issues related to implementation of research findings in practice. Though Action Learning addresses what seem to be the main challenges in gaining long-term results from teacher training programs, the different expectations arising on the local supervisor complicates the implementation and the anchoring of the training program. The training program investigated in this paper exemplifies how many actors are at play in a school setting and that each participating actor may have different agendas in and around such projects. Though this perhaps is no surprise, our research suggests that difficulties in implementing research informed training programs can be the result of the differing actors’ agendas outside the project. In Action Learning, as in many other training approaches, some actors are of immense importance in order to harvest the potential results of research informed approaches. The professional development of teachers involves and affects many others than the participating teachers and enters the professional lives of actors, which may have different priorities, agendas and available resources. A main problem about the issues identified in our research is that the co-existing cultural logics and the expectations arising to the supervisor thereof largely remain tacit. Though different agendas and the effects of such cannot be eliminated by simply making them explicit, an increased awareness and joint management of expectations would most likely be a step towards overcoming such hurdles.

Rehearsals in work with in-service mathematics teachers

An approach that has shown to give pre-service teachers rich opportunities for learning to teach mathematics is through a cycle of enactment and investigation. An important part of the cycle is rehearsal where novices rehearse their plans for enacting particular instructional activity in front of their peer pre-service teachers. The peers and the course instructor take part in the rehearsal as students, and every participant can stop the activity for discussion on different aspects in teaching. We build on the approach developed for pre-service teachers, and work on the adoption and development of the approach for work with in-service teachers in Norway. This paper reports from a pilot that was implemented with a group of in-service teachers. Our research question concerns interactions between in-service teachers and course instructors during the rehearsals and in-service teachers’ opportunities for learning in rehearsals.

Keywords: Rehearsals, in-service teachers, ambitious teaching.

Introduction

The aim of mathematics instruction is development of broad mathematical proficiency characterized by conceptual understanding, procedural fluency, adaptive reasoning, strategic competence and productive disposition to mathematics (Kilpatrick, Swafford, & Findell, 2001). This ambitious goal leads to a more demanding, and thus ambitious, conception of mathematics teaching. In this paper we aim to add to the existing knowledge base about how teacher education can support in-service mathematics teachers to learn the work of ambitious mathematics teaching.

In the Mastering Ambitious Mathematics Teaching (MAM) project we develop a course for in-service mathematics teachers in Norway. In designing our intervention, we take our lead from the Learning in, from, and for Teaching Practice (LTP) teacher education project (see Kazemi & Hubbard, 2008; Kazemi, Lampert, & Franke, 2009; Lampert et al., 2010; Lampert et al., 2013; Kazemi & Wæge, 2015). Central in the LTP-practice based approach is work with specifically designed instructional activities (IAs) in a cycle of enactment and investigation. A key innovative feature of the design is the use of public rehearsals. In a rehearsal, the pre-service teacher is responsible for teaching an IA to a group of peer pre-service teachers acting as students, with the course instructor offering guidance.

This paper reports on our work on rehearsals with in-service teachers in a pilot study. We ask: What characterizes the interactions between in-service teachers and course instructors during the rehearsals in the study, and in what ways might rehearsals support in-service teacher’s learning of ambitious teaching?
Rehearsals within a cycle of enactment

Ambitious teaching entails mathematical meaning making, identity building and creating equitable learning experiences for children. It requires teachers to engage deeply with children’s thinking - by eliciting, observing, interpreting and responding to student reasoning, language and arguments. Attending to students’ experiences and designing instruction to enable each child to do rigorous academic work in school is also a central principle of the approach (Lampert et al., 2013).

In their work on ambitious mathematics teaching, Lampert et al. (2010) build on the study of Leinhardt and Steele (2005) who identified some routines skilled teachers used in leading instructional dialogues and argued that expressing the routines explicit make them teachable for course instructors. Lampert et al. (2010) use the notion “routines” to denote well-developed practices which have shown useful in teaching, which respect the complexity in mathematics, mathematics teaching and learning. They argue that focus on learning to use these routines/practices can provide novices an opportunity to hold something constant in a process of further learning to teach. The teaching practices that are central in ambitious teaching include aiming toward a mathematical goal, eliciting and responding to students’ mathematical ideas, orienting students to each other’s ideas, setting and maintaining expectations for student performance, positioning students competently, assessing students’ understanding, and using mathematical representations (Kazemi et al., 2009; see also Hunter & Anthony, 2012). Teachers who are novices in teaching mathematics ambitiously need to learn to enact the practices in their teaching. They also need to develop the mathematical knowledge needed to teach ambitiously at a particular grade.

Grossmann, Hammerness and McDonald (2009) argue for incorporation of “pedagogies of enactment” and use of “approximations of practice” in teacher education in order to help pre-service teachers develop knowledge, skills and professional identities as teachers. As a type of approximation to practice, Grossmann, Compton at al. (2009) suggest use of rehearsals where novices rehearse a particular instructional activity in front of a group of peers. Kazemi, Lampert and Franke (2009) develop instructional activities (IAs) that are designed to be “containers” for the practices, principles and mathematical knowledge that novice teachers need to learn and be able to use in interaction with students (see Kazemi & Wæge (2015) for descriptions of the IAs). The structure of the IAs offers the novices a scaffold in eliciting and responding to student thinking and understanding. The novice teachers learn to teach IAs – through repeated investigation, discussion, rehearsal, enactment and observation. Each cycle of enactment and investigation consists of six stages (Lampert et al., 2013), as illustrated in Figure 1:

1. Observation of a teacher educator’s enactment of a particular IA
2. Collective analysis of the observed enactment
3. Preparation to teach the IA to a group of students
4. Rehearsal of the IA by novice teachers
5. Enactment of the IA with a group of students
6. Guided collective analysis of the enactment

Figure 1: Cycle of enactment and investigation
In stage four of the cycle, selected novice teachers publicly rehearse their plans for enacting an IA in front of their peers and with feedback from the course instructor. During the rehearsal, the course instructor or a peer may stop action to ask questions or suggest possible alternative courses of action. The course instructor may also act as a student, by asking and answering questions or by making errors that students are likely to make (Lampert et al., 2013). Rehearsals within repeated cycles of enactments and investigation can be considered as an approximation of ambitious teaching.

Lampert et al. (2013) argue that a rehearsal is an important setting for building novices motivation and commitment to teach ambitiously (p. 239-240). They analyzed 90 rehearsals of IAs by pre-service teachers. The study revealed that rehearsals not only allow pre-service teachers to work on routine aspects of ambitious teaching, but also to attend to more complex aspects of it. The study also showed that rehearsals give the pre-service teachers an opportunity to learn the principles of ambitious teaching while the course instructor guide their progress.

**Design of course**

The course consisted of seven sessions (each four hours in length) during a period of four months. The sessions were held in a fifth grade classroom of an elementary school.

**Session 1:** The in-service teachers (ISTs) were introduced to the principles and practices central to ambitious teaching and the instructional activities they would work on during the course.

**Session 2-6:** In these sessions ISTs were divided into three teams of 4-5, and the teams worked together in planning, rehearsing, enacting, and debriefing course tasks: 1) Teams of ISTs came to class prepared to teach an IA; 2) Teams of ISTs rehearsed the IA under supervision of a course instructor (CI); 3) ISTs observed one of the CIs teach the subsequent session’s focal IA to the whole group of fifth graders. This was part of the preparation for the following session; 4) One IST from each team taught a small group of fifth graders the IA that they had come to class prepared to teach. A CI also observed the enactments; 5) After a break, ISTs met in their teams to do a collective analysis of the day’s enactment with their CI; 6) Each team debriefed what they had learned; 7) The CIs prepared the class for the following session’s focal IA and, as part of that, shared some reflective comments on the whole group lesson that was taught.

**Session 7:** The last session was devoted to concluding discussions and try outs.

**Method**

**Participants and data**

There were 14 in-service mathematics teachers from three different elementary schools participating in the pilot study. The three schools are partner schools of the Norwegian Centre for Mathematics Education. Some of the ISTs in the study had only a few years of experience as mathematics teachers, while others were experienced teachers. A group of six course instructors (including both authors)

---

1 Due to practical reasons we had to make some changes to the cycles of enactment and investigation proposed by Lampert et al. (2013) and illustrated in Figure 1.
from the Centre participated in the study. The course instructors had little experience in leading rehearsals.

Rehearsals were carried out in three teams at five of the sessions. All rehearsals were videotaped, but two of the recordings were damaged. Our data is therefore consisting of 13 recordings. Each recording is about 25 minutes.

**Coding and data analysis**

A rehearsal consists of parts where an IST is teaching the activity, and parts where IST(s) and CI interact. We denote the interactions between IST(s) and CI during the rehearsal as CI/IST exchanges. To understand what characterizes the CI/IST exchanges during rehearsals, we take a CI/IST exchange as the unit of analysis and we analyze: 1) the substance of exchanges between CIs and ISTs, and 2) the structure of exchanges between teacher CIs and ISTs. In our analysis we used a priori codes adopted from Lampert et al. (2013). Table 1 shows a list of the substance codes and Table 2 shows a list of the structure codes that we built our analysis on. We used Studiocode video-analysis software which allowed for detailed coding of the rehearsals. For each rehearsal, we created a timeline for each video-recorded to capture the substance and structure of exchanges. Coding the video directly allowed for both verbal and visual cues to be considered, such as written representation, gesturing, and movements.

**Results**

**Substance of CI/IST exchanges**

In Table 1 we present an overview of frequency of the various substance codes in all CI/IST exchanges in the data. The most frequent codes in our data are representation, student thinking, content goals and elicit and respond. These codes were also among the most frequent in the rehearsals by pre-service teachers analyzed by Lampert et. al (2013).

Due to the complexity of CI/IST exchanges, an exchange can be coded by several substance codes. As a consequence, the percentages do not sum to 100%.
Table 1: Substance codes: description and frequency as percentage of all CI/IST exchanges in the data

Many of the CI/IST exchanges involved more than one substance code, and the same combination of substance codes were frequently found together across different exchanges. For example, student thinking, elicit and respond and representation appear repeatedly in the same exchange. The combination of content goal and representation is also very common, in many cases together with mathematics. The frequency and the combination of the codes indicate that the main substance in CI/IST exchanges consist of:

1) attending, representation, eliciting and responding to student thinking
2) content goals and representation of mathematical ideas in the activity

The following example is representative of the first category above:

Example 1. The IST who is teaching during the rehearsal shows the image of three groups of eight dots and asks the “students” how they see it. One of the other ISTs in the team suggest an answer.

IST2: I see eight times three. In the first group I saw four plus four, eight. I have eight three times.

IST: [Circles three groups of eight. See Figure 2.] So first you have one times eight, so one times eight, so one times eight. [Writes 1x8+1x8+1x8=3x8.] Some other suggestions?

CI: Can we stop for a moment? Hmm, this is not so easy. The student presents her thinking rather imprecisely, and now we need to illustrate it on the image and also write it symbolically. We lose the part about seeing eight as four plus four in the way you represent her thinking. Can we try to represent her idea more accurately?

IST: I can circle four and four…

IST3: But just in the first group. She said that she saw it in the first group and then just multiplied by three. And it is not clear whether she thinks eight times three or three times eight, she says both.3

IST: Yes, right. I tried to make “eight times three or three times eight” clearer by leading to one times eight, and so on. Because it is three times eight.

CI: Maybe you can ask the student how she would represent it? Or, if you find her explanation too vague, you can ask her to say more?

The IST2 (who plays the role of the student) says that she sees eight as four plus four and she says “eight times three”. Later she says “eight three times” which is more in accordance with the image and the convention. The IST takes no notice of the first parts of the utterance, and he grabs hold of the last part which is more in line with his goal. The CI’s first question is about attending to and representation of student thinking. The IST simplifies and changes the student’s contribution through the visual and symbolic representation. Further on, he asks for other suggestions and thus indicates that the discussion is finished. The CI’s second utterance explicitly addresses eliciting and responding.

The combination of content goals and representation of mathematical ideas in the activity appear also often within exchanges in our data, and the combination is illustrated in the following example:

Example 2. The IST’s goal is to use a string of problems to discuss multiplication by ten, hundred and thousand with the students. He starts by four times three, and asks the students for a story that would fit the arithmetic problem. A student (one of the ISTs) suggests four groups of three apples, and the IST draws the illustration as shown in Figure 3.

CI: Are you planning to use money in the discussion? Your illustration reminds me of money.

IST: Yes, I have been thinking about it. Money can be useful here, when we discuss multiplication by ten, hundred. One can use tenths and talk about 12 tenths in the next step. Same with hundreds. But, another story came up.

CI: As a teacher, you have decided what the content goal is, and you have been thinking about what representation would be appropriate. You can ask about a story with money from the start to get the representation you want in the discussion.

These kinds of exchanges, where representation and the content goal are combined, appear frequently in the data. In Example 2, the main substance discussed is the type of representation that could be appropriate for a given content goal and how to introduce it. In some other exchanges in the data that are coded with these two codes, the discussion is on ways to represent mathematical ideas so that the representation emphasizes the relations that are targeted in the activity.

---

3 In Norway, when the multiplication is interpreted as equivalent groups, the meaning of “eight times three” is eight groups of three.
Structure of CI/IST Exchanges

The structure codes used in our analyses are the same as those used by Lampert et. al. (2013). Table 2 shows the description and frequency of the various codes in our data. Similarly as with substance codes, an exchange can be coded using several structure codes. For instance, in Example 2 above, the exchange starts by “CI facilitates discussion” and develops to “CI gives directive feedback”.

<table>
<thead>
<tr>
<th>Structure-codes</th>
<th>Description</th>
<th>% of all exchanges</th>
</tr>
</thead>
<tbody>
<tr>
<td>CI facilitates discussion</td>
<td>CI lead a discussion and reflection raised by CI or ISTs</td>
<td>50.4</td>
</tr>
<tr>
<td>CI gives directive feedback</td>
<td>CI suggests new move or think aloud about possible next move</td>
<td>35.7</td>
</tr>
<tr>
<td>CI gives evaluative feedback</td>
<td>CI make evaluative comment</td>
<td>7.7</td>
</tr>
<tr>
<td>CI scaffolds enactment</td>
<td>CI takes the role of teacher or student, scaffolding the enactment by either increasing or reducing the complexity</td>
<td>23.1</td>
</tr>
</tbody>
</table>

Table 2: Structure codes: description and frequency as percentage of all CI/IST exchanges in the data

Considering the structure of the rehearsals, the analysis shows that half of all CI/IST exchanges in our data can be characterized as *discussions facilitated by CI* (at least partly, in cases where several structure codes are used in the same exchange). In rehearsals analyzed by Lampert et. al. (2013), the code “CI facilitates discussion” is the least frequently appearing code, whereas “directive feedback” is the most frequent. This indicates that the structures of the rehearsals in the two studies are quite different. One reason can be that our study concerns in-service teachers while Lampert et al. (2013) report from their work with pre-service teachers. In-service teachers have more experience with teaching than pre-service teachers, and it is reasonable to expect that their skills in teaching and their identity as mathematics teachers are more developed. A consequence can be that both in-service teachers and course instructors working with them might feel more comfortable in discussions than with CI giving directive/evaluative feedback or scaffolding enactment.

**Discussion**

Further work with in-service teachers and further data collection will take place in the coming year, and the results presented here are preliminary. However, the pilot study has already yielded a number of valuable insights. The study shows that the interactions between ISTs and CIs during rehearsals are mainly in form of discussions on some central principles and practices of ambitions mathematics teaching - using mathematical representations, aiming toward a mathematical goal, attending to student thinking and eliciting and responding to students’ mathematical ideas. More specifically, we have found that multiple substance and structure codes are present within individual rehearsal exchanges, indicating that rehearsals offer in-service teachers the environment and opportunity to work simultaneously on a variety of aspects of practice.
The study of Lampert et. al (2013) shows that rehearsals give opportunities for pre-service teachers to learn to enact principles, practices and knowledge entailed in ambitious teaching. The findings in our study indicate that rehearsals function as an approximation of ambitious teaching in work with in-service teachers too, even though the structure of rehearsals is different.

Incorporating mathematical problem solving in the Chilean school curriculum

Eugenio Chandia¹ and Maria Luz Montes²

¹Universidad de Chile, CIAE, Santiago, Chile; eugenio.chandia@ciae.uchile.cl
²SIP, Santiago, Chile; lulu.monteslira@gmail.com

Problem solving is one of the skills that is expected to develop in children who learn mathematics. To do this, school mathematics curriculum worldwide has incorporated this skill for teachers to promote it in classrooms. Though research results show what should be made, these have been parcelled and make difficult an effective incorporation of the skill, its promotion and students’ learning in schools. Therefore, the following work presents a professional development strategy that incorporate diverse research results related to the promotion of problem solving in math class. This allows to achieve a professional development complex system whose main axis is the school teacher.

Keywords: Problem solving, math curriculum, professional development.

Introduction

In Chile, the General Law of Education states that “students develop knowledge, skills and attitudes that allow them to understand and use basic mathematical concepts and procedures, related to numbers and geometric forms, in everyday problems solving, and to value the contribution of mathematics to understand and act in the world”, (article 29, section f). However, in the Curricular Study Programs of Chilean Mathematical Education there is no concrete proposal for teachers to promote such skills and attitudes in the classroom. Then, this paper shows one way to develop and include the problem solving in the Chilean Curriculum National of Math Education. To do this, is necessary to know what is needed for a successful curricular proposal implementation in math. The NCTM (2014) suggests the following points to implement a successful curricular development proposal: a) Teachers need to have a professional development of high quality to maximize the efficacy of the materials and activities they propose in the curriculum, since even the best textbooks and resources can be misinterpreted or misused. b) Collaboration among teachers throughout the school year may result in appropriate adjustments and activities adaptations for dosing topics to address the strengths and weaknesses of each student. For this reason, along with thinking about the curricular development proposal, a professional development proposal that supports teachers to incorporate in a better form the new requirements that are demanded need to be thought. On the other hand, Marrongelle, Sztajn and Smith (2013) indicate that the characteristics that make more effective a professional development program are: to be performed regularly and connected to practice; to be focused on students learning; to be directed to the teaching of a content; to be aligned with objectives of the school; and to build strong links among teachers. Considering the perspective mentioned above, in the following parts will be described the process for the implementation and the incorporation the PS in the curriculum.
Methodology

The project aims to impact the: instructional practices of participant teachers related to the delivery of opportunities to develop skills in the students, focused in problem solving; teachers’ skills to solve problems; teachers’ skills to modify and adjust activities to promote the development of skills in their students; students’ skills to solve problems; students' skills to represent, report, discuss, argue and explain mathematically. For this purpose, a proposal for curricular development that was adapted to the reality of the Chilean school system in Mathematics Education was designed. The project includes two main stages. In the first one a proposal for curricular development based on a literature review was designed, based on the Chilean curricular framework. The proposal included classroom activities for students, instructional methodologies for teachers and an annual curriculum integration plan for each participating school. In the second one, there was implemented a pedagogical technical support model in order to teachers appropriate the activities and methodology to be performed later in the classroom. The curricular development proposal will be implemented in 4 schools, which compromised their participation of teachers and students from 1st to 4th grade and the time necessary to do so. It had a population of 24 teachers and 600 students from 1st to 4th grade in total.

Discussion and conclusions

The project is still being conducted, but there are preliminary results on its implementation. In the stage 1 of the proposal design was observed that while the curricular proposals from countries such as Singapore or Finland have among their curricular objectives to promotion of mathematical skills as the problems solving, the curricular resources available for teachers in those countries do not guarantee by their own, the skill promotion and not the acquisition of teachers’ instructional practices. Again, research results corroborate the lack of professional development strategies that allow the skills acquisition by teachers (Bunyi, 2013). Given this lack and the need of the Chilean teachers in terms of mathematical knowledge, as well as in pedagogical skills to promote mathematical skills and attitudes towards it in classrooms, it is that the strategy of weekly and monthly support was crucial, both for the acquisition of pedagogical skills and mathematical knowledge.

TWG24: Representations in mathematics teaching and learning
Introduction to the papers of TWG24:

Representations in mathematics teaching and learning

Elisabetta Robotti¹, Anna Baccaglini-Frank², Gérard Sensevy³, Torsten Fritzlar⁴

¹ University of Torino, Department of Philosophy and Science of Education, elisabetta.robotti@unito.it
² University of Pisa, Department of Mathematics
³ University of Western Brittany, School of Education
⁴ Martin Luther University Halle-Wittenberg, Faculty of Education

TWG24 made its first appearance as a new Thematic Working Group at CERME10, focusing on representations of mathematical concepts or mathematical objects because of their constituting an “integral part of the doing of mathematics” (Presmeg, 2002) and thus an important part of teaching and learning mathematics. Indeed, representation has been a crucial topic in research, for instance, in PME groups, in a special issue of ESM, in a special issue of ZDM, in ICME 13 in 2016. In the group’s “Call for papers” the term representations referred to thinking tools for doing mathematics encompassing graphs, tables, diagrams, formulas, symbols, texts, concrete models, and, in a broader sense, even gestures, videos, sounds etc.

Keywords: Representation, visualization, imagine, visual-spatial abilities, visual-spatial image.

Introduction

This Thematic Working Group explicitly welcomed papers from a variety of different theoretical approaches and methodological frameworks addressing the role of representations of different types in teaching and learning processes, in particular those involving visualization (considered here as defined by Arcavi (2003)). In TWG24 there were 24 participants (authors, co-authors, and some other participants), from 13 countries (these included Chile, Denmark, Finland, France, Germany, Italy, Mexico, The Netherlands, Portugal, Sweden, Switzerland, Turkey, the UK) with 16 accepted papers and 2 accepted posters. The most part of the 16 papers, were empirical studies (related to primary and secondary school). The 2 posters reporting empirical studies conducted at the primary and secondary school levels. The poster concerning primary school described what students learn in mathematics lessons when different representations of fraction are used; and the poster concerning secondary school described how a variety of multi-sensory activities allowed 14 year old students to familiarise with some pivotal mathematical concepts such as prime and irrational numbers. The structure of the timeslots was designed in order to stimulate interaction and collaboration among participants: all participants were asked to read all papers, and prepare reaction-questions to two papers in particular that had been assigned ahead of time by the TWG leaders. After a 10-minute presentation by the presenting author, the prepared questions were posed and a general discussion was initiated and conducted for 25 minutes: first the authors of the paper would reply to the reaction-questions, then there was a discussion on issues related to the general list of questions designed for TWG24’s call for papers. Posters were also allocated a few minutes of presentation time within the working group, and a short follow-up discussion took place after each of them. The last session was completely devoted to summing up the main issues that had emerged from the
group discussions. One of these was that certain key words, present in the literature on representations and visualization in mathematics education, were not being used consistently by the participants. Therefore a list was put together with the suggestion for the upcoming CERME of making explicit the definitions used in each study. Among these (in alphabetical order): figure, gesture, mental imagery, metaphor, representation (including the distinction between internal and external), sign, symbol, visualization, visual-spatial abilities, visual-spatial image.

**Gestures and representations**

The group agreed on the following: gestures can be considered as a way to create temporary external visualizations of internal imagery or structures, to explain or communicate thinking; movement involved in the gesture can connect physical properties and theoretical properties; different kinds of artifacts affording (or fostering) the use of gestures can be involved (such as the movement within dynamic geometry software). The importance of gestures in the context of representations in mathematics education was evident in TWG24, because many of the papers presented included a focus on gestures. Okumus and Hollebrands investigated how middle school students created 3–dimensional objects from 2–dimensional figures using an extrusion method, and they identified students’ strategies for forming 3–dimensional objects with a focus on their gestural signs. The paper by Joffredo-Le Brun, Morellato, Sensevy, and Quilio focused on the relation between gestures and (other kinds of) representations (and metaphors), through the analysis of an extract from a lesson proposed in primary school during which the students work on the notion of difference, introduced with the help of several systems of representation. Ferrara and Ferrari also considered the relation between gestures and (other kinds of) representations, presenting the diagrammatic activity of secondary school students exploring motion through graphing technology, which captures a pair of space-time graphs on a single Cartesian plane. Indeed, the use of computers and technology was another transversal theme present in many papers and group discussions.

**Technology and representations**

TWG24 discussed the issue of how technology can change the dynamics of teaching-learning by offering specific kinds of representations. The paper by Okumus and Hollebrands presented findings from a study conducted during a summer enrichment program, in which students used manipulatives and a dynamic geometry program (Cabri 3D). Miragliotta and Baccaglini-Frank presented analyses of excerpts from a set of activities designed and proposed within the context of a 2D dynamic geometry software (Geogebra) for a group of 9th grade students. Schreiber and Klose focused on the role of artifacts and different forms and modes of representation when learning mathematics at primary school level, through an interactive approach, in which mathematical audio-podcasts were produced. A perspective on teachers’competencies in the context of multimedia-based representations was presented by Ollesch, Grünig, Dörfler and Vogel. Their study described findings from a project in which they used video-vignettes in order to assess the competencies of mathematics teachers for multimedia use in mathematics lessons. Taking a closer look into how technology can change the dynamics of teaching-learning by offering specific kinds of representations, a study by García Moreno-Esteva, White, Wood, and Black showed how eye movement can be tracked and used as a window to cognitive processes involved with use of representations in mathematical activities.
Theoretical frameworks used in the papers and posters presented

Several different theoretical frameworks were referred to in the papers and posters presented: Arzarello’s Semiotic Bundle theory (Bini; Robotti); Balacheff’s theoretical notion of epistemological validity (Hoyos); Bartolini Bussi and Mariotti’s Theory of Semiotic Mediation (Okumus and Hollebrands; Robotti; Schou; Schreiber and Klose); cognitive psychological approaches, applied in the problem solving context, such as Bayes’ (Böcherer-Linder and Andreas Eichler); or Vergnaud’s framework, (Serrazina and Rodrigues); Duval’s registers of representation and theory of apprehension (Miragliotta and Baccaglini-Frank; Robotti; Hoyos, Bini); Enactivism (Ferrara and Ferrari; Soto-Andrade and Diaz-Rojas); Fischbein’s Theory of Figural Concepts (Miragliotta and Baccaglini-Frank); Goldin’s definition of representation (Sveider); the Joint Action Theory in Didactics (JATD) (Joffredo-Le Brun, Morellato, Sensevy and Quilio); Lakoff and Núñez’s conceptual metaphors (Finesilver); Mishra & Koehler’s Technological Pedagogical and Content Knowledge (TPACK) (Ollesch, Grünig, Dörfler and Vogel); psychological approaches such as Bruner’s approach (Ött; Finesilver); or Ainsworth’s approach (Böcherer-Linder and Eichler; Ollesch, Grünig, Dörfler and Vogel); Krutetskii’s approach (Olgun and Ader); Tall and Vinner’s Concept Image and Concept Definition (Schou);

According to these, the authors developed different kinds of empirical studies: intervention studies (short term and long term studies; with attention to the teacher’s role or focused on learners); and observation studies (observing learners in different educational settings; observing teachers; observing classroom processes). In one case, a paper attempted to make some steps forward in elaborating a new theoretical framework emerging at the intersection between cognitive psychology and mathematics education (Miragliotta and Baccaglini-Frank). In another paper, Ferrara and Ferrari conceive mathematical thinking as a place of events instead of objects, and they bring forth inventive and speculative possibilities for learners to encounter and problematize spatio-temporal relationships, rather than seeing them as ways of being mistaken.

Concluding remarks

We conclude this summary with the two questions, from the general list, that seemed to arise the greatest interest of the participants, and sketch out the main comments advanced by the Working Group.

*What aspects of the use of different types of representation, imagery and visualization are effective in mathematical problem solving at various levels?*

Participants of TWG24 suggested that a representation does not stand alone, and it cannot be separated from how it is used. Thus, it is important to take into account interaction between the individual and the representation (both its external as well as its internal – though difficult to access – component) and between representations and context in which they are used (Joffredo-Le Brun, Hoyos, Schou). Moreover, representations are used within a social context, partly (but not only), for communication of ideas; it is important to encourage learners to express themselves using their own representational strategies, and appreciate multiple representations of information and of their ideas (Finesilver; Olgun and Ader; Robotti; Okumus). Through a careful and appropriate use of representations it is possible to increase positive affect towards mathematics and inclusion (Soto-Andrade and Diaz-Rojas; Robotti). However, there is a tension between the advantages of flexible
representation (and specific useful reps) and pushing students to use representations, which do not come naturally to them (Finesilver).

*How can teachers help learners to make connections between visual and symbolic representations of the same mathematical notions (mathematical object)?*

In response to this question participants of TWG24 suggested that there are certain registers of signs that are considered conventional (by teachers), and others which are less conventional. Indeed, teachers may be less familiar with the various alternative ways of representing, and either not accept alternatives as legitimate (e.g. drawing), or not be conscious of how they are being used (e.g. gestures) (e.g.: Bini; Olgun and Ader; Ollesch, Gruenig, Doerfler and Vogel; Schou). Finally, in various occasions, the group discussed the issue of low achievers and use of representations both by them and by teachers involved in their education processes. These discussions were fueled especially by the papers by Finesilver and by Robotti. In her paper Finesilver drew on qualitative data from problem-solving interviews with very low-attaining secondary school students, focusing on the visuospatial organization of elements in four types of non-standard student-created and co-created representations. She discussed these four types of representations in terms of relationships between representation type, scenario, calculation success, and the students’ developing understanding of multiplication and division concepts. On the other hand, Robotti presented a didactical sequence involving the use of various artifacts, introduced by the teacher, to solve tasks on fractions. She analyzed how the representations, fostered by the artifacts, produced by the students, and then picked up by the teacher, contributed to students’ development of mathematical meanings around the notion of fraction.

In this paper, we refer to the efficiency of different visualizations for mathematical problem solving. Particularly, we investigate how set relations that are potentially important in probability are made transparent by two different visualizations, i.e. the tree diagram and the unit square. In this paper, we use these two visualizations as representations of statistical information. First, we analyze theoretically the quality of visualizing set relations by tree diagrams and unit squares. Second, we briefly report a published study with students of mathematics education (n = 148) where the unit square outperformed the tree diagram when the perception of subset relations was regarded. A main focus of this paper is a replication of the aforementioned study with n = 58 undergraduate students. Finally, we discuss the significance of our results, specifically for the teaching and learning of conditional probabilities.

Keywords: Representation of statistical information, set relations, tree diagram, unit square.

Introduction

In mathematics education, it is widely accepted that representations and visualizations could have a considerable impact on students’ learning. For example, Duval claims that visualizations of mathematical concepts are “at the core of understanding in mathematics” (Duval, 2002, p. 312). However, research in mathematics education and cognitive psychology gave evidence that visualization does not necessarily foster students’ understanding. For this reason, a crucial question in research in mathematics education is to identify the one of potentially different visualizations that is most efficient referring to students’ learning. We refer to this question concerning competing visualizations aiming to support students’ learning in statistics and probability, but also in fractions. The transparency of set relations plays a crucial role in probability (Böcherer-Linder & Eichler, 2017), but is also important in many other domains of mathematics education, such as the teaching and learning of fractions.

Theoretical framework

In the context of Bayesian reasoning, research in cognitive psychology has shown that the transparency of set relations in the visualization of statistical information impacts on the performance in tasks concerning the Bayes’ rule: “any manipulation that increases the transparency of the nested-sets relation should increase correct responding” (Sloman, Over, Slovak, & Stibel, 2003, p. 302).
Proponents of this point of view, called nested-sets account, attribute the difficulties of Bayesian reasoning to the fact that some sets of events are nested (Lesage, Navarrete, & Neys, 2013; Sloman et al., 2003). For the example of a medical diagnosis, Figure 1 illustrates the nested-sets situation. “Transparency of set relations” means that it is easy to see, how many elements are in the sets and how the sets relate. The cognitive model into which the nested-sets account has been incorporated is the dual process theory (Barbey & Sloman, 2007): Representing the statistical information in a standard probability format (without visualization) obscures the nested-sets structure of the problem and, therefore, triggers the associative system which may lead to biases. Representing the statistical information with natural frequencies and / or appropriate visualizations in contrast trigger the rule-based system because nested sets relations are made transparent, enabling people to reason consciously and according to the logic of set inclusion (Barbey & Sloman, 2007). For the design of effective visualizations, proponents of the nested-sets account claim that visualizations are helpful to the extent that they make the nested set structure of the problem transparent (Barbey & Sloman, 2007; Sloman et al., 2003). There are different competing visualizations that claim to visualize efficiently set relations or situations that necessitates applying Bayes’ rule and it is an open question which visualizations are the most efficient and which properties explain these visualizations’ efficiencies.

In this paper, we investigate how set relations are made transparent by two competing different visualizations, i.e. the tree diagram and the unit square. We use these two visualizations as representations of statistical information (Venn diagrams are not considered in this paper because we focus on the visualization of statistical information and Venn diagrams are pure set representations but not representations of statistical information). First, we analyze theoretically the quality of visualizing set relations by tree diagrams and unit squares. Second, we briefly refer to a published study (Böcherer-Linder & Eichler, 2017; n = 148 undergraduate students) where we investigate whether the tree diagram or the unit square is more efficient to support the perception of subset relations. Since we used a new approach to explain the effectiveness of visualizations of the Bayes’ rule, we conducted a replication study (n = 58 undergraduate students) which results are in the main focus of this paper. Finally, we discuss the significance of our results, specifically for the teaching and learning of conditional probabilities.
Visualizing set relations

“A flower girl is selling red and white roses and carnations.” We use this situation as an example to illustrate how the tree diagram and the unit square visualize set relations. In this situation, we have sets (for example the set of all roses) and subsets (for example the subset of all red roses) and subset relations (for example the red flowers among the roses). If we attribute some numerical values to the number of roses and carnations, the situation can be visualized by showing absolute numbers in the tree diagram and the unit square:

![Tree diagram and unit square](image)

Both, the tree diagram and the unit square can be seen as nested-sets representations. In the tree diagram, the logical relations between sets and subsets are visualized by lines. The subsets are on a lower level than the sets in the tree and the branches connect the subsets with the sets. For example the subset “red roses” is on a lower level than the set “roses” and the branch connecting “red roses” and “roses” visualizes the relation between both sets. The tree implies a hierarchical structure which means that subsets are always on a lower level than sets. Therefore, only those subset relations that are in line with the hierarchy are salient. For example, the subset relation of “roses among the red flowers” where the “roses” are the subset and all the “red flowers” are the including set is not visualized by a branch in the tree and thus, is not transparent.

In the unit square, subset relations are visualized by areas being embedded in other areas. For example the subset of “white roses” is represented by a partial area of the rectangle that represents all roses. In contrast to the tree diagram, the unit square implies no hierarchy. That means that subset relations can be grasped vertically (e.g. “white roses among the roses”) as well as horizontally (e.g. “roses among the red flowers”). Therefore, all subset relations that are possible in this situation are transparent in the unit square.

Because of these differences in the properties of the two visualizations, we expected a difference between the tree diagram and the unit square when the perception of different subset relations is regarded. Therefore we hypothesized:

If the subset-relation is not in line with the hierarchy of the tree diagram, the unit square is more efficient to make the subset-relation transparent (*hypothesis 1*). If the subset-relation is in line with
the hierarchy of the tree diagram, there is no significant difference between the unit square and the tree diagram (*hypothesis 2*).

**Method**

The method in our first study and the replication study was the same. In the first study, we administered a questionnaire to 148 students who were enrolled in a course of mathematics education. In the second study, the test was administered to 58 students who were also enrolled in a course of mathematics education. In both studies, we asked the students (among other questions concerning conditional probabilities) in one task that we indicate below to calculate proportions and to indicate the result in form of fractions:

\[
\text{proportion} = \frac{\#\text{subset}}{\#\text{set}}
\]

In this way, we could analyze if the right subsets and right sets have been grasped from the visualization. The questionnaire had two versions, one showing tree diagrams, the other showing unit squares to represent the statistical information. The rest of the test-items remained constant and the participants were randomly assigned to one of the two groups. Thus, any potential difference in the results could directly be attributed to the influence of the visualizations.

To assess the influence of representation on the perception of subset relations we designed test-items that each addressed structurally different subset relations. In Figure 3, we show the questions that were accompanied by either the tree diagram or the unit square shown above. Note that the item (d) addresses a subset relation that is not in line with the hierarchy of the tree diagram and therefore a higher performance for the unit square was expected. The items a, b, c and e address subset relations that are in line with the hierarchy of the tree diagram and therefore no significant difference between the tree diagram and the unit square was expected. We rated correct answers with 1 and incorrect answers with 0.

</tr>
<tr>
<td>e) roses among all flowers.</td>
</tr>
</tbody>
</table>

**Figure 3: Items to assess the perception of subset relations**

**Results**

Figure 4 shows on the left side the results that we reported in Böcherer-Linder and Eichler (2017). As we hypothesized in this study, the unit square (*M = 0.66, SD = 0.44*) was more efficient than the tree diagram (*M = 0.38, SD = 0.48*) for the item (d) that addressed a subset relation that is not in line with the hierarchy of the tree diagram. The difference for the item (d) was significant (*t (146) = 3.579,*
with an effect size of $d = .58$. In the replication study there is again a significant difference referring the item (d) that addressed a subset relation that is not in line with the hierarchy of the tree diagram (unit square: $M = 0.63$, $SD = 0.43$; tree: $M = 0.31$, $SD = 0.39$; $t(54) = 3.101$, $p < 0.01$, $d = .82$). Thus, we replicated our result referring hypothesis 1. Further, it is interesting that the ratios of correct answers are very similar in the original study and the replication study. However, there are also unexpected differences for the items (b) and (c).

Results of the first study, $n = 148$

Results of the replication study, $n = 58$

![Figure 4: Participants performance in the first study (left side) and in the replication study](image)

In our first study, we investigated also the differences in the other four items that addressed subset relations within the hierarchy of the tree diagram. For these items a t-test for the accumulated score referring to these four items ($\alpha = .739$) yielded no significant difference between the tree diagram ($M = 3.46$, $SD = 1.023$) and the unit square ($M = 3.46$, $SD = 1.036$), $t(146) = 0.000$, $p = 1.000$. In the same way none of the items yielded a significant difference between the unit square and the tree diagram when investigated individually. Thus, there was no reason to reject our hypothesis 2 in our first study. However, we could not replicate these results in the second study. When the items were regarded individually, a t-test yielded significant differences for item (b) ($p < 0.05$) and (c) ($p < 0.01$). Also, the accumulated score referring to all four items ($\alpha = .634$) yielded a significant difference between the tree diagram ($M = 3.01$, $SD = 1.11$) and the unit square ($M = 3.67$, $SD = 0.52$), $t(54) = 2.762$, $p = 0.008$).

In the first study, the mean values of correct answers for the tree diagram were almost equal for all of the four items a, b, c and e addressing subset relations that were in line with the hierarchy of the tree diagram (88%, 85%, 86%, 86%). In contrast, in the second study for every item differences appeared. However, the performance for item (d) was lower for both visualizations. This might indicate that the subset relation (d) is more difficult to perceive than the other subset relations and that the visualization with the unit square is more helpful in this case.
Discussion of the results

For the situation of the flower girl, our results show a very clear effect in favor of the unit square. This was the case in the first study and, with very similar results, in our replication study. Nevertheless, we suggest for future research to prove this effect also for other contexts. In another study with 143 students of electrical engineering, we replicated the effect for subset relations that are not in line with the hierarchy of the tree diagram for two more different contexts. It is further desirable to investigate the effect of those subset relations used in the items a, b, c and e in more depth. This is especially the case since our results for this kind of items seems to be ambiguous. The replication study yielded significant differences referring to the efficiency of the tree diagram and the unit square in supporting students solutions in tasks where the subset relations are in line with the hierarchy of the tree diagram. Although this result was not expected and we further hypothesize that this result will not be replicated in further studies, it agrees with our overall hypothesis, i.e. the supremacy of the unit square to visualize situations in which the Bayes’ rule has to be applied.

There are further aspects that that could be investigated in more detail. For example, there is the question of the order in the sequence in the tree diagram. It might be interesting to study the effect of the transposed order (roses / carnation on a lower level than red / white) and to compare it with a rotated unit square (roses / carnation arranged vertically and red / white arranged horizontally). This setting could be clarified if the hierarchy of the tree actually is the reason for the results in our study.

Moreover for the context of Bayesian reasoning, the results of Binder et al. (2015, p.6) suggest an advantage of the 2×2-table compared to the tree diagram, although no statistical difference between 2×2-tables and tree diagrams was reported. Thus, it is an open question if 2x2-tables are equally efficient than unit squares to make subset relations transparent or if there is an additional effect of the unit square due to the redundant geometrical and numerical representation.

Finally, there are further possibilities for visualizing set relations. One of these possibilities that was used in mathematics teaching is the double tree (Wassner, 2004). Thus, it could be interesting if a specific version of the tree diagram is able to decrease the weakness of the tree diagram to identify appropriately set relations.

Implications

The main result of our research seems nearly trivial: Visualizations have to visualize the main aspects of a mathematical concept if they aim to support students’ understanding of this concept. Accordingly, a subset relation must be transparent when the aim of the visualization is to represent subset relations. However, it is by no means at all trivial to identify the crucial aspects of a mathematical concept. Actually, the tree diagram is very prominent in statistics education research (Veaux, Velleman, & Bock, 2012) and also psychological research (Binder, Krauss, & Bruckmaier, 2015) for visualizing Bayesian situation that necessitates applying Bayes’ rule. However, our research gave evidence that – compared to the unit square - the tree diagram is not efficient to visualize the set relation that is crucial to understand the structure of a Bayesian situation since it requires a subset relation that is not in line with the hierarchy of the tree diagram.

Our results have firstly some consequences if statistics education is regarded. Sloman et al. (2003) expressed that bringing out nested set structure has been identified as being important for the improvement in Bayesian reasoning tasks. Thus, restricted to teaching and learning probability, our
results imply to reconsider the role of the tree diagram to support students’ learning referring to probability and Bayesian reasoning. This would be a considerable shift in statistics education (c.f. e.g. (Gigerenzer, 2014; Wassner & Martignon, 2002). A little bit more globally, it could be considered if proportions, and in particular proportions of proportions could be appropriately visualized by a unit square to emphasize the connection between proportions of proportions and conditional probabilities. Thus, the unit square could potentially be understood as a visual connection between fractions and probabilities.

More generally, our results imply to focus the discussion of visualizations on the structure of visualization and on its relation to the structure of the represented mathematical concept. While the superiority of visualizations is a consensus in mathematics education as we outlined in the introduction, it is a crucial objective to find out which visualization best fits to a mathematical concept, especially in situations where several competing visualizations exist as it is the case for Bayesian reasoning situations. For example, Binder et al. (2015) show that the tree diagram supports Bayesian reasoning compared to pure symbolic representation, whereas our results imply that the required subset relation is not transparent in the tree diagram. Indeed, in recent research, the unit square outperformed the tree diagram in Bayesian reasoning tasks (Böcherer-Linder & Eichler, 2017; Böcherer-Linder, Eichler & Vogel, in press). Therefore an ongoing task of educational research should be to precisely identify the relation of a visualization and its structure and the mathematical concept and its structure. One main message of our paper is that this relation is not sufficiently investigated, but could considerably impact on students’ learning.

Enactive metaphors in mathematical problem solving
Daniela Diaz-Rojas¹ and Jorge Soto-Andrade²

¹University of Chile, CIAE, Santiago, Chile; diazr.daniela@gmail.com
²University of Chile, CIAE, Faculty of Science, Mathematics Department, Santiago, Chile; sotoandrade@uchile.cl

We are interested in exploring the role of enactive metaphoring in mathematical thinking, especially in the context of problem posing and solving, not only as a means to foster and enhance the learner’s ability to think mathematically but also as a mean to alleviate the cognitive abuse that the teaching of mathematics has turned out to be for most children and adolescents in the world. We present some illustrative examples to this end besides describing our theoretical framework.

Keywords: Metaphors, enaction, representation, visualisation, cognitive bullying.

Introduction
Our concern in this paper is the role of metaphor, more precisely enactive metaphor, in the teaching and learning of mathematics, particularly in mathematical thinking arising in, or triggered by, problem posing and solving. Fostering mathematical thinking in the classroom is a widespread aim in mathematics education indeed (OECD, 2014), but in our viewpoint we have a much more severe and dramatic issue to address: not only mathematical thinking is not fostered in our classrooms (Chilean and worldwide), but mathematics has turned out to be a tool of torture for millions of children, who cannot escape from it. This has been recently acknowledged as “cognitive bullying” or “cognitive abuse” in the English literature (Watson, 2008; Johnston-Wilder & Lee, 2010), a practice that is “at best marginally productive and at worst emotionally damaging” (Watson, 2008: p. 165). We thus echo Tillich’s famous statement: “the fatal pedagogical error is to throw answers like stones at the heads of those who have not yet asked the questions”. To tackle this complex and systemic problem, a multidisciplinary approach is most wanted, where a first diagnosis emerges: traditional (and abusive) teaching of mathematics tends to thwart cognitive brain mechanisms installed during millions of years of evolution, that we would need on the contrary to recognise, appreciate and tap into in the context of learning, to wit: metaphorising, enacting, collaborating…

Our main hypothesis is that practice of metaphorising, especially enactive metaphorising, in the classroom, might be a fundamental means to contribute to alleviating this situation of cognitive abuse towards students without forsaking their access to mathematical thinking, but on the contrary fostering it. It is our hypothesis that the way a mathematical situation is metaphorised and enacted by the learners strongly determines the ideas and insights that may emerge in them and may help to bridge the gap between the “mathematically gifted” and those apparently not so gifted or mathematically oriented. A big challenge is then trying to figure out under which conditions enaction and metaphorising, more precisely enactive metaphorising, impact on mathematical thinking processes as hypothesised above.
We intend here to pursue our recent research on metaphorising and enacting (Diaz-Rojas & Soto-Andrade, 2015, 2016; Soto-Andrade, 2015). Our earlier work on metaphor in the learning of mathematics was presented already in CERME5 (Soto-Andrade, 2007).

In this paper we focus on some examples and case studies that illustrate the role that metaphorising and enacting may play in the spectrum of mathematical thinking elicited by problem posing and solving. The contextual background of our case studies involves a variety of learners in Chile: prospective secondary math teachers, in-service primary and secondary math teachers, first year university students majoring in social sciences and humanities, undergraduate and graduate students in mathematics, primary and secondary students.

Research questions

Which is the role of metaphorising and enacting in mathematical problem posing and solving at various levels? To which extent do they influence mathematical thinking elicited by the problematic situation, in particular moving amongst various mathematical registers of representation to change the problem? Do they shape our understanding of the processes involved, notably the relation between problem and learner, emotional overtones included?

How does the interplay between affect and metaphoring helps in alleviating cognitive bullying in the teaching of mathematics, and even lead to enjoyment of learning and doing mathematics?

Theoretical framework and state of the art

Metaphorising in cognitive science and mathematics education.

Widespread agreement has been reached in cognitive science that our ordinary conceptual system, in terms of which we both think and act, is fundamentally metaphorical in nature (Gibbs, 2008; Johnson & Lakoff, 2003). In mathematics education proper it has been progressively recognized during the last decades (English, 1997; Lakoff & Núñez, 2000; Sfard, 2009; Soto-Andrade, 2007, 2014, and many others) that metaphors are not just rhetorical devices, but powerful cognitive tools, that help us in grasping or even building new concepts, as well as in solving problems in an efficient and friendly way. See Soto-Andrade (2014) for a recent survey. We may visualize (conceptual) metaphors (Lakoff & Núñez, 2000) as mappings from a more down-to-earth “source domain” into a more abstract “target domain”, carrying the inferential structure of the former into that of the latter. For the learning of mathematics we emphasize the “poietic” role of metaphor that brings concepts into existence, through “reification” (Sfard, 2009). In view, here lies the main difference between representation and metaphor: we re-present something given beforehand but we metaphorise to try to fathom something unknown or a concept not yet constructed. For instance, we construct the concept of probability when, studying a symmetric random walk on the integers (a frog jumping on a row of stones in a pond), we see the walker splitting into 2 equal halves instead of going equally likely right or left (Soto-Andrade, 2007, 2015). In what follows we will use metaphorical language as a meta-language to describe cognitive or didactic theories of interest to us, since – we claim – a theory is essentially the unfolding of a metaphor (Soto-Andrade, 2014).

Enaction in cognitive science and mathematics education

Varela metaphorized enaction as the laying down of a path in walking (Varela, 1987, p. 63), as in Machado’s famous poem, when he introduced the enactive approach in cognitive science (Varela,
Thompson, & Rosch, 1991). In his own words: “The world is not something that is given to us but something we engage in by moving, touching, breathing, and eating. This is what I call cognition as enactment since enactment connotes this bringing forth by concrete handling” (loc. cit). Less radical enactment in mathematics education may be traced back to Bruner (1966), inspired by Dewey’s “learning by doing” (Dewey, 1997), who characterised enactive, iconic and symbolic modes of representation. For recent significant theoretical and practical developments see Proulx (2013). In what follows we are especially interested in enactive metaphors, where the learner is whole bodily engaged, as opposed to “sitting metaphors” in the sense of Gallagher and Lindgren (2015).

(A) didactic situations and didactic contract

The theory of didactical situations (Brousseau & Warfield, 2014) might be described as the unfolding of the emergence metaphor in math education: mathematical concepts we intend to teach should emerge in a suitable challenging situation the learner is enmeshed in, as the only means to “save his life”. No real learning is possible if mathematical concepts are airborne from Olympus. Such a situation is called a didactic situation, because of the didactical intent of the teacher who set it up. It becomes an adidactic situation when the teacher definitely steps back to let the learners interact on their own with the setting, with no hope of fathoming beforehand her didactical design or the mathematical content she is aiming at. Key metaphors are likely to emerge, as sparking voltaic arcs, in and among the learners, when enough “didactical tension” is built up in an adidactic situation for them. The notion of didactical contract (Brousseau, Sarrazy, & Novotna, 2014) is also of interest to us, in the context of the teacher-student relation. It is in fact a keen metaphorical description of the mainly implicit and unspoken mutual expectations, beliefs and commitments regarding the actions and reactions of the partners involved in a didactic or adidactic situation.

Affect in mathematical problem solving

The role of affect in mathematical problem solving is often neglected in spite of its significant incidence in learner’s performance (Mason, Burton, & Stacey, 2003; Hannula, 2014). Here we are specially concerned by the role of negative emotions that trigger a learner’s emergent metaphorising that can transform a problem that is a tool of cognitive bullying into a friendlier one. The outcome of this may be, for most learners, a positive feeling of liberation from the Procrustean bed of arithmetic and algebra, for instance (see example 2 below).

Methodology and experimental background

Our research includes an experimental facet, where our methodology mainly relies on qualitative approaches, to wit: Case Studies (Stake, 1995), Participant Observation techniques and Ethnographic methods (Spradley, 1980).

In all, 4 cohorts of learners have been involved in our teaching and learning according to our metaphoric and enactivist approach from 2014 to 2016. They include prospective secondary school physics and mathematics teachers in a one-semester course in number theory at the University of Chile; students in a one semester first year mathematics course in the social sciences and humanities option of the Baccalaureate Programme of the same University; in service primary and secondary school teachers engaged in one week professional development workshop in the South of Chile, in service primary school teachers engaged in a 15 month professional development programme (mathematics option) at the University of Chile at Santiago; graduate students working towards a
Ph.D. in Didactics of Mathematics, at the Catholic University of Valparaiso (UCV), most of them secondary school math teachers holding a Master in Didactics of Mathematics. They were chosen because they constituted a broad spectrum of learners we had access to while performing our usual teaching duties at the University of Chile, besides some invited workshops elsewhere, with whom our overarching approach could be tested. Learners, working most of the time in (random or spontaneous) groups of 2 to 4, were observed by the teacher or facilitator and an assistant, the latter assuming the role of participant observer or ethnographer (Spradley, 1980; Brewer & Firmin, 2006). Among aspects observed were: level of participation, questions and answers, horizontal (peer) interaction, emergence of metaphors, especially idiosyncratic ones, spontaneously or under prompting, gestural language of learners and teacher, expression and explicit acknowledgement of affective reactions from the learners. Snapshots of their written output in problem solving activities were taken and videos of their enacting moments were recorded.

Illustrative examples and case studies

We present and discuss here two paradigmatic examples, in geometry and arithmetics, that we have come across during our teaching at the University of Chile, to illustrating important aspects of our theoretical perspective, often neglected in usual approaches. The case of randomness has been dealt elsewhere (Diaz-Rojas & Soto-Andrade, 2015). Our geometrical example deals with the exterior angles of a polygon and their sum: a typical geometrical notion often abusively and gratuitously introduced, with no context or motivation. In arithmetic, we recall the consecutive sums of positive integers problem, thoroughly discussed in the literature (e.g. Mason et al., 2003)

Example 1. The sum of the exterior angles of a polygon

We have observed that almost every in service and prospective secondary mathematics school teacher in our country, after introducing exterior angles coming out of the blue after inner angles and explaining them in terms of the latter, calculates dutifully the sum from the sum of the inner angles, that depends on the number of sides of the polygon. Doing a bit of algebra they finally wind up discovering that the sum of all exterior angles is 360°, independently of the number of sides! Surprising! This traditional way to “get into” the task (Proulx, 2013), is not very appealing for most students, that experience it as “blind calculation” (a case for cognitive bullying). When trying to fathom out exterior angles of a polygon however a first thing to do – from our perspective – would be to metaphorise it, to get into the task in a more transparent way. Not just reciting its formal definition, of course. Among the metaphors emerging amongst the learners we work with, the most frequent are “a polygon is an enclosure between crossing sticks” (most popular among primary school teachers) and “a polygon is a closed path, made out of straight segments”. Enacting the first metaphor triggers the idea of manipulating the sticks, as to make clearly visible the exterior angles first and then shifting them parallel to themselves to get smaller and smaller homothetic polygons. In this way teachers see that the sum of all exterior angles is 360°, instead of blindly calculating. Enaction of the metaphor “polygons are closed paths” by the learners themselves, literally lying down a polygonal path in walking, enables them to immediately “see” that the sum of the polygon’s exterior angles corresponds to a complete revolution (Diaz-Rojas & Soto-Andrade, 2015). In this way they realise that exterior angles, not inner angles, are the convenient data for the walker to inflect or bend his path as wanted. Analogously for the sum of all acute angles of a pointed star… We noticed that metaphorising a polygon is an unusual challenge, almost a violation of the
didactical contract, for both students and teachers. But once they feel they are allowed to, even prompted to, metaphors begin to arise, shyly at first. The enactive metaphoric approach conveys here a completely different experience of mathematics than the traditional one, including the role of gestures, movements and, more broadly embodiment, in the learning of mathematics, particularly in problem solving (Libedinsky & Soto-Andrade, 2015).

**Example 2. Which numbers are consecutive sums? Just an arithmetic problem?**

The question is: Which numbers are sums of a string of consecutive (positive) integers. An unexpected question to many learners, however familiar with Gauss well known trick to sum $1 + 2 + \ldots + 100$ in a wink. From our perspective it is interesting to observe how easily this question (or any question) emerges in the learners, once their attention is drawn to this sort of sums. Our hypothesis is that learners’ reaction here is heavily dependent on their previous schooling and the amount of cognitive abuse they have endured. As a typical example we recall an informal short meeting to chat about "the mathematical experience" with a class of 12th graders from a Waldorf school, to whom we told about consecutive sums (just what they are), period. After a few seconds, a girl said: Which series of numbers do you obtain that way? We claim than in usual problem solving this is an often neglected aspect: enactively letting questions emerge instead of asking them… Another often neglected aspect in problem solving is the affective reaction a problem elicits in the learner. This sort of arithmetic problem quite often triggers a feeling of distaste, especially in adolescents. This negative emotion may have the immediate positive effect of stimulating the learner to metaphorise, to transform the problem into a more attractive or friendly one, i. e. a creative reaction! This is very rarely observed in our prospective teachers and Ph. D. students.

Apparently didactical contract weights heavily here: learners are not supposed to transform or metaphorise the problems they receive, nor are they supposed to like or dislike mathematical objects or procedures, just to understand them or not.

We observed that every learner tackled the problem arithmetically first, doing some experimenting (some calculating small consecutive sums, others following the opposite path: checking whether 2, 3, 4, 5, etc. might be consecutive sums). Some got a closed formula for a consecutive sum but did not see what numbers are so obtained. Those who checked numbers one by one arrived quickly to the (surprising) conjecture that powers of 2 cannot be reached. In fact they re-traced Mason et al. (2003). The proof of the conjecture remained elusive until some noticed that powers of 2 do not have odd divisors and so devised an algebraic proof of the conjecture. The fact that conversely a number which is not a power of two must be a consecutive sum remained in the shadow for 45 minutes or so. At this point, we asked prospective teachers whether they liked the way we were tackling and solving the problem. Two of them said that the conjecture was interesting and that they understood the algebraic procedure but that they were not very happy about it. Fernanda said that she was not fond of this algebraic yoga, although she was able to carry it out. For Enrique this algebraic approach was easy but he was unhappy because he had noticed (giving private lessons to secondary school students) that for most students algebraic calculations are not appealing at all. So both were motivated to look for different, may be geometric, approaches.

For Ph. D. students, didactical contract played in the opposite direction: after working on metaphorising some months before, when asked now whether they were satisfied with their discovery regarding powers of 2, several students thought about metaphorising the problem, looking
at the numbers as quantities of dots arranged in clever ways. Andrea, an insightful female student, drew a trapezoidal house with a slanted roof (of slope 1) and so transformed the problem to a question about the area of this trapezoid. Some tried to remember the area formula, but others, like three clever prospective teachers, saw by rearrangement or compensation that their trapezoid could be turned into a rectangle with the same base. But then they realised that this worked only “half of the time”: for an odd basis! In that case the area has an obvious odd divisor. For the even case, some conjectured that they could get a two-step horizontal roof, each step of equal length and so the idea emerged of slicing vertically the trapezoid into two “halves” of equal base and putting one on top of the other. Some went into distinguishing the cases: half base odd or even. But others had the idea of putting one “half trapezoid” topsy-turvy on top of the other, getting in this way a rectangle of odd height and half base. Then, a prospective teacher had the idea of borrowing from scratch a copy of the original trapezium and coupling both to obtain a rectangle with either odd base or odd height and whose area is twice the original one! The proof of the converse conjecture was left open. Regarding liking or disliking, graduate students at UCV were more enthusiastic about the geometric approach than prospective secondary teachers. Roughly two thirds of the latter said that they did not feel comfortable with geometry so that they preferred calculating algebraically! In fact even when trying to think in geometric terms, they quickly reverted to algebraic calculation. On the other hand happy visualizers realised that the trapezium area may have any value in the continuous case but not in the discrete one, because something pops up that has no continuous analogue: Parity! A surprising fact for them, who knew, from their laptop screens, that the discrete models the continuum well. The question remained open as to whether we can see geometrically that the area of a rectangular trapezium cannot be the volume of a hypercube.

From our perspective this is an emblematic example of the possible “unfolding” of an “arithmetic” problem that that can be solved by some algebraic yoga (that many students do not appreciate at all) but can also be metaphorised as a geometric problem, more appealing to others. This metaphorising "prompts" us to jump naturally into the continuous world and get some inspiration there. We realise also the hard way that there is a tricky property of discrete shapes with no analogue in the continuous world: parity! Discrete lengths, areas or volumes may be odd or even, although asymptotically however parity vanishes… Remarkably, even insightful discussions of this problem found in the literature (e. g. Mason et al., 2003) remain confined in the arithmetic-algebraic realm, not taking advantage of the avenues and possible generalisations that metaphorisation may open up.

Discussion

We have shown several important aspects of the role of metaphorising and enacting in mathematical thinking elicited by problem posing and solving. First, we have seen that the way we metaphorise and enact determines the ideas and insights we may have when tackling a problem. Then, how metaphorisation triggered by distaste of the problem may allow the learners to move from one realm to another, instead of remaining confined in just one. By so doing, they may take advantage of different intuitions and handlings, eventually much friendlier to them, that enhance their mathematical thinking and also alleviate the cognitive abuse they have been exposed to. Indeed, an acknowledged negative affective reaction to a proposed problem may trigger creative metaphorisation to change it. In this way metaphorisation appears as a means to empower students to transform an unappealing problem given to them, something especially relevant for adolescents
who otherwise have the feeling of being abused by being forced to follow prescribed rules to solve nonsensical tasks (Watson, 2008). Also visualization appears as concatenation of metaphors: In the case of consecutive sums: “numbers are quantities”, “summing is putting together”, “factorizing is rearranging to form a rectangle” etc. Furthermore, it appears that usual problem solving, as found in the literature, tends to neglect, the important role of metaphorisation and enaction, as a learner’s first reaction when tackling a problem that looks opaque to him or her. Not only because this may allow the learner to solve an otherwise unyielding problem but also because it may allow him or her not just to solve the problem but to “see” a solution, turning a hitherto blind calculation into pellucid insight. Finally the enactive and metaphoric perspective reshapes our understanding of the relation between problem and learner in problem posing and solving, that appears as a quite more circular and entangled process than usually acknowledged, where each one codetermines the other.

Diagrams and mathematical events: Encountering spatio-temporal relationships with graphing technology

Francesca Ferrara and Giulia Ferrari

University of Turin, Italy; francesca.ferrara@unito.it, giulia.ferrari@unito.it

This paper presents the diagrammatic activity of some secondary school students exploring motion through graphing technology, which captures a pair of space-time graphs on a single Cartesian plane. Focus is on a written task about the connections between two imaginary movements and (between) the corresponding graphs. Drawing on a vision that conceives mathematical thinking as a place of events instead of objects, we discuss three unexpected diagrams for how they bring forth inventive and speculative possibilities for learners to encounter and problematize spatio-temporal relationships, rather than seeing them as ways of being mistaken.

Keywords: Graphing technology, movement, diagram, event, problematic.

Introduction

In this paper, we deal with the issue of how students might learn about a representational system in which temporospatial relationships are the ground for the mathematical doing. Our interests are also in how visual, proprioceptive and kinaesthetic aspects of experiencing these relationships might move the learning of mathematics in unexpected and unconventional directions. We follow here de Freitas (2013) in rethinking mathematics as the place of events, instead of objects, where creativity and contingency prevail and the problematic—rather than the axiomatic—better capture the vitality of mathematical activity. The idea is that deduction “moves from the problem to the ideal accidents and events that condition the problem and form the cases that resolve it.” (Smith 2006, p. 145). Thus, mathematics is concerned with the occurrence of events more than with the existence of objects, and attention is on the material encounters with the mathematical.

In this perspective, we present an activity that was carried out with grade 9 students working with graphing motion technology to study function. In particular, the technology requires that two remote controllers of the Nintendo Wii game console (Wiimotes) are moved at the same time in front of a sensor bar, and it displays two space-time graphs on the same Cartesian plane. In the graphs, space is given by the distance of each controller from the bar. Thus, the software captures the movement of the Wiimotes over time. Our focus is on a written task that asks the students, divided into groups, to draw a space-time graph related via movement to a given graph. The task is called “Rob and Bob”. In it, Rob and Bob are the names of two little robots that are imagined to be moving the controllers in front of the sensor. The graph associated to Rob’s movement is given on paper, together with the instructions with which Bob is supposed to be moving with respect to Rob. The students are expected to complete the task adding Bob’s graph on the Cartesian plane. We will discuss how three different graphs are presented as solutions to the task from different groups, and we will develop how we think that these are significant in terms of the novel mathematical meanings that the students are articulating. In the meanwhile, we will also draw attention to aspects of the experience with the technology that might support this novelty, raising issues about the role of perception on the one side, and about the features of the technology on the other side.
Theoretical highlights

The representational system we refer to in this paper is the (space-time) Cartesian plane, which our students encounter through activity with the technology. However, we want to trouble traditional ideational assumptions that conceive such system as inhabited by mathematical figures or functions that, in their essence, are representations (particular instantiations or attributes, concrete instances) of some form, inert, transcendent, abstract and disembodied. In fact, claims de Freitas (2013), “the process of instantiation fails to capture the creative and material act of individuation that is entailed when we do mathematics.” (p. 586). We instead embrace an animate vision of the mathematical drawing/creation or act of drawing/creation of a figure or a function as event-structured, full of potentiality, temporality and movement, immanent, contingent to material circumstances, and incidentally subject to transformation. This positions us in the broad discussion on the theorising about the embodied nature of mathematics thinking and learning, which attempts to look at knowledge in non-representational ways and to overcome body/mind Cartesianisms (see e.g. Nemirovsky et al., 2013; Sinclair, 2014; Ferrara, 2015; Roth, 2016). According to this view, learning is much more about encountering concepts than about recognizing concepts. Cutler & MacKenzie (2011) might argue that thus the challenge is to treat learning as an ontological rather than an epistemological problem, staying away, we would add, from opposing the mathematical and the physical. The issue of representations is crucial here. As Sinclair (2014) points out, it is not that “symbols, diagrams, programming languages and even gestures” (and any other system, we would add) “do not at times function to re-present mathematical concepts and relations”, rather “they are inevitably bound up with bodies and discourses and thus potentially poised to open up new meanings.” (p. 174, emphasis in the original). Our own reading of this makes sense as regards our commitment to a mobile view of mathematics and mathematical doing that tries to escape concrete versus abstract and matter versus thought divides (Ferrara & Ferrari, 2016). In Ferrara (2015), these divides are challenged through a vision of perception and creation in/of mathematics for which perceiving is conceiving, thinking is acting and creating is learning. The work of philosopher Gilles Châtelet (1987, 1993/2000) on inventive diagramming was provocative to us in considering the centrality of mobility or virtuality to bridging the physical and the mathematical. The virtual is the necessary link between the two realms. Roth (2016) also draws on Châtelet to underline how one way of thinking about dynamic systems is just in terms of the virtual. We can better understand this if we take the examples that Châtelet (1987) makes about historical contributions of new ideas by Leibniz and Abel. Leibniz theorised differential calculus thinking of points as if they were alive, as powers of explosion (“puissances d’explosion”), while Abel saw the curve not as fixed but in terms of its power of receiving intersections (“comme puissance à recevoir des intersections”). The virtual restores concepts to mobility, granting them inventive force and power. For de Freitas (2014), Châtelet shows us “how we might study a particular practice for how its lines of flight flourish and act generatively in unfolding new intensive dimensions.” (p. 290, emphasis in the original). The virtual is that which nourishes encounters with mathematics, linking the concrete and the abstract and allowing recoding the indeterminate contours of the sensible and the intelligible. This has to do with the potentiality or virtuality that is always entailed in perception: “We never just register visual information from that which is in front of our eyes: we see potentiality, relationality, mobility, occurrence. Students are not seeing an object; they are seeing an event” (de Freitas, 2014, p. 298).
In this paper, we take this perspective to look at the students’ mathematical encounters with spatio-temporal relationships, focussing on the material and virtual dimensions of these encounters.

**Method and activity**

The activity, which is the focus of this paper, is part of a classroom-based intervention (Stylianides & Stylianides, 2013) aimed at introducing the concept of function through the use of graphing technology. The wider research had the main purpose of investigating how learners might articulate meanings for functional relationships through modelling motion, and how their embodied activity with the technology might affect these meanings. A class of 30 grade 9 students and their regular mathematics teacher participated in the study, which lasted for a period of about three months with weekly sessions. During this time, the students worked on individual tasks, in groups of three people and in pairs of groups, taking part in class discussions. The authors were both present in the classroom and two cameras were used to film the mathematical activity of the students during all the sessions. Data for the research analyses are based on the films and students’ written productions and diagrammatic activity. A microethnographic methodology (e.g. Streeck & Mehus, 2005) is essentially chosen for studying interactions and discourse in the classroom through strands of semiotic and representational activity over short periods of time, drawing attention to the material circumstances of the mathematical events.

The technology the students used in the case we consider here is WiiGraph, an interactive software application, which leverages two Wiimotes to display the space-time graphs of two users moving the remote controllers in front of a sensor bar. WiiGraph provides several challenges and composite operations, including shape tracing, maze traversal and ratio resolution. Choosing the plain visualisation (Line), the software captures the distances of the controllers over time and two graphs appear, in real time and with different colours, on a single Cartesian plane. Figure 1 shows a case of this type of visualisation for a 30-second default time and two students who move the controllers.

![Figure 1: The graphical system in Line and two students moving](image)

Visual and bodily (especially proprioceptive and kinaesthetic) interactions partake in the students’ encounters with the graphical system in relation to experiencing spatial and temporal aspects with the technology. We will not refer to other types of graphical activity, since this is the one of interest in the case of Rob and Bob.

The task was given in a written form to the class during the second session and did not imply direct use of the technological devices. In the first session, the students explored Line and its graphical potential, became acquainted with the devices and started discussing about pairs of functions (for example, horizontal or slanted straight lines), with graphs originating in real time and projected on an interactive whiteboard. The activity of Rob and Bob was designed with the purpose of unfolding the
slope/speed relation (early insights emerged out of class discussion in the first session), and how it may reveal relationships between two space-time graphs (functions).

**Rob and Bob**

The task was faced by the students divided into groups of three people, and followed by a class discussion led by one of the authors. It focuses on an imaginary experience with WiiGraph in which two little robots move (the controllers) in front of the sensor bar, but only the graph associated to one robot’s movement is given (Figure 2a). The text of the task is the following:

Rob and Bob are two little robots, which can be taught to move in front of the sensor very precisely. Suppose that, in response to Rob’s movement, WiiGraph produces the line below (Figure 2a). Imagine that Bob also moved: it started together with Rob, at the same distance from the sensor, but moved at a double speed and in the opposite direction.

- *Which graph would WiiGraph show for Bob’s movement?*
- *Did Rob and Bob meet again after the start?*

**Justify your answers.**

The task has an unconventional nature with respect to the representational system offered by the technology, because it does not ask the students to merely reason on the model to motion, or motion to model, shift. Instead, information about the missing graph is given in terms of the relationships between the two robots’ movements (“double speed”, “opposite direction”), so that the students are moved to think about the relationships between the two graphs (double slope with opposite sign), through their perceptual and bodily experience with the tool. In addition, the simultaneity of the two movements, which by the way recalls the usual way of using the tool, is embedded in information about the starting instant/point (“it started together with Rob”, “at the same distance”).

![Figure 2: (a) The given graph, (b) The expected solution to the task given by one group](image)

The given graph is that of a piecewise function made up of four pieces, which capture alternate ways of moving by Rob: stepping further from the sensor for the first five seconds, stopping for the next fifteen seconds, returning to the starting position in other five seconds, and stopping for the last five seconds (Rob keeps constant speed in each time interval). We expected the students to complete the Cartesian plane drawing a graph like the one in Figure 2b. It is the graph of a piecewise function again made up of four pieces, defined on the same sequence of time intervals as the given graph. These pieces correspond to four ways of moving by Bob: getting close to the sensor for the first five seconds, stopping for the next fifteen seconds, returning to the starting position in five more seconds, and stopping for the last five seconds (however, Bob is supposed to cover double space with respect to
Rob, according to the constraint of moving at a double speed. Of course, this is true when he moves, and trivially when he does not, since the distance covered is null).

Instead of looking at the expected graph as the correct one and speaking of difference in terms of being mistaken, we dwell on different unexpected solutions emerged from the groups about their potential to bring forth new relational possibilities for the two robots’ movements as well as for the pair of graphs. In the next section, we take these solutions as the problematic actualizations of the mathematical events that the groups encounter in solving the task. It is this idea of novelty that speaks directly to inventive mathematics and makes students alive to their engaging with the task.

**Graphs and discussion**

The groups worked on the task for half of the time, then they took part in a collective discussion in which their graphical solutions were compared. Only one group drew the expected solution (Figure 2b), while eight out of ten created one of the three unexpected lines shown in Figure 3 (For the sake of ease, we refer these lines to three graphs labelled with numbers 1, 2 and 3).

![Figure 3: Unexpected solutions — (a) graph 1, (b) graph 2 and (c) graph 3](image)

The three graphs added for Bob’s movement have some similarity. They all show that taking into account information about opposite direction and capture it visually in the diagram is not an issue for the students. Each added graph is made up of four pieces, which embed the opposite way of moving with respect to Rob: first getting close, then returning to the start (first a decreasing piece, then an increasing piece). Not even slope is an issue: the double speed of movement is double slope in the three diagrams. However, the duration of Bob’s movement is problematic for the students. In fact, while there is correspondence between ways of moving there is no embodiment of duration: there is no correspondence between time intervals in which both robots either move or stand still. The lengths of the horizontal pieces are different from each graph to the other, and the constraint for Bob to move at a double speed with respect to Rob is no longer preserved. Thus, the problematics of duration evolved along various accidental threads for the students, driven by their perceptual and bodily engagement with the task. These broke with causal connections and direct determination, opening up to speculative and inventive investments and to a generative movement, implicating the perturbation of spatio-temporal relationships. For example, in the case of graphs 1 and 3 (Figures 3a and 3c), some encountered the event for which Bob already stands still while Rob is still moving and, later, Bob moves towards the starting position while Rob is still standing still. Some groups introduced the new event in which the second robot stops just after fifteen seconds, in the very middle of the experience with WiiGraph, and ideally disappears from the view of the sensor, so that the second graph might accidentally stop in the middle of the diagram (Figure 3a). Almost all the students engaged with the kinaesthetic question of Rob and Bob always covering the same space, no matter the time spent, as
shown in the three diagrams. These threads are actualized through the groups’ written explanations, then during class discussion. Types of explanation are the following:

Graph 1: “The line we represented is half of Rob’s line. The lines are steeper because speed is doubled and Bob moved faster than Rob and in the opposite way. The graph ends at 15 because Bob, moving at a double speed, stopped at half of 30.”

Graph 2: “The two configurations are different from each other, indeed slopes also change since times change: Rob is slower. So, covering the same space in different time, there will be a higher steepness.”

Graph 3: “Bob goes at a double speed with respect to Rob, so it finishes “the lap” before Rob. The rest of the way it stood still and at the end it met Rob. Speed changes between the ways of Bob and Rob, indeed Bob has to cover the same space backwards using half of the time.”

The logical equivalence between double speed as double distance in the same time and as the same distance in half of the time is lost, and the problematic of covering a fixed space in less time drives students’ perception and visualisation in the diagramming of the missing graph. Graph 1 (Figure 3a) is the most coherent in respect to the axiomatic way of reasoning about double speed but at once the most incoherent in relation to kinaesthetic actions with the technology. Briefly speaking, it is nothing but a temporal shrinking of the given graph. Instead, graph 3 (Figure 3c) is in line with the usage of WiiGraph, because it embraces all the thirty seconds of the modelling process. The same occurs in the case of graph 2 (Figure 3b), which is particular though, since it struggles to depict the simultaneity of the two robots’ movements. In the discussion, different students actualize in different ways the problematics that sustain the mathematical events that occurred in solving the task. Below, Lorenzo, Luigi, Giulio and Oliver bring forth in the discourse the issues of duration and simultaneity of movements, of moving at a double speed and of covering the same space, issues that are entangled in their diagrammatic and written activity. Lorenzo speaks about graph 1 (Figure 3a), Luigi and Giulio refer to graph 2 (Figure 3b), while Oliver argues about graph 3 (Figure 3c).

Lorenzo: ’Cause, moving at a double speed, distance remained constant, even though it was the opposite, but maybe, if Rob performed a movement in 10 seconds, Bob performed it in 5 seconds because speed was double.

Luigi: For me, hem, the graph took up the same time because, moving simultaneously, maybe, at the time they were moving, it took less time for one than for the other one to cover the same space, to move in the same space, but then one stood still until the other one also did move again, so both graphs last for 30 seconds. (...)

Giulio: For me, it [the graph] finished at 30, ’cause it’s not that Rob [Bob] could know Bob’s [Rob’s] movement in advance, so it [the graph] cannot finish at 15, it [Bob] has to wait for it [Rob] to perform the same but opposite movement, ’cause we did see Bob’s graph (miming it in the air) but if they move simultaneously, it means that one cannot anticipate the movements, so it cannot finish at 15 seconds. (...)

Giulio: We depicted slope at 2,5 seconds but then we stood still until 20 seconds, ’cause anyway it’s true that time is halved, but Bob doesn't know what Rob will do later, so it has to wait for it.
Researcher: Did you say that time is halved?

Giulio: Yes, ’cause it [Bob] does things in half of the time, it’s true, however it’s not that he can know what it [Rob] will do later, hem, ’cause we do know it, but if they move simultaneously...

Oliver: Bob does our graph with the movements with which it’s been set up, and then, in the end, it’s not that it waits for Rob, it goes on just as it likes and wants, then at a certain point, when movements are finished, it stops and the line keeps straight for the rest of the time.

Researcher: Are you saying that time is halved?

Oliver: Yes, because of the double speed. (...)

Lorenzo: Indeed, for explaining a little the graph, I said that if there’s a distance to cover, and that distance is 50 kilometres and you go at a speed of 50 kilometres per hour, it takes you 1 hour to cover that distance. Instead, if you go at 100 kilometres per hour it takes you 30 [minutes].

Giulio: Yes, for me he’s right about the first piece, but then if you stand still, so speed is null, zero times two is always zero and so speed has to be equal in the positions in which it stands still, for me.

Discourse with the researcher unfolds the event-nature of unexpected threads traversed in solving the task. We see how the students inscribe themselves into the temporality of imaginary situations with the robots. The ways of perceiving this temporality are different for different (groups of) students: some imagine that one robot has to “wait for” the other to know what to do (Giulio, Luigi); for others, coordination is not needed (Oliver) or considered (Lorenzo). Time is duration and simultaneity of movements: both aspects become problematic for learners. Both are crucial in making sense with WiiGraph of time as the independent variable in space-time functions.

**Conclusive remarks**

In this paper we have discussed some unexpected graphical solutions to a given diagramming task based on modelling motion through the use of Wii graphing technology. We have focused not on how these solutions were incorrect with respect to the expected diagram, but on ways in which they brought forth new possibilities for the students to encounter spatio-temporal relationships. In so doing, we looked at visual, proprioceptive and kinaesthetic aspects of experiencing the technology as that which sustained the occurrence of new mathematical events in the classroom, bringing into being problematic perturbations of the given situation, like shrunk graphs as well as not coordinated movements and fixed paths, which break with the conventional visualization and activity of the representational system in use. The written, the diagrammatic, the discursive and the bodily, as the groups attempted to grapple with the task (to make sense of it), have to be seen as that which animated the task without ever exhausting it or fully determining it. The temporality of the events speaks directly to the material contingency of learning: the students are dynamically affected by the diagrammatic activity while telling stories of motion related to graphing technology.

Emerging and developing multiplicative structure in students’ visuospatial representations: Four key configuration types

Carla Finesilver
King’s College London, UK; carla.finesilver@kcl.ac.uk

Visuospatial representations of quantities and their relations are widely used to support the understanding of basic arithmetic, including multiplicative relationships. These include drawn imagery and concrete manipulatives. This paper defines four particular configurations of nonstandard representation according to the spatial organization of their visual elements. These are: unit containers, unit arrays, array-container blends, and number containers, all of which have been observed to support developing multiplicative thinking, allowing low-attaining students to work with the equal-groups structures of natural number multiplication- and division-based tasks. Student-created examples are discussed, and pedagogical and diagnostic implications considered.

Keywords: Visuospatial representation, multiplicative thinking, arithmetic, low attainment.

In their early encounters with quantitative relationships, children become aware of concepts such as conservation of number, counting, etc., through interactions with collections of objects. For example, addition as the joining of collections and subtraction as removing a subset of objects from a collection – in which the ordering of individual objects is unimportant – can be considered conceptual ‘grounding metaphors’ (Lakoff & Núñez, 2000). Various models of children’s arithmetical problem-solving development indicate a broadly similar progression from early concrete/enactive-based reasoning, to imagic/iconic, to abstract/symbolic reasoning (e.g. Bruner, 1974; Piaget, 1952). Within this broad outline, the actual external representations of learners’ thinking during problem-solving include many possible sub-varieties (e.g., sets of actual objects, pictures of objects, tally marks in different configurations, dot arrays, etc.), and many possible categorizations of these for analytical purposes. The construction of appropriate analytical frameworks is necessary for the discerning of inter-individual differences and intra-individual trajectories (Meira, 1995; Voutsina, 2012). This is particularly the case when studying atypically-developing learners (Fletcher et al., 1998).

This aim of this paper is to share one aspect from the qualitative analytical framework for student- and co-created visuospatial data used in Finesilver (2014), delineating four particular types of visuospatial representation and demonstrating their use with selected examples. The project took an essentially grounded analytical approach, and so whilst this paper does not report results as such, a sample of research data is included with brief description of the process.

Theoretical background

To understand multiplication and division represents a significant qualitative change in learners' thinking compared to understanding addition and subtraction (Nunes & Bryant, 1996). These authors, amongst others, have recommended a replications model of multiplication, which is highly relevant both to counting-based strategies and to unitary drawn or modelled representations of multiplicative relationships. A central concept for considering this particular aspect of representation is spatial structuring:
We define spatial structuring as the mental act of constructing an organization or form for an object or set of objects. The process […] includes establishing units, establishing relationships between units […] and recognizing that a subset of the objects, if repeated properly, can generate the whole set (the repeating subset forming a composite unit). (Battista & Clements, 1996, p.282)

There are two main forms of spatial structuring with which unitary visuospatial representations of multiplicative relationships emphasise their replicatory structure: by creating some kind of boundary to separate groups of units from each other, or by organising them in a pattern based on regular spacings. These two organisational strategies roughly correspond to Lakoff and Núñez’s (2000) grounding metaphors Arithmetic as Object Collection/Construction, and to two of the common unitary configuration types I introduce below, Unit containers and Unit arrays (see Figures 1Figures 2).

Creating container configurations – i.e. visible boundaries within which the individual units of each group may be in any configuration – is particularly intuitive. Research that includes container representations (or equivalent) has been mainly focused on young children and their intuitive concrete models, such as sharing items (e.g. Carruthers & Worthington, 2006; Kouba, 1989). Rectangular array configurations, in which the groups are structured and defined by a configuration of all units in regular rows and columns – are also widely used in educational contexts. Research including array representations generally focuses on older children, grid arrays, and involves content such as rectangular area measurement; however, dot arrays have been shown as a powerful tool for supporting work in multiplication (Barmby et al., 2009; Harries & Barmby, 2007; Izsák, 2005; Matney & Daugherty, 2013), and, less frequently, division (Jacob & Mulligan, 2014). No prior studies were found that included both container and array representations, focused on the secondary age group and allowed freedom of representational strategy across multiple interviews and tasks.

Data

The data discussed below, including all examples, derive from a larger research project using microgenetic methodology to elicit and study emerging and developing multiplicative structure in low-attaining students’ visuospatial representations within a flexible context (Finesilver, 2014).

There were thirteen participants, aged 11-15, attending mainstream schools in London, and identified by their teachers, educational histories, and initial sifting assessments as particularly numerically weak compared to their peers. Although having complex individual etiologies and patterns of arithmetical issues, they had in common difficulties experienced at the particular stage of moving from additive to multiplicative thinking (as highlighted by Nunes and Bryant, above).

The representations were produced during individual or paired problem-solving interviews carried out by the author (four per participant). Participants worked on tasks based within two multiplicative scenarios chosen for their ease and likelihood of visuospatial representation. These were ‘Biscuits’ (numbers of biscuits shared between numbers of children) and ‘Passengers’ (numbers of different-sized vehicles required to transport numbers of passengers). There were also some calculations presented symbolically with no scenario. The representational media available were multilink cubes, coloured pens and paper. Some representations were co-created by student and researcher at ‘cognitive snapshot’ points (Schoenfeld, Smith, & Arcavi, 1993), i.e. when a participant was unable to proceed further independently, and support was given in the form of a minimal ‘nudge’ prompt;
(e.g. ringing or counting a group aloud). Due to project methodology, support cannot be easily quantified (especially gestural interaction) and is not attempted in this paper. Documentation was via audio recording, photographs, scans of students’ papers, and field notes.

**Four key types of representational configuration**

Over 200 visuospatial representations were collected (exact figures cannot be given as participants re-appropriated whole and parts of prior representations for subsequent tasks and expansions). The great majority were found to group into four types; inclusion criteria, as defined below, were allowed to emerge, then refined, as part of a grounded analytical process. The most common types, *(unit) containers* and *arrays*, will be familiar. A smaller substantial proportion combined both container and array elements, and a further type emerged which I call *Number Containers*. (There is only space to include a few examples here; more will be included in this paper’s accompanying presentation, or see Finesilver (2014) for a complete set.)

**Unit Containers (UC)**

*Criteria: Groups of two or more units enclosed by visible boundaries. Includes representations where units are aligned in rows and/or columns, but these do not represent divisor/quotient or multiplier/multiplicand.*

![Figures 1(a-d): Examples of Unit Containers](image)

Overall, this was the most common type (106 instances); eleven of the cohort chose to draw unit containers at some point while working on a task, although some much more frequently, and even the least able could sometimes use them independently. For the students with the severest arithmetical difficulties (e.g. dyscalculia), who could not make any start independently, visuospatial prompts were provided, e.g. drawing a set of circles (“plates”) for ‘Biscuits’. UCs were for the most part drawn, often with various scenario-based decorative elements, but some made use of mixed-mode, mixed-media representations with cubes or other physical units placed in drawn containers (see Figure 1d).

**Unit Array (UA)**

*Criteria: Groups of two or more units aligned in rows and columns, where number of units in the rows/columns represents divisor/quotient or multiplier/multiplicand.*

![Figures 2(a-d): Examples of Unit Arrays](image)
Plain unit arrays (of dots, tally marks, etc.) were used frequently (47 instances), the majority being produced independently by nine of the cohort, and an almost exclusive choice for three participants. All were drawn, and none constructed with cubes. (This may be surprising, as it is easy and visually effective to produce cube arrays. However, in general it was the arithmetically weakest students who made greatest use of concrete media, and that group also tended to prefer container representations.)

With a shift of perspective between vertical and horizontal structure, a learner may see that both rows and columns are formed of a set of equal groups, which underlies the commutative principle. This was independently noticed by some participants; e.g. on being asked to work out 28 biscuits shared between four people followed by 28 shared between seven, some re-used the same array, while others produced both $4 \times 7$ and $7 \times 4$, only realizing the equivalence after completion.

**Array-Container Blend (ACB)**

*Criteria:* Unit array representation with additional containing rings, where number of units in each row/column/container represents divisor/quotient or multiplier/multiplicand.

![Figures 3(a-d): Examples of Array-Container Blends](image)

While 47 instances of successful ACB use were collected, many of these were co-created and/or drawn during one particular task (see below); however, 27 were otherwise produced independently by participants. These were used mainly in ‘Passengers’ and the bare tasks, usually (although not always) with each row or column being counted out then ringed before proceeding to the next. Taking the additional time and effort to superimpose rings onto an array was thus clearly considered advantageous for certain participants on certain tasks. One student in particular began with a strong preference for plain dot arrays, but once she had seen an ACB, switched almost exclusively to that representation type for subsequent tasks.

In one particular (and uncharacteristic) task on multiplicative relationships, students were directly encouraged to produce an ACB which had both rows and columns ringed. A certain behaviour was observed with this representation type alone: some students independently looked back at it during later tasks and interviews for reference, in some cases ‘bookmarking’ it. As the numbers involved were different to those in their current task, and they only took a brief look, I suggest the images were functioning as an instant visual reminder of the commutative property of multiplicative structures.

**Number Containers (NC)**

*Criteria:* Container representation with numerals (rather than unit marks) representing the number in each group written inside, or close by, each container.
Figures 4(a-d): Examples of Number Containers

Unlike the previous three configuration types, NCs were not found in the literature or theorized prior to fieldwork, and some students introduced them spontaneously. Having observed their successful use, I included them in some later interactive support occasions, but of the 30 instances collected (from 9 participants), 22 were entirely independent. This change from unitary (iconic) to non-unitary (partially symbolic) representation is very significant cognitive step. Note, however, that some participants still chose to incorporate decorative elements from the task scenario (i.e. the vehicles were still depicted, although individual passengers were not).

Discussion

Students’ use of the four types of representational configuration

Unit container representations allowed those students with the greatest arithmetical difficulties to create manipulable simulacra of imaginable scenarios, with as much visual resemblance as they preferred, to carry out organized sharing and grouping distributions and record their thinking. Unit array representations (with or without rings) allowed those students with a grasp of equal-groups structures, but who were not yet confident working symbolically, to perceive and make use of replicatory patterns spatially structured along two dimensions. However, the split between participants choosing to include container and/or array structuring elements also indicated personal preferences as a separate factor to arithmetical ability. (This has potential for further investigation, involving testing participants’ visual pattern recognition).

While some individuals displayed firm preferences for container- or array-based forms throughout, others’ representational strategy choices changed over the course of interviews, and sometimes intra-task. For example, Figure 5 shows a student’s representation for calculating the number of 7-seater vehicles needed for 21 passengers, starting with a container resembling a car, then immediately discarding decorative elements and containers, in transition towards an array format.

Increasing the quantities within tasks (for those students judged likely to cope with the challenge) sometimes resulted in strategic change, in particular the introduction of number symbols. However, the general persistence of container elements surrounding those symbols (i.e. Number Containers) is striking. As seen in Figures 4b and 4d, non-mathematically-functional decorative elements (bus wheels, aeroplane wings) were included inconsistently. From a purely calculation-based viewpoint, students using NCs might as well be using plain columns of numbers – therefore the container elements clearly fulfil some other, non-enumerative, yet important, function. I suggest containers forms are a powerful visuospatial/perceptual phenomenon relating to equal-groups number structures and relationships, which persists later than might be expected. It is reasonable to expect that as
confidence is gained, the containers begin to disappear (but could be retrieved as a reassuring strategy at times of low confidence – for example, when tasks increase in difficulty).

Obviously, all types of representational configuration were used to a great extent for the enumeration of quantities, and for the visuospatial organization of these quantities so that the correct set of objects (units or groups) could be enumerated. However, it is worth noting that the representations created were not immediately rendered useless once a task solution was found. Students completed visuospatial patterns when an incomplete pattern would have been sufficient to obtain an answer; they sometimes added further organizational (or decorative) detail after giving an answer. Occasionally they even created a whole new representation to record their working retrospectively, or to help them explain an exciting discovery they had just made about numerical relationships (e.g. the commutative principle). The fact that these representational activities were important to the students for their own sake (i.e. not just for obtaining the answer in a single task) suggests that they can be an important part of these students’ developing arithmetical reasoning, and their real and perceived agency in this development.

Representational configurations and developing multiplicative thinking

Representations of mathematical objects […] can be seen as concretizations of abstract mathematical concepts and at the same time as representations of real objects. (Wittmann, 2005, p.18)

The four related types of representational configuration defined and discussed above integrate numerical and spatial concepts to form visuospatial mathematical objects that allow such a dual role: concretizing numerical relationships and representing real-life objects referred to in scenario tasks.

Whilst all four types represent equal-groups arithmetical structures, they do not fall along a single line of progression (see Figure 6, below). In the same way that concrete representations (e.g. modelled with cubes) are not necessarily less mature than iconic ones (e.g. drawn images), different types of configuration have different affordances which may be relevant at certain points. Number Containers, being non-unitary, are a clear progression from Unit Containers in terms of calculation, by requiring step-counting or repeated addition rather than unitary counting. However, Unit Arrays better instantiate the two-dimensional, reversible, nature of multiplicative relationships, whilst the ringing of rows or columns in ACBs could link procedural and static conceptions of multiplication/division.

The analysis of a set of relatively open-ended, student-generated, qualitative data based on their use of four key types of representational configuration highlighted a particular aspect of these students’ late- and slow-developing multiplicative thinking: the many small adjustments that together can indicate a gradual change of focus of attention from units to groups, all happening within what is often considered to be a single stage of ‘counting-based strategies’. Whether a task is multiplication- or division-based, there is a total quantity which is made up of, or can be separated into, equal groups. In terms of enumeration, the most basic strategies involve counting without any awareness of the repeating structure, while the more advanced ones make use of it. In terms of representational strategy, the most basic involve manipulating concrete or drawn units individually, to seeing and using visuospatial repeating patterns of units, to manipulating component groups as though they were units, to – eventually – focusing on these groups as new, composite units.
An individual’s progress in this move from units to groups as main focus may be diagnosable via their representational strategic choices, along various possible trajectories (see Figure 6). (The bracketed items are likely or potential subsequent steps which, however, did not feature in the project from which this data derives.)

![Diagram](image)

**Figure 6: Potential developmental trajectories through representation types**

Regarding this change of focus, there is a particular point of interest in ACBs: although they are still unitary representations (i.e. every unit is visibly present and countable), the visual and enactive emphasis on ringed subgroups serves to shift the student’s level of visual focus, drawing attention away from the units and towards the groups. Thus, it encourages the possibility of seeing containers (enclosing well-aligned sets) as the new ‘units’ for manipulation. Meanwhile, with NCs, the replacing of (iconic) units with (symbolic) numbers is not only important for its progression toward standard notation, but as another part of this change of focus from units to groups – the change from using one mark to stand for one thing, to using one mark to stand for a collection of many things.

Even from a small sample of students it is clear that their patterns of capability, difficulty, and the representations which work best for them, are complex, interrelating, and individual. There is no single ideal path through from, for example, dealing out a pile of physical items to a set of actual present people, and carrying out a fully symbolic division calculation. However, from a teaching/learning perspective it appears important that at no stage is the leap too wide or too hasty, and that there are visual links when moving from more intuitive to more abstract representational strategies. From an analytical perspective, I suggest that tracking students’ use of these four key representational configuration types in their arithmetical problem-solving (both in their initial choice of type, and in the emerging and developing spatial organization of elements within representations) may be beneficial in further study of the progression from additive to multiplicative thinking.

Identifying key visual-cognitive processes in students’ interpretation of graph representations using eye-tracking data and math/machine learning based data analysis

Enrique Garcia Moreno-Esteva, Sonia White, Joanne Wood and Alexander Black

1U. of Helsinki, Faculty of Educational Sciences, Helsinki, Finland; enrique.garciamoreno-esteva@helsinki.fi
2Queensland University of Technology, Brisbane, Australia; sl.white@qut.edu.au

We present a mathematical and computational analysis, partially based on machine learning techniques, of the visual scan-paths obtained during a graph interpretation task which allows us to identify when the problem solver succeeds in solving the problem with a fair degree of accuracy, and helps to understand the visual-cognitive processes at work during the problem solving task.

Keywords: Graph interpretation, eye-tracking, machine learning, mathematics education, gaze metrics

As a way of introduction: About the task and machine learning

Eye-tracking is quickly becoming an established technique for investigating cognitive processes involved in the learning of mathematics and other subjects (Lai, et al., 2013). Unfortunately, the analysis of eye-tracking data is difficult and laborious, often involving frame by frame analysis (Garcia Moreno-Esteva, Hannula & Toivanen, 2016). We partially overcome this difficulty here, with the use of machine learning and other mathematical techniques. Using a desktop eye tracking system, children completed a mathematics problem that incorporated a bar graph. The visual scan-paths and the accuracy of the response are analyzed in order to understand how a child “reads a graph”. We are trying to gather from our data and its analysis, a story of what happens when several children are confronted with such a task. What do they look at? Do the gaze patterns influence the success or accuracy when responding to the task? With this information we may be able to more reliably infer the cognitive processes completed by children.

The problem-solving task

In Brisbane, Australia, a group of 113 children (mean age 8.67 years), all in the second half of year 3 in school, completed the graph problem solving task. As part of a larger project, children completed a series of eye tracking tasks (reading, mathematics) in a quiet room near their classroom. The mathematics tasks included odd-even judgement, magnitude comparison, and problem solving tasks: interpreting a bar graph and navigating a coordinate grid. The focus of this presentation is the graph problem solving task. This task was designed based on the Grade 3 Australian Curriculum Mathematics where Grade 3 children are expected to be interpreting and comparing data displays (ACARA, 2016). A similar graph interpretation task features in a Grade 3 Australian standardized achievement test. The children were shown the following: a) a bar-chart, where the height of each bar indicated a the number of hours worked by Sarah during a given week; b) a labeled coordinate system, where the x-axis had the week number labels, and the y-axis had numbers corresponding to hours; c) a sentence indicating Sarah’s hourly wage; d) another sentence indicating the task to completed related to Sarah’s wages in Week 3. Curcio (2010) describes a sequential framework for children's
data comprehension, this framework includes; *understanding, interpretation and prediction* with data. The current graph task required each child to *understand* and *interpret*: reading the question and basic details of the graph (*understanding*), and then reading between the different elements of information (*interpretation*) in order to complete the computation and arrive at the correct solution for Sarah’s Week 3 earnings. A Tobii eye-tracker operating at 300 Hz recorded the locus of focus of their eyes throughout the activity - including the initial *understanding*, and steps involved in *interpretation*. The threshold for fixations was set at 100 ms (Tobii Technology, 2014). It was hoped that the eye tracking information (fixations and saccades) might shed light on the different cognitive steps involved in the task. Initial qualitative evaluations of the eye movements demonstrated children who did not progress past the first *understanding* stage, as they did not identify the question being asked or relevant information on the graph. Other children were able to *understand* the task and progressed to specific *interpretation* of relevant information - with a variety of behaviors demonstrated. For example, some children had high numbers of fixations and saccades around relevant areas, whereas others had fewer and longer fixations on relevant areas. These initial qualitative observations were systematically investigated using machine learning techniques.

The data included 113 visual scan-paths (for purposes of the forthcoming discussion, the *inputs*), and 113 answers (the *outputs*), considered as correct (1) or incorrect (0). The visual scan-paths consisted of sequences of pairs, each pair including the duration of a fixation in milliseconds (ms), and the location of the fixation. The visual scan-path information can be visualized as a video (or a static picture) in which the fixations appear as a sequence or red dots that have a size proportional to the duration of the fixation, and which are connected by lines to neighboring fixations. After inspecting the visual scan-path videos, it was evident that it would be difficult to disentangle patterns of visual processing that might reveal cognitive processing of different children. It was decided that further mathematical/computational analysis of the data might provide further insight. Since the nature of the input data is sequential, classifying the visual scan-paths and test results (inputs and outputs) with a Markov model based machine learning technique was selected as an appropriate analytic method.

**A word about machine learning techniques**

The proprietary algorithm (*Mathematica*’s Classify function) was used to do the machine learning analyses, using a Markov model method (Wolfram Language and System Documentation Center, 2016). In this analysis you select a subset of the sample (input – visual scan-path - and output – result - data) to analyze (classify) with the machine learning algorithm. From that analysis a classifier is then used on all the inputs (visual scan-paths) to predict the outputs (0 or 1, incorrect or correct). The predicted outputs from the classifier are then compared to the real outputs, and the percentage of correctly classified outputs can be calculated (some examples are provided in subsequent sections).

**Our research question**

Our research question is simply, what can we learn or infer about cognitive processes related to the graph interpretation task described with mathematical/computational/machine learning based analysis techniques of the eye-tracking data, and maybe, could these techniques be of further help in analyzing the data pertaining to other well defined mathematics problem solving tasks?
Our techniques are general, in that they can easily be applied to other eye-tracking data consisting of a sequence of fixations given by the coordinates and the durations of the fixations as inputs, and a set of two or even more categories as outputs. We hope to make the programs available to other researchers wanting to undertake this kind of analyses at a later stage or our research.

The analyses and corresponding results

In this section we will describe three kinds of analysis for which we obtained encouraging results. Other possible analyses will be discussed in a later section pertaining to directions of future work.

We partitioned the visual stimulus (the graph on the screen; Figure 1) into areas of interest (AOIs), where the most critical areas of interest are labeled as A1 (wage information), A2 (week number), A3 (week 3 bar), and A4 (number region containing the number of hours corresponding to week 3), and other areas of interest which are less critical, or irrelevant, are labeled with letters B and C and a number, respectively. In addition, we labelled the whitespace around the critical areas as ZZ.

As a result, data items look like the following:

\{\{227, A1\}, \{563, B2\}, \{267, C2\}, \ldots, \{287, C2\}, \{517, A1\}, \{1443, A3\}\} \rightarrow 1,

Figure 1: partition of the task sheet into areas of interest (AOI’s).

In the example above, the first fixation occurred on area of interest A1 and lasted 227 ms, the second one on AOI B2, with a duration of 563 ms, and so on. At the end the arrow with a 1 after it indicates that the child solved the problem correctly.

Finding a small and highly representative subset of data (developing a training set)

In order to find small and highly representative sets of data items corresponding to correctly and incorrectly solved instances of the task, we tried to find the smallest subsets of data items (henceforth called training sets) on which we could generate classifiers that predicted outcomes with a high degree of accuracy. After a building classifiers based on randomly selected subsets of data items, we could generate a classifier that correctly predicted up to 75% of the test results, and this was using only four data items in the training set (3.5% of the sample). It would have been impossible to test all sets of four data items out of 113 (there are 6,438,740 such combinations) so we made a number of
classifying testing runs for randomly selected subsets of size 4, and chose some of those sets which yielded classifiers with a high prediction rating. We then inspected the videos of some of these sets and tried to observe what might have been visually outstanding in these. Our prediction rate is marginally better than human experts can do after training on very large data sets. In the world of machine learning, a rating of 75% with a training set of size 3.5% is an extremely good result in what is called Supervised Learning (since the training set we found is so small, this is called semi-supervised learning (for machine learning principles, consult Hastie, Tibshirani & Friedman, 2009).

From this inspection, we detected parameters to investigate further with machine learning and other techniques, including sequencing, duration and number of fixations and other more elaborate metrics.

**Analysis type 1: the order of fixations in the sequence – does it matter or not?**

One question we had was whether the order of fixations in the sequence matters, or whether there is something else at work. Some literature in psychology indicates that the order of fixations affects certain cognitive function such as memory (e.g. Bochynska, & Laeng, 2015; Rinaldi, Brugger, Bockisch, Bertolini, Girelli, 2015). First, we tested overall order, building a classifier using the entire sample data. Its predictive rate is over 99% (using this technique we get only one mismatch between predicted and real outputs, due to a faulty item which we were able to locate through the application of the classifier itself). We then permuted the order of the fixation duration and AOI pairs at random in the visual scan-paths, and passed the permuted input data through the classifier we obtained using the entire sample. Even with the permuted data, we obtain a classification rate which is over 97%. From this we cautiously concluded that the order of the fixations in the sequence has little impact on whether the child responds to the question accurately.

As an additional check, we investigated whether the order of fixations within critical AOIs mattered. If this were occurring, it might distinguish understanding and interpretation of the graphical information (Curcio, 2010). In order to study this, we extracted just the pairs of elements corresponding to critical elements, and eliminated the rest of the data elements. With these modified data items, we built a classifier, using training sets of size 13 (approximately 11% of the sample size), and passed the rest of the modified data items through the classifier. This resulted in a prediction rate of up to 66%, which is good but not nearly as good as we had hoped. This indicates that the order in which students inspect critical areas might be of some importance, and it deserves further study. This also led us to a different form of analysis (type 3), even though much more needs to be done than we did here.

**Analysis type 2: number of fixations and duration of engagement on task**

The number of fixations and their duration (see figure 3) for the subjects is extremely revealing even though the analysis is less complex. These fixation duration profiles could be interpreted like a simple fingerprint of student engagement and ability. Our analysis of the number of fixations and their duration gives a clear indication that visual scan-paths can be quite revealing about what the students can or actually do. To state the results briefly, children who respond correctly take a short amount of time (under 30 000 ms) to provide and answer and have a smaller number of fixations (mean of 69) than children who respond incorrectly. Most of the children who respond incorrectly take at least 35 000 ms to respond or have more than 69 fixations. The statistically significant duration averages for children who respond correctly and those who do not are 30 000 ms and 35 000 ms respectively, and
69 fixations vs 77 fixations respectively. Interestingly, a few children (34 out of 113) who take a short amount of time and have a small number of fixations, typical of children with a correct response, provided an incorrect response. In most of these cases children had gathered the correct information from the graph but had made a calculation error. There are 17 children for which we have not yet determined an adequate explanation of their performance. Had those children read the graph incorrectly? Had they understood the task? When interpreting the graph and performing the computation, did concepts become confused? We found that these 17 children completed the task very quickly relative to the other participants, with a mean response time of approximately 25 000 ms. This information leads us to speculate that these children may not have been fully engaged in the task or in some respect confused or wandering. In summary, we can pick out, in each case, the children according to their response from a quantitative analysis by looking just at the duration of their engagement and the number of fixations during their involvement in the task. In the future, we plan to do an Artificial Intelligence based cluster analysis of the number and duration of fixation profiles only, hoping that they will separate out into four categories: those of children who respond correctly, those of children who do not read the graph correctly, those of children who read the graph correctly but miscalculate, and those of children who “do something else”. There is interest and possibly a growing body of work around this topic, whether it is possible to classify gaze patterns according to the state of mind of the participant subject. It is definitely one of our goals in this and future research (e.g., Horrey, Lesch, Garabet, Simmons, Maikkala, 2017).

Figure 3: number of fixations and duration profiles of successful child (blue) and unsuccessful child (orange) – the x-axis is the number of fixations, the y-axis is time, the duration of fixations, in ms

Analysis type 3: duration ratios and frequency ratios

From viewing the videos it appeared that children who get the problem right seem to spend a substantial amount of time looking at critical data, and seem to look at such data more frequently. These parameters were assessed quantitatively, making a distinction between the importance of the area of interest (e.g. A, B, C), and not between the areas themselves (e.g. A1, A2, A3 etc.). Thus, we measured the total amount of time a subject spent looking at critical AOI’s (with labels Ax), and non critical areas (Bx, Cx, and ZZ), and also measured the frequency with which a subject inspected an AOI labeled with A, B, C, or ZZ. The total duration of fixations on areas A, B, C, ZZ became DA, DB, DC, and DZZ, and the we considered the ratio DA/(DB+DC+DZZ). We then computed the means of this ratio for the students who successfully solved the problem and for those who did not. The means were used to compute a threshold value and make predictions as to who would
successfully solve the problem or not. The same approach was used for frequencies (call the total frequency on A-critical areas FA, FB for B-critical areas, FC for C-critical areas, and FZZ). We computed an analogous ratio where the quantities FA, FB, FC and FZZ were weighted by coefficients 1, .5, .25, and 0, respectively. The rationale for using weights in the case of frequencies is to account for the fact that looking at less critical AOI’s, for example, whitespace (ZZ), can easily occur as a result of distraction while inspecting the graph or while moving from a fixation in an important area to another one, and therefore, they are overrepresented and should carry a smaller weight in the frequency count. We acknowledge there are alternative approaches that could be used.

With the two thresholds used in combination one can predict the results with an accuracy of 77%. The thresholds were combined in such a way that if a child spent both, enough time on critical areas, and looked at them frequently enough, the result would be success, and otherwise, it would result in an incorrect response. So it seems that both these parameters are indicative of a child’s ability to successfully solve the graph interpretation task. A post-hoc statistical analysis was done on the means obtained for the duration ratio and the frequency ratio to show that they differ in a statistically significant way. Assuming a normal distribution of the duration ratios, the means of children who were successful and unsuccessful were 1.13 and .76, with a standard deviation of .43 and .42 respectively. These means are statistically significantly different p << .001. Similarly, having tested for the normal distribution of frequency ratios the means are 1.81 and 1.33, with standard deviations of .53 and .54, and p << .001, showing again a very significant difference.

A note about validity and reliability

The results discussed here would need to be validated with further experimentation. For example, do the results hold if the experiments are repeated with systematic variations, changing the height of the bars, the number of the week, and the salary for Sarah? Similarly, do the results remain invariant cross-culturally? We have thought of replicating the experiments, with children of the same age and/or background knowledge, in different English speaking countries and in different cultures with different languages. This work remains to be done. The reliability of these results is given in as much as the calculations are straightforward and easy to check, and the data is clean data as provided by a commercially tested device. It is hoped that in the future, a functional version of the paper can be republished in a way that the reader can verify the programs and use the programs with his/her own data.

Conclusions and direction of future work

In this report we have discussed the kind of visual processes that might be at work when a child is solving a graph interpretation task, a discussion derived from a machine learning analysis of eye-tracking data collected during the problem solving sessions. It would seem that there is strong evidence to support the claim that the order of the fixations during the problem solving session plays almost no role in the child’s ability to succeed in the problem solving task. It would also seem that the amount of time and the number of times spent looking at areas where there is information which is critical for the solution of the problem relative to the amount of time and frequency of glances at other areas is definitively an important indicator of a child’s ability to successfully complete the task. As to how these results would affect teaching practices, one could conclude that it is important that
the teacher directs the student attention to what the critical information might be, where it might be located, and how to use it when teaching how to interpret graphs of this sort.

There are many other measures that can be studied (or have been studied, but are not reported here). We mention just a few, without further explanation: string edit analysis, lag analysis, cluster analysis, longest common sequence analysis. The limit in how to analyze gaze tracking data is our imagination.

Acknowledgements

The first author wishes to acknowledge very valuable on-going discussions with Nora McIntyre, at the Department of Psychology, University of Sheffield, with whom very valuable discussions ensued about the possible measures discussed here, and about classifying gaze patterns according to the subjects state of mind.

Epistemic and semiotic perspectives in the analysis of the use of digital tools for solving optimization problems in the case of distance teacher education

Veronica Hoyos
National Pedagogical University, Mexico; vhoyosa@gmail.com

The purpose of this work is to revisit from an epistemic and semiotic point of view the use of technological tools for solving problems of optimization accomplished by in-service secondary teachers participating in an online course intended for their professional development. This approach allowed to analyze teacher limitations on operational resolutions, and drew hypothesis about difficulties for experiencing processes of reflection on their own resolution without the implementation of adequate collaboration tools for working between them or by themselves and at a distance.

Keywords: Epistemic and semiotic framework, teaching and learning of mathematics at distance, resolution of optimization problems using technological tools, online teacher professional development in mathematics.

Theoretical frame

In the work that it is presented here it is reviewed new data on the resolution of in-service secondary teachers using mathematics technology (GEOGEBRA in this case) to solve optimization problems. These teachers were participating in an online course for their professional development, mainly in relation with the incorporation of mathematics technology into their practice, but primary they were learning to use technology and learning to do mathematics with technology(i). In this context, it has been important to know teachers’ strategies during the resolution of complex mathematical tasks using technology, because these allowed to identify the mathematical resources displayed by teachers, as well as their understanding of the content that were at stake.

Is in relation with the teacher (or student) understanding of the mathematics content at stake that this paper deals with the role of representations in mathematics teaching and learning, because in according with Duval (1994), “there couldn’t be understanding of the content represented without coordination of the representation registers, regardless of the representation register used. Because the peculiarity of mathematics in relation to other disciplines is that the objects studied are not accessible independently of the use of language, figures, schemas, symbols(ii)…” (Duval, 1994, p.12)

Moreover, school optimization problems in general are designed for the modelling of real situations. However, the mathematical representations that come into play (e.g. formulas, graphs or symbols, and the treatments or operations carried out with them) obey a set of rules and operative principles within a context of mathematical theories previously established. Thus, when a statement is made in mathematical terms, the validity or not of such statement comes into play, and this within a well-defined theoretical context (Habermas 1999, quoted in Balacheff 2010, p. 5/36). Balacheff expresses this complexity of mathematical work as follows: “mathematical ideas are about
mathematical ideas; they exist in a closed ‘world’ difficult to accept but difficult to escape” (Idem, p. 5/36).

Finally, it is from the perspective of determining the domain of epistemological validity (iii) of the computing devices for human learning (Balacheff, 1994), that Balacheff & Sutherland (1994) have found a way to characterize a computational learning environment with reference to a given field of knowledge, but also the forms of analysis that make sense of the differences between distinct computational environments, as well as its potential contribution, specific to the enterprise of teaching and learning of mathematics.

Therefore, for the sake of the work that is being presented here it is worth to be mentioned that in order to specifically analyze what the teachers were mathematically doing when solving the optimization problems with the technological tools (see more in Hoyos 2016), it was only possible using Balacheff and colleagues’ theoretical notion of epistemological validity (e.g. Balacheff 1994-2004; Balacheff and Sutherland, 1994), and Duval’s work on the coordination of representation registers of mathematics, specifically of graphs (Duval, 1994). These authors have illustrated the different contributions certain software has in different virtual learning environments (Balacheff et al, 1994-2010), and here it is noteworthy not only that the teacher (or student) learns to recognize those different register of representations (Duval, 1994) that are put in play by distinct computational devices or digital tools, but also the need of the coordination of representation registers than an appropriate use of computational devices involves when the validation of a solution is in question.

Collection of data and analysis

The data that are going to be showed here were part of performances of the in-service secondary mathematics teachers participating in certain online courses implemented by the MAyTE (an acronym for Mathematics and Technology) team (Hoyos, 2009-2012). These data are presented here for identifying what these teachers accomplished specifically for their mathematics learning during the six-month of online training courses they were participating into. In the MAyTE team’s courses, the mathematical activities were developed around an understanding of concepts, learning procedures or mathematical techniques that relied mainly on asking participants in the program for the resolution of some specific mathematical problems, while only providing a brief list of instructions and explanatory text on the mathematical content. In this context, these courses generally did not include tutorial indications related to the mathematical resolution of the tasks requested.

It is noteworthy to emphasize here that it was possible until now to analyze the means or the strategies that participant teachers displayed using GEOGEBRA to solve the problems or learning situations provided by the MAyTE team by applying the constructs of epistemological and didactical validity of computational environments. Briefly, in the online MAyTE program (see Hoyos, 2012), the activities consisted of using digital tools that were freely available on the Internet to solve math problems. The mathematical content was approached synthetically through a capsule of the content, and the digital tools for solving the mathematical problems consisted of a variety of mathematical software, particularly software of dynamic geometry (SDG). Next it is described one of the prototypical math problems to be solved by the teachers participating in the program, the
practical context in which it was proposed and how the teachers finally managed to solve the tasks involved. Two of the selected optimization problems that teachers should solve are as follows:

1) A refinery can process 12,000 barrels of oil per day and it can produce Premium [high octane] and Magna [unleaded] gasoline. To meet the demand, the refinery must produce at least 2200 barrels of Premium and 1500 of Magna. The distribution center for the Premium is 30 km from the refinery and the Magna distribution center is from 10 km. The transportation capacity of the refinery is 180,000 barrels/km per day (This means that 180,000 barrels are transported 1 kilometer per day). If the benefit is 20 pesos per barrel of Premium and 10 pesos per barrel of Magna, how many barrels of gasoline should be produced daily to maximize the benefit?

2) A certain animal fodder is a mixture of two food products, namely A and B. Each kilogram of A has 100 units of protein, 18 of fat, and 400 of carbohydrates. The kilogram of B has 200 units of protein, 2 of fats, and 300 of carbohydrates. The aim is to make bags with a mixture of A and B products, each of which should contain at least 500 units of proteins, 18 of fats, and 1500 of carbohydrates. If the kilogram of A costs 3 pesos and the one of B costs 4 pesos, determine the number of kilograms for each of these products that must contain each bag of food so that the cost is minimal. (Week 8, Task 1. Geometry and Algebra Course. Specialization MAyTE, Hoyos et al., 2009-2012).

Most teachers’ solutions to these problems were based on the identification and formulation of several algebraic expressions that modeled the given actual situation, and they were accorded to the data provided; as well as doing a graphical representation using GEOGEBRA, based on the algebraic expressions that firstly were elicited. Such procedures were needed to determine the region of feasibility and the coordinates of the points from which it was possible to obtain the maximum or the minimum cost, depending on the initial conditions of each problem. The solution that is going to be showed here (a data table and a graph in GEOGEBRA) was taken from the documents the teachers uploaded to the platform, and were evidence of a solution strategy composed of these elements: translation from the initial conditions to algebraic expressions, and representing the data through the software GEOGEBRA. Therefore, the teachers obtained a representation of the feasibility region from which the value of maximum benefit should be deducted (in the case of the first problem). In their graph, the feasibility region was shaded, and the problem in all cases was still unsolved after the graphic was made, because a point (with coordinates (x,y)) needs to be found by means of exploration and through calculating the values of the function of two variables f(x,y), and that in the region of feasibility (for attaining or not the benefit maximum for Problem 1 or the minimal cost for Problem 2).

Next it is shown that the teacher solution starts by constructing a table to organize the information of the data included in the text of the problem, and immediately afterwards it refers to the graph included in his solution.

T1 [One of Participant Teachers]:

If the benefit is 20 pesos per barrel Premium and 10 pesos per barrel Magna. How many barrels of gasoline must be produced each day for maximum benefit?
Solution:

According to the problem data, inequalities are the following:

\[ x + y \leq 12,000 \]
\[ 10x + 30y \leq 180,000 \]
\[ x \geq 1500 \]
\[ y \geq 2,200 \]

Where \( x \) is the number of barrels of Premium, \( y \) the number of barrels of Magna, the function that gets the maximum benefit is:

\[ f(x)=20x+10y \]

To obtain the benefit maximum, it should be drawn the graph of the following functions using ‘geogebra’:

\[ x+y=12,000 \]
\[ 10x+30y=180,000 \]
\[ x=1,500, \ y=2,200 \]

To find the value of \( x \) and \( y \) that maximizes \( f(x) \) function, we take the points that meet the initial conditions of the problem. Using the graph, you can see that the solution set is drawn within the limits of the lines and the shaded region.

In the graph, we can see that the points A, B, C, D, E, and F are some of the points that are possible solutions, but points C and D are not feasible, so substituting each of these points in the function to maximize the number of barrels of Premium gasoline, the solution obtained is \( x=9,800 \). And the number of barrels of Magna is: \( y=2,200 \).

Giving a maximum benefit for \( f(x) = 218,000 \) bpd

The reader should note that the image of GEOGEBRA showing the representation of the feasibility region is part of the teacher’s solution and it shall be inserted here.

Also it should be noted that seeing the image, in first place it must be considered that in T1’s solution there is a mistake related to the notation that the teacher T1 chose, by which instead of denoting the function of two variables as \( f(x,y) \), the dependence of the function \( f \) was only indicated on a single variable, insofar as writing “\( f(x) = 20x + 10y \)” to refer to the function from which the maximum benefit will be established. Note that T1, after having adequately defined the region of points that satisfied the initial conditions, ended by not carrying out an exploration of the values in the region of feasibility, question that would bring T1 to obtain the requested maximum value.
Moreover, what is perhaps most interesting is to note that for the computer learning environment in question, in this case constructed mainly for exploration and use of GEOGEBRA and for the conversion of mathematical representations (Duval, 1994) required to solve the problem, an epistemological change in the conditions of the teacher (or student) is raised (Balacheff, 1994-2010) linked to the use of the software in the situation or problem proposed, and to the mathematical complexity of the task involved. A sign of this could be that a real graph of a function in two variables should be represented in a three-dimensional space. The difficulty then in the problem of optimization posed resides in that for solving the situation in question it is also required reflection, specifically when following the suggestions included in the capsule of content. These suggestions appeared beneath to the text of the problem: (i) to draw lines parallel to the axis and intersecting inside the feasibility region, and (ii) to explore the variability of the values of the benefit function f(x, y) within the feasibility region and/or on points of the indicated parallel lines, which would allow to calculate the maximum value requested in Problem 1.

Of course, there is another way to solve this problem, for example, by associating any point within the feasibility region to the value of the benefit function, such exploration could thus be carried out directly using GEOGEBRA, starting by dragging the point over the feasibility region and verifying the increase or decrease as the chosen point were varying. Moreover, this type of exploration would also help to reduce or eliminate the confusion T1 had concerning the double variability upon which the function f was dependent. For example, for point E with coordinates (2507.66, 6006.86) the value of the function f(x,y) equals 110,222 approximately. And it can be proven that the value of maximum benefit is f(x,y) = 149,924.05 when the approximate values for x and y are x = 2993.81, and y = 9004.79.

Briefly, to finally arrive to solve a problem posed in a classical school context of optimization problem solving, the teacher (or student) shall find that there is a very close relationship between the modeling of a real situation, the use and treatment of mathematical representations that come into play and the coordination of the representation registers in use. Thus, a possible trajectory for the resolution of such problems could consists of: (a) surpassing the initial difficulty of the formulation of a series of mathematical statements that model the real situation by the usage of mathematical
representations to model the actual situation; (b) advancing to get a diagram where the possible solution could be found by putting into play certain digital tools (in this case GEOGEBRA inherent digital tools) for the mathematical treatment or the conversion of such representations (Duval, 1994); (c) formulating a new mathematical statement, namely the possible mathematical solution to the posed problem. However, it is noteworthy that from a mathematical point of view the teacher (or student) having passed by (a), (b) and (c) has not yet concluded with the mathematical task in question, mainly because in the mathematics ‘world’ it is always necessary to carry out the validation of any mathematical statement last obtained or formulated (Balacheff, 2010, p. 19/36).

Conclusions

Because the difficulty to solve resides in to reflect on at least one of the three following possibilities: (i) on $f$ as a function of two variables and that its graph would then be in $\mathbb{R}^3$ and not in $\mathbb{R}^2$, while plotting the region of feasibility is being carried out in $\mathbb{R}^2$; or, (ii) to reflect on the sense of the instructions and/or suggestions given at the end of the text of the problem, suggestions that concerned with the construction of parallel lines to explore the maximum value of the function $f$; or, (iii) on the possibility of carrying out an exploration using GEOGEBRA, starting by dragging a point over the feasibility region and verifying the increase or decrease of the function $f$ as the chosen point was varying; it is worth to see that all of them are entirely relied on a necessity of feedback or teacher (or student) control of their activity within the software (see Balacheff & Sutherland, 1994, p. 15). But this control usually is relied on the coordination of the representation registers or on the comprehension of the mathematical content in question, which is usually not accessed directly by working alone within the software and at a distance.

Briefly, in a trajectory to finally arrive to solve a problem posed in a classical school context of optimization problem solving, the teacher (or student) shall find that there is a very close relationship between real situation modeling, the use and treatment of mathematical representations that come into play and the coordination of the representation registers in use. Therefore, the principal results in the analysis that has been instrumented here are as follows:

(1) The learning environment was in part defined using a computational device (in this case GEOGEBRA) as a procedural tool for the conversion, use and treatment of the different mathematical representations (Duval, 1994), in this case the equations and graphs that came into play in the given situation of optimization;

(2) However, to transit from a procedural context where a possible solution was found to a theoretical one to validate it, an epistemological change is required (Balacheff, 2010, p. 6/36). In this case, it consisted in instrumenting reflective tools, which are not automatically available within GEOGEBRA by itself.

Therefore, this work has allowed to advance a hypothesis of necessity of digital collaboration according to specific participant’s (teacher or student) activity, a support to accomplish the epistemological change already mentioned. It would be included in the computational device, or otherwise it would be provided by tutorial intervention (e.g. Soury-Lavergne, 1997).

These final remarks mean it is not enough to have access to mathematics technology and/or Internet free resources to achieve expertise or comprehension of certain mathematical content addressed. Yet
perhaps what is most interesting is that the analysis from this epistemic and semiotic perspective sheds light on how to move forward by correcting the design, incorporating elements missing in the programs reviewed, instrumenting teaching guides (or constructing hypothetical learning trajectories) or working with digital materials as collaborative tools that could promote exploration and reflective thinking to be applied in the solution of certain mathematical tasks, as those that were showed now in the situations under study. In other words, in the same way that social interactions do not in principle have an impact on learning but rather depend on the content and forms of interaction chosen, the use of Internet digital tools and computational devices will have an impact on teachers and teaching (or students and learning) when instrumentalization of Internet resources had been exercised to gain knowledge, or to teachers (or students) get control of the activity within the software (Balacheff & Sutherland, 1994, p. 15), specially by themselves.

Notes

(i) Both modes are at the beginning of the incorporation of innovation at the school, according to the PURIA model. Following this model implies that teachers should experiment with the mentioned modes to advance toward successfully incorporating technology into classrooms (Zbiek and Hollebrands, 2008; Hoyos 2009-2012).

Briefly, the PURIA model consists of five stages named the Play, Use, Recommend, Incorporate, and Assess modes: “When [teachers are] first introduced to a CAS… they play around with it and try out its facilities… Then they realize they can use it meaningfully for their own work… In time, they find themselves recommending it to their students, albeit essentially as a checking tool and in a piecemeal fashion at this stage. Only when they have observed students using the software to good effect they feel confident in incorporating it more directly in their lessons… Finally, they feel they should assess their students’ use of the CAS, at which point it becomes firmly established in the teaching and learning process” (Beaudin & Bowers 1997, p.7).

(ii) French is the original language of this quote: “il ne peut pas y avoir de compréhension du contenu représenté sans une coordination des registres de représentation, quel que soit le registre de représentation utilisé. Car la particularité des mathématiques par rapport aux autres disciplines est que les objets étudiés ne sont pas accessibles indépendamment du recours à un langage, à des figures, à des schémas, à des symboles…” (Duval, 1994, p.12)

(iii) The domain of epistemological validity of a computational environment is characterized by at least four dimensions: (1) the set of problems that the device can propose; (2) the nature of the tools and objects that provide its formal structure; (3) the nature of the phenomenology that is displayed on the interface that is accessed directly by the user; and (4) the kind of control available for users in the computational environment with the feedback that the latter provides (Balacheff & Sutherland, 1994, p. 15).

University of Nice, Nice, France², serge.quilio@gmail.com

Our study is based on a national research project called Arithmetic and Cooperation at Elementary school (ACE). The main objective of this research is the designing of a curriculum for first grade students. This communication focuses on the analysis of an extract from a lesson proposed by this curriculum. During this lesson, the students work on the notion of difference, which is introduced with the help of several systems of representation. These systems are already known by the students. The analysis of the extract shows that the past and future situations can be related to each other. We point out that the students’ continuity of experience can produce knowledge growth. This growth specifically occurs when the teacher’s uttering activity directs the students’ actions while they use the systems of representation. This uttering activity allows a reshaping / remodeling /modification of former knowledge through the systems of representation.

Keywords: Elementary school mathematics, continuity of education, semiotic representation.

This paper focuses on the continuity of epistemic experience in mathematics. We argue that systems of representation constitute a prominent way of achieving such continuity. We sketch the role of a specific system of representation (the number line) to build of the number sense at first grade. This research is based a larger French national research, arithmetic and cooperation at Elementary School (ACE). It offers a complete arithmetic program to 6-7 year-old-students (First grade). The conception of this curriculum relies on available scientific knowledge in different areas (Cognitive Neuroscience, Science of Education, Developmental Psychology and Didactics of Mathematics). A specific part of the conception of the curriculum is built within what we call a cooperative engineering (Sensevy, Forest, Quilio, Morales, 2011; Morales, Sensevy, & Forest, in press). This engineering consists of two spheres. The sphere 1 gathers a multi categorical team (PhD, teachers of study classes, researchers, teacher’s trainers, pedagogical advisors) and the sphere 2 is constituted by 120 experimental classes. In the first year of the experiment (2011-2012), the sphere 1 designed the mathematical situations of the curriculum. These situations were implemented in the « study classes », and redesigned on line in the course of the implementation process. The first year of the experiment, the sphere 1 designed eleven modules corresponding to forty-five sessions. The second year of this experiment, this curriculum has been implemented in 60 experimental classes (versus 60 control classes) and in 120 experimental classes (versus 120 control classes) the third year (2013-2014). The experimental classes' involvement in this curriculum and their feedbacks allowed numerous improvements of the initial design proposed by the research team situations.

This cooperation between researchers and teachers showed a willingness to create a didactic continuity in student’s experience through the use of representation of the number systems that are present in the progression throughout the year. We assume that in the joint action between students
and teacher, the systems of representation may authorize the continuity of the student’s experience. But, how precisely this can be built in joint action between teacher and students? Here we can rely on Dewey's conception of continuity. “The principle of continuity of experience means that every experience both takes up something from those which have gone before and modifies in some way the quality of those which come after” (Dewey, 1998, p.27).

The Joint Action Theory in Didactics

Our analyses will build on the Joint Action Theory in Didactics (JATD) originated in comparative approach in didactics (Sensevy, 2011; Sensevy, Gruson, & Forest, 2015; Ligozat, 2009; Tiberghien & Malkoun, 2009; Venturini & Amade-Escot, 2013). Among the theoretical tools provided by the “JATD”, we use mainly the contract/milieu dialectics and the reticence/ expression dialectics. When facing a new problem, students are confronted to what we call to a milieu (Brousseau, 1997; Sensevy & Tiberghien, 2015), as the epistemic structure. This milieu can be seen as the state of problem, what "has to be known" (Sensevy et al, 2015). Students have to face a rather enigmatic set of elements that they have to relate in order to build a system of meanings, in the knowing of what has to be known » (Sensevy, Gruson, & Forest, 2015). For example, for someone who has to do something with a representational system, the milieu is a specific symbolic organization of the system of representations itself. The milieu offered opportunities of enquiry, in which students have to connect elements of knowledge. They deal with this milieu by relying on the knowledge built in the preceding didactic joint action, the didactic contract, what "is already known". This relationship between contract and milieu is a dialectal one, because the understanding of a given milieu depends on the nature of the contract that guides the student's efforts.

In order to enable the student to learn, teacher enacts strategies to engage student’s action. Interactions between teacher and students are determined by the didactic contract (Brousseau, 1997). In fact, the teacher knows the knowledge that students will have to learn. But he must not tell directly all what he knows. Thus, he has to make choices, in his teaching, about the equilibrium between saying/showing (expression) and remaining tacit/hiding (reticence). This is the reticence-expression dialectics. The two dialectics (contract-milieu and reticence-expression) are entangled, in that expression or reticence can be oriented to "contract " ("what is already-there"), or "milieu " ("what has to be known").

The research on the using of manipulatives and representations focus on the necessity of enabling the students to rely first on manipulative and concrete “objects”, then to study iconic (analogue) representations of numbers (Bass, 2015; Schmittau, 2005, Davydov, 1975) then to write down equations in canonical form. This process seems very close to the tradition in Chinese textbooks (Bartolini Bussi et al., 2011; Sun, 2011; Ding & Li, 2014) and can be thought of as “concreteness fading” (McNeil et al., 2012; Fyfe et al., 2014). In this communication, we will try to show how in the new situation in which the notion of the difference (subtraction) is introduced, the systems of representation of number can guarantee a kind of continuity of experience. In fact, the “translational principle for representations systems” in a representational game (Morales, Sensevy & Forest, 2016) can allow students to understand the concept of the difference between two numbers.
Methodology

To discuss these questions, we focus on a specific moment of teacher’s practice in a study class, with an experimented teacher, who belongs to the research team (sphere1). The data were collected in December 2013, in a first grade classroom of a French primary school. The twenty-five students of this classroom were aged 6-7. This study follows a qualitative approach.

In this extract, the students collectively search the difference between two additive writings with two terms. In this communication, we focus on the introduction of a new piece of knowledge, the notion of difference between two numbers. In the preceding sessions, the students orally compared the production of two hands ads (students showed a number on the two hands, the statement) and a launch of two six-sided dice. The statement wins if it was bigger (in some cases smaller) than the two-dice throw. Then, students compared the two additions with two terms in reference to the situation of the “Statements” (fingers and dice). The result of this comparison was written in the form of a quality or an inequality with the mathematical signs « =, ≠, >, < ». These two additions were represented in two number lines to solve or prove the comparison, as we can see below (figure 1).

![Figure 1: An example of comparison between 2 + 4 and 5 + 3 on the number line](image)

The choice of this extract is motivated by the following reason: this extract shows how the continuity of student’s experience could be developed through the use the systems of representation. This extract can be considered as a mesoscopic level of the description, the pivotal level (Sensevy et al., 2015), which allows relationship between what preceded and what is going to follow. So, we can analyze the didactic transactions *hic et nunc*. We can characterize and describe the motives and the forms that directed teacher and students ‘action. This description can show the teacher’s strategies to make the didactic time forward.

Analyze

Presentation

This part of the curriculum “ACE” is organized around a connected series of situations. The initial situation of this curriculum is the situation of the “Statements game” (fingers and dice). One die (marked with standard dot patterns for 1-6) is about to be thrown. Beforehand, the students use their fingers to make a “statement” (for example, a student shows two fingers on her right hand, and three fingers on her left hand). The die is thrown. The students compare their statement with what is indicated by the die. If the sums are equal, the pupils have won. After this oral comparison, students compare an addition (two terms ≤ 5 with a number ≤ 6). The progressive complexification of the situation guides students to increasingly rich comparisons: the number of hands (students) is increased, so the number and the nature of dice (1 to 10 dice are played with), the rules of the game are changed (for example a pupil no longer wins because he has the same number as in the
statement, but because he has a lower or higher number). These connected situations should allow the students to build a real mathematical experience, particularly in the handling of representation and symbolic writing systems, as we will show in what follows. A number line is also introduced on which students represent the numbers. Indeed, the students manipulated a concrete object (the fingers) and they translate fingers by an iconic (analogical) representation of number (the number line) and wrote down equation in canonical form \((2 + 4 = 6)\). For example, a student shows two fingers on his left hand and four fingers on his right hand, then she draws these numbers on a number line:

![Number line with 2 and 4 fingers]

And she writes down this addition: \(2 + 4 = 6\)

To understand various properties of numbers, students had to compare different representations of the same mathematical reality to become progressively able to recognize the differences and the similarities between these representations.

Since the beginning of the year, students acquired knowledge related to compare numbers. This comparison is performed first orally with the production of "two or three hands ads" and a launch of six-sided die. Then, students compared an addition in two or three terms with a throw of dice. They used the mathematical signs \(<, >, =, \neq\) (for example, to compare \(3 + 1\) et \(5\), students write \(3 + 1 < 5\)). This situation become more complex when students have to compare two additions in two terms. Finally, students deal with the question of the subtraction on the basis of the comparison between two additions, in the continuity of the previous situations. The study is accompanied by the use of the number line.

The students have built a semiotic knowledge to represent the comparison between two numbers. The number is seen as a measurement. It refers to "the quantity of fingers" in two hands. The number line shows the number like a length measurement. This ancient knowledge is the didactic contract, the habits of action with which teacher and students are going to approach the new knowledge, the difference between two numbers. The extract of the session that we chose introduces the difference between two numbers from the comparison of two additions and the terms “larger than and smaller than”. The difference is a gap between two numbers, two length measurements. Four episodes will be analyzed. Here is a synoptic view of this analyzer.

Table 1: Extract division
We abstract the four episodes and provide a short analysis.

**Search for the difference between two numbers (episode 1, 2, 3)**

The teacher asks the students to look for the difference between “$1 + 3$” and “$1 + 1$”. He presents the instructions like this:

Teacher: Today, we are going to begin a new game. It is always a game with statements. But today what we are going to make, it is to compare ours statements. We look for which is the larger statement, the smaller statement but that I would know how much more and how much less (…) we are going to find, this calls in fact the difference.

Actually, the students meet difficulties to find the difference between “$1 + 3$” and “$1 + 1$”. They compare the two numbers and look for the larger number or the smaller number with the term-by-term strategy or by computing. They do not focus on "difference". Confronted to the difficulties of the students, the teacher suggests to illustrate «the two additions “$1 + 3$” and “$1 + 1$” » by a statement with both hands. The following picture (figure two) shows such a statement comparison.

![Figure 2: Translation of “1 + 3” and “1 + 1” by two statements](image)

Unfortunately, this translation between the mathematical symbolic writing and the hands statements in a game of representation does not bring the students to produce an adequate answer. "The semiotic habit" of the contract, which considers fingers as instruments to compare numbers, impedes a new designation of numbers, the difference.

**Using the number line**

Therefore, the teacher introduces in a milieu two number lines on which students have to represent both additive writings. A student writes a first bridge above the first interval of the number line (hence representing the number "1") and a second bridge above three intervals (between the second and a fourth graduation, hence representing the number "3"). He writes down above these bridges the numbers 1 and 3. Then, he draws below the number line a bridge of four intervals and writes down the sum number (4).

Teacher: It is good the statement makes four as Neil shows us. On the second line, what are you going to draw?

On the second number line, the same student draws two consecutive bridges and a bridge of two intervals, signifying the sum number (2)
Figure 3: the representation of “1 + 3” and “1 + 1” on the number lines

Teacher: What do you see in the two number lines? Do you see if the 1+3 is largest than 1+1?

The students provide answers different answers: “three”, "four" and "two". The teacher asks one student to show how he knows that his statement is largest.

Student: because here is the two [He slides his finger from the third graduation (number "2") on the first number line to the third graduation (number "2") of the second number line] It’s a part of four…

Figure 4: Representation of the difference on the number line

The teacher's expression encourages a translation between the symbolic writing and the number line. But, in the same time, she’s reticent because she doesn’t say how to draw these additions on the number lines. The teacher thus refers to the preceding contract. She just says: “What do you see in the two number lines? Do you see if the 1+3 is largest than 1+1?” This question can be seen as a ‘milieu-oriented situation’. The action of the student is moved toward the effective representation of the difference on the two number lines. But, though this expression, the teacher is reticent because she remains silent when the student searches the difference. She indicates where the student must look but the research stays under the responsibility of the student. The number line affords to show concretely the gap between the two numbers, the difference between the two length bounded by the bridges, the sum of the two additions. The students investigate an instrument, the number line, on which they know already how to play (in the situation of comparison). By using this instrument, they achieve not yet explored potentialities of this semiotic system. In particular, the number line shows a number included in another.

Results

The students investigate different systems of representation to find the difference between two numbers: symbolic writing, concrete representation with the hands, number line. All these
representations are known by the students. First, the symbolic writing is translated by statements on the two hands. Then these statements are translated into two number lines in what we may call a translation game, which is a particular representational game (Sensevy, 2011; Morales, Sensevy & Forest, in press). The preceding semiotic knowledge is "re-experienced" by the students. In this way, we can say that the systems of representation are instrumental (Dewey, 1938/1998) in that they allow investigating new knowledge. The semiotic habits are accommodated in a new situation, a new knowledge, allowing the continuity of experience. However, the re-experience of a semiotic system for introducing a new knowledge requires a subtle enunciative work for the teacher, given that the different strategic systems in teacher’s action can be a contract oriented or a milieu-oriented transactional activity. In this communication, we have shown how the expression-reticence game of this teacher enable her to introduce in the milieu a system of representation (the number line) already known by the students (contract) in order to understand new properties of this system (then considered as a milieu). This teacher's strategy enables the students to investigate the difference between two numbers while leaving them the responsibility of this enquiry (Dewey, 1938/1998).

Discussion and conclusion

However, these results ask to be worked. It is necessary to explore on a long duration this continuity of the experience of the students in mathematics through the systems of representation (Joffredo-Le Brun, 2016). In particular, it is necessary to note that such continuity can be built only through a real epistemic continuity of the knowledges within the curriculum. The design of such a curriculum has to be performed through the effective experience of the teachers, within an iterative process, as it is the case in the ACE research.

We propose a theoretical interpretation of visuo-spatial abilities, as classified in the field of Cognitive Psychology, in the domain of Euclidean Geometry. In this interpretation we make use of Fischbein’s theory of figural concepts and of Duval’s cognitive apprehensions. Our interpretation lays the foundations for a new theoretical framework that we propose as a tool for qualitative analysis of students’ processes of visualization as they carry out geometrical activities. In particular, we present analyses of excerpts from a set of activities designed and proposed in a didactical intervention aimed at strengthening visuo-spatial abilities of a group of students identified as the weakest from a selected 9th grade class of an Italian high school.

Keywords: Geometric reasoning, spatial thinking, visualization, visuo-spatial abilities.

Introduction

Research in the domain of visualization and spatial thinking has pursued several purposes: understanding the different imaginative strategies used by students (Owens, 1999); studying the effects of teaching practices, aimed at encouraging processes of visualization (Presmeg, 2006); developing theoretical constructs, useful for the interpretation of students’ perception of geometric shapes and how this perception improves in learning geometry (Duval, 1995; Fischbein, 1993, Mariotti, 2005). Some ideas in this field have been developed from the psychological studies on mental imagery. Since the advent of Cognitive Psychology and contemporary Neuroscience, researchers have been elaborating models to describe processes related to visualizing and using mental imagery, and they have listed sets of visuo-spatial abilities involved (e.g., Cornoldi & Vecchi, 2004). However, a shared definition of these abilities does not exist yet. Nor have the fields of Mathematics Education and Cognitive Psychology been able to elaborate common grounds to study visualization processes, in which they are both interested.

In this paper we propose a theoretical interpretation of visuo-spatial abilities, as classified in the field of Cognitive Psychology, in the domain of reasoning in Euclidean Geometry, that was developed as part of a study that has been recently carried out (Miragliotta, 2016; Miragliotta, Baccaglini-Frank & Tomasi, submitted). The study had two main objectives: on the one hand, we attempted to give a theoretical analysis of some visuo-spatial abilities in the context of learning Euclidean Geometry; on the other hand, we used such theoretical interpretation to study the effects of a set of activities proposed (for the most part) using a Dynamic Geometry Environment (DGE) in terms of strengthening the students’ visuo-spatial abilities (as it is widely accepted that DGEs yield great potential in fostering processes such as visualization, as well as in mediating, in general, the learning of geometry: e.g., Mariotti, 2005; Baccaglini-Frank, 2010; Leung, Baccaglini-Frank & Mariotti, 2013). In this paper we will concentrate on the description of theoretical analysis of the
visuo-spatial abilities considered and on its power as a tool for qualitative analysis of students’ behavior as they carry out geometrical activities. As an example of how the framework can be used, we will analyze an excerpt taken from a question (not involving the use of any DGE) of the post-intervention interview of a student from the group of students identified as the weakest of the Italian high school class of involved in the study. Since for what we present in this paper the role of the DGE is marginal, and space quite constrained, we will not discuss visualization in a DGE.

Theoretical background

According to Clements and Battista (1992), spatial reasoning “consists of the set of cognitive processes by which mental representation for spatial objects, relationships, and transformations are constructed and manipulated” (ibid., p.420). Referring to Kosslyn (1983), these authors observe that geometrical reasoning requires spatial reasoning, which includes four classes of image processing: generating an image; inspecting an image to answer questions about it; transforming and operating on an image; maintaining an image in the service of some other mental operation. In particular we are interested in processes involving two-dimensional geometric objects.

From the perspective of Cognitive Psychology, generating and processing mental images take place within a complex process of acquisition and use of cognitive abilities, including those denoted visuo-spatial abilities. A list of these appears in Cornoldi and Vecchi (2004, p. 16). We elaborated our theoretical interpretation starting from the following set of abilities: visual organization, the ability to organize incomplete, not perfectly visible or fragmented patterns; planned visual scanning, the ability to scan a visual configuration rapidly and efficiently to reach a particular goal; spatial orientation, the ability to perceive and recall a particular spatial orientation or be able to orient oneself generally in space; visual reconstructive ability, the ability to reconstruct a pattern (by drawing or using elements provided) on the basis of a given model; imagery generation ability, the ability to generate vivid visuo-spatial mental images quickly; imagery manipulation ability, the ability to manipulate a visuospatial mental image in order to transform or evaluate it; spatial sequential short-term memory, the ability to remember a sequence of different locations; visuo-spatial simultaneous short-term memory, the ability to remember different locations presented simultaneously; visual memory, the ability to remember visual information; long-term spatial memory, the ability to maintain spatial information over long periods of time.

To interpret how these general cognitive abilities might come into play during reasoning in the specific context of Euclidean Geometry, we referred to theoretical constructs elaborated in mathematics education to this purpose.

Fischbein’s theory of figural concepts

The Theory of figural concepts (Fischbein, 1993) describes geometrical figures as follows:

A geometrical figure may, then, be described as having intrinsically conceptual properties. Nevertheless, a geometrical figure is not a mere concept. It is an image, a visual image. It possesses a property which usual concepts do not possess, namely, it includes the mental representation of space property. [...] all the geometrical figures represent mental constructs which possess, simultaneously, conceptual and figural properties. (ibid., pp. 141-142).
According to Fischbein figural concepts “reflect spatial properties (shape, position, magnitude), and at the same time, possess conceptual qualities - like ideality, abstractness, generality, perfection” (ibid., p. 143); a geometrical figure is made up of two fundamental components: the figural component and the conceptual component. From the developmental point of view, initially the visual aspect is dominant, and gradually the role of formal constraints becomes more important, until the construction of figural concept is reached (Mariotti, 2005).

**Duval’s types of cognitive apprehension**

Today the importance of visualization in mathematics is widely recognized. Since several studies have addressed visualization in different ways, we clarify that our interpretation is in line with the definition given by Arcavi (2003).

Visualization is the ability, the process and the product of creation, interpretation, use of and reflection upon pictures, images, diagrams, in our minds, on paper or with technological tools, with the purpose of depicting and communicating information, thinking about and developing previously unknown ideas and advancing understandings. (ibid., p. 217, emphasis added)

Peculiarities of visualization in geometry have been highlighted by Duval (1995) in describing different approaches to dealing with geometric figures: cognitive apprehension stresses that “there are several ways of looking at a drawing or a visual stimulus array” (ibid., p. 143). Duval speaks of four cognitive apprehensions. Perceptual apprehension responds to the laws of figural organization and identification of form, and helps to “recognize something (shape, representation of a thing,...) in a plane or in depth” (ibid., p. 145) at first glance. In a perceived figure we can also recognize sub-figures that do not depend on its construction. Sequential apprehension “is required whenever one must construct a figure or describe its construction” (ibid., p. 146). Here the sub-figures emerge in a specific order, depending on the geometrical construction, on technical constraints of the instrument used and on mathematical properties. Furthermore, Duval (1995, p. 146) claims that “mathematical properties represented in a drawing cannot be determined through perceptual apprehension”, indeed, “a drawing without denomination or hypothesis is an ambiguous representation”. So, indications given through speech help us to identify properties of a perceived geometrical figure, thanks to the discursive apprehension. Here we are in the domain of deductive reasoning. The apprehension that has a heuristic function in problem solving is the operative apprehension. This apprehension depends on different ways of modifying a figure that happen only within the figural register and that are independent from mathematical knowledge.

Each type of apprehension seems to be related to different cognitive processes that could be accomplished through the coordination of different visuo-spatial abilities as we hypothesise below.

**Grounding for a new visuo-spatial abilities framework**

While maintaining the classification proposed by Cognitive Psychology, we selected a subset of visuo-spatial abilities and provided an interpretation in the specific context of geometrical reasoning. We used the Theory of Figural Concepts to interpret the terms “model” and “image” as follows: image is the figural component of a geometric figure; model is a synonym of figural concept in which image and concept realize their dialectic. Since our interpretation aims at being a
stronger lens for analyzing students’ processes than the visuo-spatial abilities as described in the Cognitive Psychology literature, there is not always a one-to-one correspondence with such abilities.

- **Visual organization** is the ability to recognize figural concepts from incomplete or not perfectly visible representations.

  Visual organization seems to be an ability that intervenes in tasks that require the recognition of figures within another figure, or in the recognition of a simple figure within a more complex figure. This ability echoes Duval’s perceptual apprehension.

- **Visual scanning** is the ability to recognize the properties of a figure starting from its representation.

  This representation can be static or dynamic. It depends on the task and on the context in which it is proposed. For example, in the case of a dynamic figure in a DGE, visual scanning is involved in the recognition of properties that are invariant under dragging (see Leung et al., 2013). This ability echoes Duval’s perceptual apprehension, but we also recognize in this ability some aspects of his sequential and discursive apprehension. For example, when observing a quadrilateral obtained through steps of a specific construction starting from two perpendicular lines, we can notice that quadrilateral seems to have a right angle. However, to recognize the property “having a right angle” only observing the figure on the screen, one needs to look at its written geometrical construction and deduce that the point one vertex is at the intersection of two perpendicular lines.

- **Visual reconstructive ability** is the ability to reconstruct, in a given representation, the figural component of a figural concept, starting from written or verbal instructions, or staring from partial representations.

  For instance, the reconstruction could be realized following a sequence of construction steps given explicitly, using appropriate tools (ruler and compass, primitives in DGE, …), otherwise it could be realized planning these construction steps. It involves the ability to correctly visualize the relationships between the elementary figural units involved (such as points on lines, perpendicular lines) following the steps of a geometric construction or creating a new construction. This ability echoes Duval’s sequential apprehension and his discursive apprehension. The visual reconstructive ability seems to intervene, for example, when carrying out the construction steps of a known geometric figure; when completing the steps of an incomplete construction; when following the steps of a given geometric construction.

- **Imagery generation ability** is the ability to instantly mentally reproduce the figural component of a figural concept recovering it from memory or generating it anew.

  This ability seems to intervene when one is asked to visualize a geometric concept, for example, while imagining a sequence of construction steps. Coupled with long-term spatial memory, this ability seems to be involved in the retrieval of the prototypes (that is, in Kosslyn’s terms, a “stored model of a shape”) of geometric shapes and of their properties. Coupled with spatial sequential short-term memory, it seems to intervene in the identification of particular geometric loci.

- **Imagery manipulation ability** is the ability to use the properties of a figural concept or to manipulate figural aspects of a figural concept, taking into account the theoretical relationships between elementary figural units of which it is composed.
This ability is involved in tasks that require mental manipulation of a figure in order to transform it into a new one. This ability echoes Duval’s operative apprehension, but also differs from it. The mental manipulations on figure are tightly connected to the figure’s conceptual component. Indeed, to manipulate a figure maintaining given properties, strong conceptual control over it is required, as highlighted also by Arcavi (2003), who emphasizes, as well, the high cognitive demand involved:

Seeing the unseen may refer to the development and use of an intervening conceptual structure which enables us to see through the same visual display. (ibid, p. 234)

When visualization acts upon conceptually rich images (or in Fischbein’s words when there are intervening conceptual structures), the cognitive demand is certainly high. (ibid, p.235).

- **Spatial sequential short-term memory**: this ability seems to be present in various processes of geometric reasoning; here we consider it, in particular, as the ability to remember different configurations assumed by the figural component of a figural concept during an observed or imagined manipulation.

- **Long-term spatial memory** in our interpretation this refers, in particular, to the ability to maintain in long-term memory the figural components of a figural concept.

The last two abilities are involved in solving geometric tasks and are always used in combination with other visuo-spatial abilities. For example, combined with the imagery generation ability, spatial sequential short-term memory seems to be involved in tasks that require recognizing a particular geometrical locus. Combined with the imagery manipulation ability, spatial sequential short-term memory seems to be involved in tasks that require remembering the configurations assumed by a figure during an imagined manipulation.

When a solver faces a geometrical problem, s/he interacts with visual or mental images in different ways; a process that seems to occur frequently is imagining the consequence of a (mental) manipulation of the figure. Such process can be carried out through the use of the various abilities listed above that expert solvers combine in an immediate and automatic way. So consider this as an ability in its own right, that we will call geometric prediction, intending the identification of certain properties or configurations of a new figure, arising from a process of manipulation. This process appears to be coherent with respect to the notion of anticipatory image (Piaget & Inhelder, 1966), which suggests an ability to make predictions, orienting both perception and imagination, in the presence of a specific goal.

**Visuo-spatial abilities framework as a tool of analysis**

In this section we use the framework to analyze an excerpt taken from a question of the post-intervention interview of a student; he was part of a group of students in the 9th grade (students aged 14-15) class of an Italian scientific high school (Applied Science option), identified through a pre-test as having low performance on geometry tasks heavily involving visualization processes; the teaching intervention lasted five lessons and had been carried out using open problems, mostly proposed in the DGE GeoGebra. The post-intervention interview involved tasks both in the context of a DGE and with only pen and paper (if requested by the student). In the excerpt the student is solving a task proposed outside the DGE setting. The analysis has the aim of showing the power of
the framework in identifying the proposed visuo-spatial abilities and showing how they can come into play, shedding light onto visualization processes.

Activity: the student is given the following task and allowed to use paper and pencil:

Imagine a quadrilateral. Focus on the midpoint of each side. Trace the segments that join the midpoints of consecutive sides. What can you tell me about the figure that is formed?

Below is an excerpt describing what the student says [and does].

Student: It is a quadrilateral, which… which looks like a rhombus, so to speak. [Initially he closes his eyes. Then he places four finger tips (two thumbs and two indexes) on the desk to form what looks like a square, and then, moving along two parallel lines in opposite directions, a non-square rectangle. He drags his fingers back and forth between these two positions.] If quadrilateral is a square it forms a rhombus with congruent diagonals, but if is a random figure…I mean, it depends on the figure. It changes depending on how the points are placed.

Interviewer: Draw it. What are you drawing?

Student: Four scattered points. [He draws (freehand) a quadrilateral with different sides, as shown in Figure 1]

Interviewer: Can you say more about the figure that is formed?

Student: It is a quadrilateral. Mmm…it is a parallelogram!

In addition to what the student says, the excerpt is interesting also for what he does, which gives further insight into visuo-spatial abilities he may be using. After the first answer, he keeps his eyes closed and moves his fingers on the desk. This seems to suggest that a purely mental process is taking place, and the gesture on the desk seems to be a window onto this process. In order to answer the question, first of all, we would say the student is using the imagery generation ability for imagining the first configuration. To this end he needs to recall a prototype of the quadrilateral that is as general as possible (this involves the imagery generation ability and long-term spatial memory); then he needs to visualize the required elementary figural units (imagery generation ability) and go through the steps of the construction (imagery reconstructive ability).

Now, the student’s use of his fingers on the desk is an extremely insightful window onto processes he could be enacting. Our interpretation is that he is using the imagery manipulation ability, helping himself with an external image (the quadrilateral with vertexes at his four finger tips) that he can act upon. What is visible of this manipulation are the positions (and their continuous change) of the vertexes. As he moves his fingers (forming what look like various rectangles) he is using geometric prediction, possibly aided by visual scanning, to visualize the quadrilateral with vertexes at the midpoints of the sides of the manipulated quadrilateral. This interpretation is supported by the fact that the student moves his fingers on his desk seamlessly, he never lifts them up from the surface, and then he selects a position which is coherent with respect to the configuration that he wants to (mentally) observe, and starts to move fingers again. The student seems to be able to manipulate the figure in a manner that goes beyond the kind of transformation described by operative
apprehension. Indeed, the manipulation recalls much more dragging of the vertices, as can be accomplished in a DGE. This cognitive effect could have been promoted by the kind of problems proposed within the DGE during the activity sessions. The student seems to be looking for extra external support for his imagery manipulation and geometric prediction abilities. Moreover, this excerpt is very interesting because of what the student then decides to draw on the sheet of paper when invited to so do. Although he has only mentioned the case in which the quadrilateral is a square and realized with his fingers various cases of it being a rectangle, he draws a much more general convex quadrilateral. This behavior supports our previous hypothesis that the student seems to need external support for his imagery manipulation and geometric prediction abilities. On paper it is as if he gains confidence, possibly because the cognitive load from the conceptual control he would need to exercise over the general figure is lowered this way. Once he sees the general quadrilateral and sketches the midpoint quadrilateral he recognizes (visual scanning and conceptual control) a parallelogram.

**Conclusion**

The fields of Mathematics Education and Cognitive Psychology share various research interests; one of these is the identification and classification of strategies and processes involved in visualization. According to Cognitive Psychology, generating and processing mental images take place within a complex process of acquisition and use of abilities, including those denoted visuo-spatial abilities. Attempting to interpret visuo-spatial abilities in the context of geometrical reasoning could be beneficial to both fields. In our attempt to give a theoretical interpretation of some visuo-spatial abilities in the context of learning Euclidean Geometry, we used theoretical constructs from the field of Mathematics Education, which led to the introduction of an ability different from the basic visuo-spatial ones, geometric prediction, and they also led to highlighting the fundamental contribution, in solving geometric tasks, of geometric conceptual control over figures.

This interpretation, which can be seen as groundwork for a new theoretical framework, has allowed us to: (1) design an educational intervention aimed at strengthening visuo-spatial abilities of a group of students identified as the weakest in a selected class; (2) gain insight, through qualitative analysis, into students’ geometrical reasoning. We believe that this kind of research can provide new insight into students’ difficulties in learning Geometry, and be used to design educational material for strengthening students’ visuo-spatial abilities.

**References**

In this research study, we investigated how middle school students created 3–dimensional objects from 2–dimensional figures using an extrusion method. In a summer enrichment program, students used manipulatives and a dynamic geometry program (Cabri 3D). We identified students’ strategies for forming 3–dimensional objects with a focus on their gestural signs. The results demonstrated that they most often employed dynamic–pointwise and dynamic–objectwise gestures to demonstrate the lateral faces or edges of 3–dimensional objects. Also, students linked their gestural signs and the Segment tool of Cabri 3D to indicate their reasoning.

Keywords: Gestural signs, 3–dimensional objects, extrusion, middle school students.

**Introduction**

Gestural signs are important to understand how students make sense of mathematical problems (Arzarello, 2006; Bartolini Bussi & Baccaglini–Frank, 2015; Radford, 2009). Signs (e.g., verbal or oral texts) are characterized as “something which stands to somebody for something in some respect or capacity” (Pierce 1932; 2.228). Also, students produce signs using an artifact such as manipulatives. Bartolini Bussi and Mariotti (2008) refer to signs that are produced using an artifact or any action related to the use of it as artifact signs. Students reason about tasks with the use of an artifact and exploit mathematical signs (e.g., mathematical definitions, proofs). Research studies address that students link artifact and mathematical signs employing gestures (Bartolini Bussi & Baccaglini–Frank, 2015; Maschietto & Bartolini Bussi, 2009). Gestures that are interwoven with other sets of signs facilitate mathematical communication between students (Arzarello, Paola, Robutti, & Sabena, 2009; Bartolini Bussi & Baccaglini–Frank, 2015; Radford & Sabena, 2015). In the current study, with a focus on students’ gestural signs, our research question is: “In what ways do middle school students relate the features of 2–dimensional figures and 3–dimensional solids that are created using an extrusion method?”

**Theoretical framework: Semiotic mediation**

Semiotic mediation “sees knowledge–construction as a consequence of instrumented activity where signs emerge and evolve within social interaction” (Mariotti, 2009, p.428). In a cultural learning environment, students use an artifact or a set of artifacts during a semiotic activity, so a piece of mathematical knowledge is mediated. The teacher is aware of the affordances (and constraints) of the artifact and assists students in using the artifact as a tool of semiotic mediation. In other words, students produce artifact and mathematical signs (or hybrid signs), so personal signs transformed into the mathematics culture’s signs (Bartolini Bussi & Mariotti, 2008).

A student may exploit personal signs that may be unclear for others. Having the role of cultural mediator, such signs become meaningful for others under the teacher’s supervision. For example,
Bartolini Bussi and Baccaglini–Frank (2015) addressed that a preschooler used a non–existing Italian word “quadratizzato” referring to the movement of a programmable robot that made turns in a circular motion. The researchers translated it into English with another non–existing word as “squarized O.” They identified children’s and a student teacher’s turning gesture and spiral arrows with reference to the word “quadratizzato.” The personal sign linked artifact and mathematical signs, and became a meaningful sign in the mathematics culture. The researchers characterized it as a pivot sign.

Pivot signs “may refer both to the activity with the artifact; in particular they may refer to specific instrumented actions, but also to natural language, and to the mathematical domain” (Bartolini Bussi & Mariotti, 2008, p. 757). They link artifact and mathematical signs or an artifact/mathematical sign may become a pivot sign (Bartolini Bussi & Baccaglini–Frank, 2015; Bartolini Bussi & Mariotti, 2008). Suppose a student is given a rectangular card and asked to draw the container he should order to hold the stack of the identical rectangular cards until it reaches a certain height. The student may produce a mathematical sign and draw a rectangular prism denoting its edge lengths. On the other hand, he may illustrate the stack of objects and draw a deck of rectangular cards (pivot signs). The deck of cards links the rectangular cards (artifact signs) and the rectangular prism (mathematical sign).

Research studies demonstrated that students’ gestural signs were intertwined with other sets of signs such as verbal signs (Radford & Sabena, 2015; Sabena, 2008). For example, Sabena (2008) characterized high school students’ production of signs while they were engaged in tasks about derivative of functions. Sabena found that students emphasized the dynamic character of derivatives employing gestural signs with other sets of signs. Also, previous research indicated that students’ gestural signs linked artifact and mathematical signs (Bartolini Bussi & Baccaglini–Frank, 2015; Maschietto & Bartolini Bussi, 2009). Bartolini Bussi, Boni, Ferri, and Garuti (1999) characterized the geneses of students’ gestures as pointwise or global (objectwise) with a focus on artifacts (gears) students used. Maschietto and Soury-Lavergne (2013) addressed that artifacts created for the same mathematical topic resulted in exploiting different signs. Primary school students were given to a hands-on tool (gear train of five wheels) and its digital counterpart for learning the place values of numbers. Students employed different gestural signs with the use of each artifact because they had different semiotic potentials. For example, students employed gestures to start the turning mechanism of the wheels using the hands-on tool and denoted these gestures in their written texts. The decimal values were explored in the counterpart digital artifact by mouse clicks. So, using a set of artifacts gives students an opportunity for mathematical learning.

**Methods**

The research design was a case study in which the data were collected from a bounded system – a summer enrichment program that took place in a state in the southeastern United States (Stake, 1995). The unit of analysis was semiotic activities. The participants of this research study were selected from a group of rising seventh and eighth grade students (three boys, five girls) attending a summer enrichment program that aimed at promoting students’ thinking in different STEM (Science, Technology, Engineering and Mathematics) areas. A five–day instructional unit was planned. Eight middle school students (three rising seventh grade students, five rising eighth grade students) participated in the research study. Their ages ranged from twelve to fourteen.
On the first day of the program, students were given a spatial ability test and an open-ended survey that indicated their experience with geometry, computers, games, etc. The participants were characterized by these instruments and students with different spatial abilities were paired up. On the second and third days of the program, students created 3-dimensional objects from 2-dimensional figures using an extrusion method (e.g., stacking identical circular cards on top of each other and forming a cylinder). Students were given worksheets and they answered the questions in pairs. In the semiotic activities, they were asked to identify containers (3-dimensional objects) that would hold the stack of identical objects or objects decreasing in size (e.g., coins with a different radius). They used manipulatives and a dynamic geometry program, Cabri 3D. Students were provided pre-image and image figures in pre-constructed Cabri 3D sketches and manipulatives. They were asked to drag objects in Cabri 3D sketches and make an observation. Afterwards, they identified the resultant 3-dimensional objects for holding the stack of 2-dimensional figures. Students formed right and oblique prisms, cylinders, pyramids and cones.

Prior to the summer enrichment program, a pilot study was conducted. Students were allowed to use the Trajectory tool of Cabri 3D that allowed tracing points and objects. However, at times, they traced the objects and Cabri 3D showed the answer. Based on the feedback from the pilot study the Trajectory tool was disabled from the menu bar. However, the teacher activated the Trajectory tool on his computer that was hooked up the projector during he generated a whole-class discussion.

Data included videorecordings of four dyads during each class session including whole class discussions, and students’ written and oral responses to the tasks. Also, a program that recorded the computer screen when students used Cabri 3D was used. The researchers watched the videos of students while they worked on the semiotic activities in groups. Their computer screen recordings were watched synchronously. Some screenshots and students’ gestures were inserted into the verbatim transcripts.

We focused on students’ written/oral responses to semiotic activities and their use of artifacts (manipulatives and Cabri 3D). Students’ artifact, pivot and mathematical signs were identified. In the current research study, we analyzed students’ strategies for forming 3-dimensional objects from 2-dimensional figures with a focus on their gestures. Students’ gestural signs were categorized as static and dynamic taking into account how they were employed. If students’ static or dynamic gesture signified an object, it was identified as objectwise. If the gesture stood for a point or a set of points, then we categorized it as pointwise gesture. Four gestural signs were identified: objectwise–dynamic, objectwise–static, pointwise–dynamic, and pointwise–static.

Results

We identified students’ strategies for forming 3-dimensional objects from 2-dimensional figures with a focus on their gestural signs. Students’ gestures that linked artifact and mathematical signs were characterized as pivot signs. Also, students produced other sets of signs that were characterized as pivot signs (e.g., graphical signs, verbal signs). However, we give students’ strategies in which gestural signs were characterized.

Some students suggested 3-dimensional objects (containers) that allowed no extra space and focused on the exact fit. Students employed objectwise–dynamic gestures to demonstrate lateral surfaces of
solids. For example, Charlotte emphasized that the container for identical triangular cards would be a triangular prism. She employed an objectwise–dynamic gesture as shown in Figure 1 and said:

Charlotte: …because the prism is gonna come around the edges of the triangles.

![Figure 1: Charlotte makes an objectwise–dynamic gesture to denote the triangular prism](image)

Some students focused on geometric objects in the artifact and suggested solids based on how the geometric shapes were stacked on top of each other. They interpreted artifact signs and employed static or dynamic gestures to indicate the resultant 3–dimensional objects and focused on the parts of the given artifact. For example, Vince had difficulty identifying the container (rectangular pyramid) for rectangular cards decreasing in size. He kept the height almost in the middle and positioned the rectangle. Afterwards, he employed an objectwise–static gesture to demonstrate the container as shown in Figure 3. He said:

Vince: For this one, I was trying to figure out so if it is – it is coming– it is going like that (makes an objectwise–static gesture as shown in Figure 2). As it decreases it’s going like this, it’s going like that. Do you see? It’s going inward like that.

![Figure 2: Vince makes an objectwise–static gesture to demonstrate the rectangles decreasing in size](image)

Students connected the geometric shape on the bottom and top in the given artifact producing a gestural sign. They most often made a pointwise–dynamic gesture and connected the pre–image and image points. For example, Sloane identified the resultant object for holding the stack of identical circles employing a pointwise–dynamic gesture. She posited:

Sloane: Because there is a circle on the top and the bottom and that makes a cylinder. Because there is like a straight line right here kinda (Figure 3).
Figure 3: Sloane makes a pointwise–dynamic gesture to denote a cylinder

On the other hand, some students made hybrid or objectwise–dynamic gestures to demonstrate the 3–dimensional objects. Virginia denoted the top and bottom of the cylinder with a static–objectwise gesture. Then, she made an objectwise–dynamic gesture and demonstrated the lateral faces of the cylinder as shown in Figure 4. She said:

Virginia: Because basically the same reason as the triangular one (triangular prism). If you place a figure on the top and the bottom, and you connect them, you would create a cylinder (Figure 4), which is basically just a 3–dimensional flat version.

Figure 4: Virginia’s objectwise–dynamic gesture for denoting the lateral faces of a cylinder

Students’ gestural signs resulted in using the Segment tool of Cabri 3D. On the one hand, some students connected pre–image and image points using the Segment tool to demonstrate their thinking (e.g., Figure 5). On the other hand, with the prompt of the teacher, some students used the Segment tool and connected pre–image and image points to demonstrate the 3–dimensional objects.

Figure 5. Vince connects pre–image and image points

During the whole-class discussion, the teacher exploited the semiotic potentials of Cabri 3D. For example, he activated the Trajectory tool and described the 3–dimensional as a collection of two-dimensional objects (Figure 6). He made a stacking action employing an objectwise-dynamic gesture to demonstrate the extrusion (Figures 6). He said: “continuously, I am adding more and more [triangular cards], right?” and emphasized the continuous motion of stacking the figures on top of each other.

Figure 6. The teacher activates the Trajectory tool of Cabri 3D and makes a stacking action
Some students used a metaphor and referred to a real–life object or entity to describe the shape of the 3–dimensional objects for holding the stack of 2–dimensional figures. For example, Vince made a connection between the given artifact and a daily life object with which he was familiar. He used a metaphor and made a pointwise–dynamic gesture to denote a CD container. He posited:

Vince: Like a CD. Do you have like a… It’s kind of a thing when you… It’s like a plastic you put on CD’s and you put a nob to stack all the CD’s. It’s like that.”

We identified objectwise–static gestures during students demonstrated the top and bottom of geometric objects or a cone/rectangular pyramid. On the other hand, students most often employed objectwise/pointwise–dynamic gestures. Their gestures signified the lateral faces or edges of 3–dimensional objects.

The aforementioned strategies were not disjointed from each other. We identified that students (during group work or whole–class discussion) used multiple strategies to support their claims. For example, Sloane and Stan had difficulty naming 3–dimensional objects. The researcher having the role of cultural mediator handed the artifact to them and elicited their thinking about the resultant 3–dimensional object for holding the stack of identical triangular cards. Sloane said:

Sloane: Just imagine there are a bunch of triangles in the middle. And then it’d be like (she makes a gesture as shown in Figure 7). It’d have like a longer length on the outside probably be slanted but I don’t know… I don’t know. It’s kind of like a roof to a house. And, I think it would be like a 3D trapezoid. That’s kind of how I see it.

Figure 7. Sloane makes a pointwise–dynamic gesture to denote a triangular prism

Sloane thought of the 3–dimensional object as a collection of 2–dimensional figures. Then, she produced a pivot sign making a pointwise–dynamic gesture and connected the vertices of the top and bottom triangles. After her gesture, she used a ”roof to a house” metaphor to describe the 3–dimensional object (triangular prism). She had difficulty naming the object and called the resultant object a 3–dimensional trapezoid producing an invented signifier. In her reasoning, Sloane used three strategies: focusing on the collection of figures, connecting pre–image and image figures, and using a metaphor. A pointwise–dynamic gesture was employed during she connected pre–image and image figures.

Discussion and implications

In the current study, we identified students’ strategies for forming 3–dimensional objects from 2–dimensional figures producing gestural signs. Students employed gestures frequently to demonstrate extrusion of objects. Similar to what Bartolini Bussi et al. (1999) found, students made objectwise/pointwise and dynamic/static gestures. Students’ gestures linked artifact and mathematical
signs, and were characterized as pivot signs. Similarly, Bartolini Bussi and Baccaglini–Frank (2015) identified gestural signs that linked artifact and mathematical signs. Students’ gestural signs were intertwined with other sets of signs such as metaphors. For example, students produced gestural signs and a used a metaphor when they had difficulty naming an object. Researchers found that gestures facilitated communication between students and teachers (Bartolini Bussi & Baccaglini–Frank, 2015; Arzarello et al., 2009; Radford, 2009; Radford & Sabena, 2015; Sabena, 2008). Gestures facilitate communication, in particular when students produce an invented signifier (Bartolini Bussi & Baccaglini–Frank, 2015).

Students’ strategies for forming 3–dimensional objects were associated with each other. When students reasoned about the extrusion activities, they used multiple strategies and defended their conjectures about the resultant 3–dimensional objects. Students used the Segment tool of Cabri 3D and connected pre-image and image points to demonstrate 3–dimensional objects. On the other hand, some students used the Segment tool with the prompt of the teacher. Students should be given an opportunity to interact with an artifact in a longer period, so they become more comfortable using it and exploit mathematical knowledge.

In Cabri 3D, when a transformation is made, one can see initial objects/points (pre-image) and transformed points/objects (image). We enabled students to see pre-image and image figures in pre-constructed sketches and hands–on tools. New research may demonstrate how students’ approaches may differ if they are not provided pre-image figures to identify 3–dimensional objects using an extrusion method.

We were unable to built hands-on tools in which rectangles/circles decrease in size to demonstrate a rectangular pyramid and cone. Students most often used Cabri 3D and changed the height of objects during semiotic activities. They interpreted artifact signs and produced mathematical signs. However, students most often exploited gestural signs during they used hands-on tools. As Maschietto and Soury-Lavergne (2013) emphasize, counterpart artifacts lead to a co-emerging of signs and using a variety of artifacts that have different semiotic potentials gives students an opportunity for mathematical learning.

Preservice mathematics teachers’ types of mathematical thinking: Use of representations, visual-spatial abilities, and problem solving performances

Beyza Olgun¹ and Engin Ader²

¹Boğaziçi University, Faculty of Education, İstanbul, Turkey; beyza.olgun@boun.edu.tr

²Boğaziçi University, Faculty of Education, İstanbul, Turkey; ader@boun.edu.tr

The main purpose of this study was to examine preservice mathematics teachers’ types of mathematical thinking and to investigate whether there are any differences between different types of thinkers based on their problem solving performances, use of representations and visual-spatial abilities. The sample of the study consisted of 113 preservice mathematics teachers in a private and four public universities. The results showed that although problem solving performances were similar for each type of mathematical thinking, preservice teachers who adopted harmonic and geometric types of mathematical thinking preferred to use schematic representations more than analytic thinkers in their problem solving processes. The findings provided an insight about preservice teachers’ preferences for a visual approach and the implications of these preferences for teacher education programs were discussed.

Keywords: Types of mathematical thinking, use of representations, visual-spatial abilities, word problems.

Introduction

Problem solving has an important role in mathematics and lies in the focus of almost every math curriculum (Van De Walle, Karp, & Bay-Williams, 2010). According to the American National Council of Teachers of Mathematics “one of the most significant aims of mathematics teaching and learning is to develop students’ problem solving ability” (Deliyianni, Monoyiou, Elia, Georgiou, & Zannettou, 2009, p. 96). Understanding of problem solving process includes identifying, exploring, implementing, and using visual images, which is related with visualization (Deliyianni et al., 2009). With the rise of constructivism, the importance of the role of visualization in the learning process was emphasized more. The role of visualization in mathematical problem solving is investigated through three main constructs. These are mathematical thinking in terms of predisposition of visualization in problem solving, the use of visual-spatial representations and visual-spatial abilities.

Studies on visualization in mathematics often linked it with mathematical thinking. In a problem solving context, three types of mathematical thinking were suggested according to disposition of visualization (Krutetskii, 1976): the analytic type, the harmonic type, and the geometric type. Students who embrace the analytic thinking style do not feel the need to benefit from visual supports and also they do not have enough strength for the use of visual components. For geometric thinkers it is the contrary. They make use of visual-pictorial components and verbal-logical components have poor influence on their reasoning. The reasoning of harmonic thinker students includes both verbal-logical components and visual-pictorial components and their preferences can change according to the problems that they face.
Teachers’ mathematical beliefs and learning experiences affect their mathematical thinking and visual approaches (Presmeg & Balderas-Cañas, 2001). Their thinking styles and use of visuality have an impact on their teaching (Presmeg, 1986b). Therefore preservice teachers’ approaches towards different types of mathematical thinking and visual-spatial representations could be an important component of teacher education programs. This necessitates a careful study of the interrelations among teachers’ visualization, mathematical thinking and problem solving performance before focusing on how these can be supported through teacher education programs.

The main purpose of the study was to investigate preservice teachers’ preferences of problem solving strategies and how their mathematical thinking (analytic, harmonic or geometric types) might affect the visualization process in mathematical word problem solving. Considering the purpose, this study aimed to explore whether there is a significant difference in preservice teachers’ mathematical word problem solving performance, use of visual-spatial representations (pictorial or schematic), and levels of visual-spatial abilities based on their types of mathematical thinking.

**Method**

Participants were selected by convenient sampling. The study was conducted with senior preservice teachers from one private and four state universities in Istanbul and Ankara, Turkey. 113 students were involved in the study and they were enrolled in Primary Mathematics Education (n = 91) and Secondary School Mathematics Education (n = 32) programs.

The data were collected with the implementation of two instruments; the Mathematical Processing Instrument (MPI) and the Spatial Ability Tests (SAT) during the second semester of the 2015-2016 academic year. The MPI, which was developed by Presmeg (1985) and adapted to Turkish by Taşova (2011), was used to measure participants’ types of mathematical thinking, use of visual-spatial representations, and mathematical word problem solving performances. In order to measure preservice teachers’ levels of visual-spatial abilities, SAT developed by Ekstrom and colleagues (1976) and adapted to Turkish by Delialioğlu (1996) were used.

The MPI was developed for the first time by Krutetskii (1976) to measure students’ preferences of the use of visual methods. Then Suwarsano (1982) designed the instrument with the same name for elementary school students. According to Presmeg (1995), the instrument that was designed by Suwarsono (1982) was not convenient for teachers. Thus she arranged the instrument in three sections according to fieldwork in which both students and teachers participated. With the new arrangement, the instrument took its final form that consists of three sections. In this study, since participants were pre-service teachers, Section B and Section C of the MPI that were designed as appropriate for teachers was used.

The MPI has two parts: a test that consists of 18 mathematical word problems and a questionnaire that includes a list of possible solutions for each problem. According to participants’ responses on the test section of MPI, four different scores were generated. These were mathematical word problem solving performance, pictorial representation score, schematic representation score and visual-spatial representation score. The first score was the total number of problems solved correctly. The others were the total number of times that students reported using the specified type of representation. We used van Garderen and Montague (2003)’s coding for the classification of the representations. As shown in Figure 1, if preservice teachers “reported or drew an image of objects
or persons referred to in the problem” (van Garderen & Montague, 2003, p. 248), the representation was scored as primarily pictorial and if they “drew a diagram, showed the spatial relations between objects in a problem, or reported a spatial image of the relations expressed in the problem” (van Garderen & Montague, 2003, p. 248), the representation was scored as primarily schematic. Visual-spatial representation score was the summation of pictorial and schematic representations score.

C-2: If the elapsed time since noon (12:00) is accounted for 1 in 3 of the remaining time to midnight, what time is it now?

Figure 1: Examples for preservice teachers’ pictorial and schematic representations

According to participants’ responses on the questionnaire of the MPI, visualizing mathematical scores were generated. In this score, without taking into consideration whether the students solved the problem correctly, if the participant chose only a visual problem solving strategy for a problem, 2 points were given. For the responses that did not include a visual problem solving strategy 0 points were given. For the responses including both visual and nonvisual strategies, 1 point was given. Therefore the possible minimum and maximum scores for preservice mathematical teachers’ visualizing mathematical scores were 0 and 36 respectively. In order to group preservice teachers based on their mathematical thinking, participants’ visualizing mathematical scores were used.

The SAT involves spatial orientation and spatial visualization tests. A person’s SAT score was the summation of his or her spatial orientation test score and spatial visualization test score. A person’s spatial orientation test score was obtained from the Card Rotation Test and the Cube Comparison Test. A person’s spatial visualization test score was obtained from the Paper Folding Test and the Surface Development Test.

Results

In Table 1, descriptive statistics results of participants’ scores for mathematical word problem solving performance, use of representations, and the SAT are presented.

Table 1: Descriptive statistics results for the variables

In particular, the participants used totally 1047 visual-spatial representations, of which 925 were schematic and 122 were pictorial. Although all participants used schematic representations in their problem solving processes, pictorial representations were rarely used by preservice teachers. The
results also showed that especially for five specific problems, participants did not prefer a visual method for the solutions.

**Preservice teachers’ types of mathematical thinking**

In the literature, there were different methods suggested for the classification of analytic, harmonic and geometric thinking. For example Richardson (1977) determined the groups according to percentages as the first 15% segment of the distribution was analytic type, the last 15% segment of the distribution was geometric type, and others were harmonic type. Galindo-Morales (1994) determined the groups according to prearranged visualizing mathematical scores. Such as who had 22 points and above was a geometric thinker. In Taşova (2011)’s study, the range of visualizing mathematical scores was divided into three equal intervals. However, data from this study necessitated considerations upon the classification method. Results showed that for 5 specific problems preservice teachers did not tend to use any representations and also they did not select a visual solution in the questionnaire section. A participant with a visualizing mathematical score of 18, which is half of the maximum score, preferred a visual method in at least 9 of the remaining 13 problems. Under these circumstances, such a participant who preferred visual methods over nonvisual methods in approximately 70% of the remaining problems needed to be classified as a geometric thinker.

Due to the considerations mentioned in the previous paragraph, a new approach was adopted for the classification of types of mathematical thinking. The mean visualizing mathematical score was used while deciding on the center of the interval for the harmonic type and the intervals for all three types were found by taking the standard deviation of the scores into consideration. The minimum and maximum scores of the type of harmonic thinking were assigned by the half of the standard deviation of the preservice teachers’ visualizing mathematical score around its mean. According to this classification, the number of people grouped for each type of mathematical thinking was 34 (30%) for the analytic type, 48 (43%) for the harmonic type and 31 (27%) for the geometric type.

**Investigation of group differences**

A Kruskal-Wallis H test was run to determine whether there were any differences in mathematical word problem solving performance between three groups of preservice teachers having different types of mathematical thinking. The results revealed that the distributions of mathematical word problem solving performance scores for each group with different types of mathematical thinking were similar. The medians of mathematical word problem solving scores were not significantly different among the analytic type (mean rank = 15.5), the harmonic type (mean rank = 15), and the geometric type (mean rank = 15), $\chi^2(2) = 14.468$, $p = .24$.

In order to determine whether there were any differences in the use of schematic, pictorial, and visual-spatial representations between three groups for types of mathematical thinking a Kruskal-Wallis H test was run. The results revealed that mean ranks of schematic representation scores and visual-spatial representation scores were significantly different between the groups. As a result of post hoc analysis, it was discovered there were statistically significant differences in preservice teachers’ schematic representation scores and visual-spatial representation scores between the analytic type (mean rank = 6) and the harmonic type (mean rank = 8) ($p = .01$) and the analytic type and the geometric type (mean rank = 9) ($p = .01$). On the other hand, there were no significant
differences in schematic representation scores and visual-spatial representation scores between the geometric type and the harmonic type (p > .05). The results revealed that mean ranks of pictorial representation scores between the analytic type (mean rank = .5), the harmonic type (mean rank = 1), and the geometric type (mean rank = 1) were not significantly different, (χ²(2) = 2.281, p = .32).

One-way ANOVA test was run to investigate any differences between the SAT scores of groups of participants with different types of mathematical thinking. Shapiro-Wilk test was used to determine the normality of the distribution and the results showed participants’ SAT scores were normally distributed (p > .05). Levene's Test of Homogeneity of Variance was used to investigate the homogeneity of the variances. A homogeneity of variances was discovered (p > .05). However, the SAT scores from the three groups, the analytic type (M = 161.83, SD = 50.1), geometric type (M = 179.02, SD = 43.62) and harmonic type (M = 174.57, SD = 45.57) did not differ significantly (F (2, 97) = 1.233, p = .30).

**Discussion**

In this section, a discussion of the group differences among types of mathematical thinking according to mathematical word problem solving performance, the use of visual-spatial representations, and levels of visual-spatial abilities is presented.

**The structure of mathematical thinking adopted by preservice teachers**

The findings showed that 30% of the preservice teachers were analytic type, 43% of preservice teachers were harmonic type, and 27% of preservice teachers were geometric type. The slightly high proportion of the trend for the harmonic type was consistent with the literature. Hacıömeroğlu and Hacıömeroğlu (2013) found that most of preservice teachers adopted the harmonic type of mathematical thinking. Taşova’s findings (2011) supported that the harmonic type of thinking was the most commonly adopted by preservice teachers whereas the least percent of the preservice teachers were geometric thinkers. In the current study, these differences were not clearly seen and the classification method could be the reason for it. Hacıömeroğlu and Hacıömeroğlu (2013) found that senior preservice teachers used visual methods more than juniors. Therefore they related this difference with seniors’ experiences through teaching mathematics and practicum courses. Since participants of the current study were also seniors and the data collection was done close to end of the second term, their final year experiences may have had an impact on their preferences.

**Mathematical word problem solving performance according to types of mathematical thinking**

Results showed that there was no significant difference among groups with analytic, harmonic, and geometric types of mathematical thinking in terms of problem solving performance. While the findings were supported by some studies (Kolloffel, 2012; Suwarsono, 1982) there were some conflicts in the literature. While Lean and Clements (1981) suggested that the preference had a significant effect on performance and students who preferred nonvisual strategies outperformed visualizers, Moses (1977) claimed that visual solution methods guide college students to more effective solutions. These controversial findings in the literature might be caused by sample selection. The studies applied the same instrument with some adjustments to different groups such as elementary school students, college students, and teachers. The participants’ individual
differences like how they were taught, grade level, courses they were enrolled also could be factors influencing this relationship. In terms of performance, Presmeg (1986a, 1986b) suggested that there were internal and external factors, which could make a group superior compared to others. She discussed that textbooks and teachers’ teaching styles emphasized nonvisual methods. Therefore this situation could favor for analytic thinkers. It could be also that school exams might constrain students’ use of visual methods, which could take more time for solutions (Presmeg, 1986a). However with the educational developments the role of visualization and its importance in problem solving was recognized (Deliyianni et al., 2009). Visual approaches were included in both teacher education programs and curriculums. Therefore preservice teachers could be experienced with both visual and nonvisual approaches during their methods courses and school practices. These experiences through university life may reduce the influence of these internal or external factors on performance.

**Use of visual-spatial representations according to types of mathematical thinking**

The results showed significant differences in the use of schematic representations and visual-spatial representations among groups with different types of mathematical thinking while no difference was found in the use of pictorial representations. Preservice teachers did not tend to use pictorial representations as much as elementary or high school level students did as the previous studies suggested (van Garderen & Montegue, 2003). The frequency and the variance of preservice teachers’ pictorial representations scores were very low. The rare use of pictorial representations by participants may be one reason for not observing significant differences between the groups.

In the current study harmonic thinkers and geometric thinkers had similar preferences for use of representations in problem solving whereas analytic thinkers were separated from the others by using fewer representations. These findings were different from Sevimli and Delice’s study (2011). They found that analytic thinkers and harmonic thinkers had similar preferences for use of representations and their use of representations were significantly less frequent than geometric thinkers. There might be two reasons for the differences in these findings. One of them was the mathematical context of the studies. Sevimli and Delice (2011) carried out their study on a specific topic: definite integrals. They discussed that in calculus courses students were mainly taught nonvisual methods and algebraic expressions. The context of definite integral and how it is taught can lead the students to using algebraic solutions. On the other hand word problems that were used in this study might have promote preservice teachers to use representations in solutions.

The second reason could be that the participants did not express all problem solving procedures in their mind on the paper in the current study. For the context of working on definite integrals, although representations were not preferred by preservice teachers during the problem solving processes, when they used it might be a difficult procedure to operate representations in mind. The context requires specific graphical representations that include complex processes (Sevimli & Delice, 2011) and they could push the preservice teachers for operation on paper. However the representations that were used in solutions of word problems could be formed in mind. They did not have a complex structure as much as graphical representations that used in integral context. Further studies could be conducted for different mathematical contexts. Researchers might prefer interviews in data collection processes to detect representations that people construct in their mind.
Levels of visual-spatial abilities according to types of mathematical thinking

The findings of the current study did not show statistically significant differences in preservice teachers’ visual-spatial abilities in terms of types of mathematical thinking. Taşova (2011) suggested that geometric thinkers were more successful in visual-spatial ability tests than analytic or harmonic thinkers. However, he did not run a statistical analysis to compare the groups for types of mathematical thinking in terms of their levels of visual-spatial abilities. There are various other studies that documented no significant relationship between people’s visual-spatial abilities and their preferences for visual or nonvisual methods (Hagarty & Kozhevnikov, 1999; Moses, 1977; Lean & Clements, 1981; Suwarsono, 1982). Krutetskii (1976) suggested that there were many other factors, which affects people’s preferences like learning experiences. Therefore, further studies could investigate such factors beyond focusing only on people’s visual-spatial abilities.

Teaching mathematics with multimedia-based representations – what about teachers’ competencies?

Julia Ollesch, Fabian Grünig, Tobias Dörfler and Markus Vogel

Heidelberg, University of Education, Germany; olleschj@ph-heidelberg.de; gruenig@ph-heidelberg.de; doerfler@ph-heidelberg.de; vogel@ph-heidelberg.de;

Multimedia-based representations play a major role in mathematics and mathematics education. Consequently, they are important with regard to teaching purposes, as they are supposed to be useful to represent mathematical structures and processes in different ways. Within the presented project we developed an instrument by using video-vignettes in order to assess the competencies of mathematics teachers for multimedia use in mathematics lessons. For coping with complexity we reduced the instrument’s focus on two facets: cognitive load and mutual supplement of multimedia representations. As the work is still in progress, we here focus on the project’s theoretical background as well as on the development of the assessment instrument based on video-vignettes.

Keywords: Multimedia-based mathematical representations, technological pedagogical content knowledge, assessing teachers’ competencies, video-vignettes, secondary school mathematics.

Introduction

Since mathematical objects are conceptual and invisible, the meaning of representations plays a major role in mathematics and mathematics education. The necessity of representations for the fundamental understanding of mathematical concepts has already been postulated by Duval (2006). Therefore, it is of importance that students work with multiple representations of the mathematical content early on. Doing so they can benefit from complementary expressions and viewpoints of the subject matter and are able to improve and deepen their understanding (Ainsworth, 1999). However, as a teacher it is insufficient to simply present multiple representations to the students. It is necessary that the students build and understand the connections between different representations and gain a coherent mental model (Seufert, 2003). Schnotz and Bannert (1999) illustrate the interaction between descriptional and depictional representations in their integrated model of information processing. According to their work, these two different kinds of representations complement each other in a synergetic way to form a mental model of the represented content. With the construction of a mental model through multiple representations, students also gain in cognitive flexibility (Spiro, Coulson, Feltovich, & Anderson, 1988). According to Mayer (1997) students can also achieve better results when learning with multiple representations, however, there is practical as well as empirical evidence that this is not always the case in classroom instruction. A teacher’s knowledge about multiple mathematical representations and their kind of use in the classroom can obviously not be neglected.

In this paper we first establish the theoretical background for the use of multiple, dynamically linked representations in mathematics education and the related professional competencies required of teachers in this context. After that we describe the development of a test instrument to assess these competencies from a particular theoretical point of view.
Theoretical background

Especially multimedia can offer possibilities to develop and implement learning environments containing multiple mathematical representations. When working with multimedia-based representations, mathematics teachers should, among many other things, know the benefits and pitfalls of (dynamically) linking multiple representations while also being aware of the cognitive load generated by them. Therefore a variety of technological knowledge, skills and competencies must be combined with pedagogical knowledge and content knowledge of the subject matter.

Linking multiple mathematical representations

Computer-applets based on multimedia representations are not only suitable to illustrate both descriptional and depictorial representations (Schnotz & Bannert, 1999) at the same time, but they are also useful to establish a dynamic link between them. That way it is possible to present even more information about the mathematical content than the representations could provide without being linked to each other (Kaput, 1989). The dynamic linking and the mutual supplement of the different representations provide different approaches to the mathematical content, especially because of the automatic translation of effects when changing one representation. Providing different approaches could cause synergetic effects on the construction of coherent knowledge structures (Seufert, 2003). Moreover, the automatic translation between unrelated representations could decrease the cognitive load of the learner and leaves more capacities for the process of understanding (Ainsworth, 1999). Especially in the subject of mathematics, multimedia-based representations are appropriate to demonstrate the character of mathematical processes (Vogel, Girwidz, & Engel, 2007).

However, there are also disadvantages that come along with multimedia-based representations. As much as they can encourage a deeper understanding, they could also lead to misconceptions (Hadjidemetriou & Williams, 2002), if they are misleading with regard to their external arrangement. Likewise too many multiple dynamical representations could cause a heavy extraneous cognitive load, so that the students do not have any capacity for the intended germane load (Chandler & Sweller, 1991). If the extraneous cognitive load gets too heavy, students often tend to split their attention (split-attention-effect) and focus on one form of representation only (Brünken & Leutner, 2001). Hence reducing the extraneous cognitive load is of high importance when using multiple dynamic representations in mathematics teaching.

In his work, Mayer (2009) gives different principles that should be considered in constructing multiple dynamic representations: The coherence principle, for example, states that people learn better when irrelevant material is excluded. Particularly regarding the mutual supplement of multiple representations these principles are a good guideline for constructing effective multimedia-based mathematical learning environments.

Technological pedagogical content knowledge

Apparently, the profitable use of multimedia-based representations in mathematics lessons is not only a question of mathematics education, but concerns didactics of mathematics and psychology as an interdisciplinary field of multimedia learning. Certainly, teachers first have to decide from a mathematical point of view whether the mathematical content is adequate for the use of multimedia and which aspects of the content should be presented within this use of multimedia. In the second step it is important to implement the mathematical content into a computer-applet with regard to
available pedagogical and psychological insights of multimedia learning. The technological pedagogical content knowledge, that is needed for the profitable use of multimedia-based representations, is an “emerge of knowledge that goes beyond all three ‘core’ components (content knowledge, pedagogical knowledge and technological knowledge)” (Koehler & Mishra, 2009, p. 66) and requires extensive knowledge about all the aspects of multimedia learning. The TPACK-framework (Koehler & Mishra, 2009) extends the taxonomy of Shulman (1986) by adding technology knowledge which results in three new intersections: technological content knowledge, technological pedagogical knowledge and technological pedagogical content knowledge (TPACK).

Accordingly, the complexity of competencies needed to use multimedia-based representations in an effective way in mathematics lessons is high. Beyond their mathematical content knowledge teachers need an extensive knowledge about the media and technology they want to use as well as its chances and difficulties for multimedia learning. Consequently, teachers are confronted with new challenges (Koehler & Mishra, 2009) and need to develop the competencies to identify the chances and difficulties that go hand in hand with the use of multimedia-based representations (Spanhel, 1999). However, according to Koehler and Mishra (2009) many of the teachers do not feel prepared for the use of modern technologies to present these kinds of representations.

TPACK in context of multimedia learning in mathematics education

The internet provides many existing computer-applets which mathematics teachers could use in their lessons (for example see www.geogebra.org/materials). The question is if a chosen applet supports or prohibits the understanding of mathematical concepts and processes and how to determine its benefit. As far as we know there are no criteria given for evaluating an applet with regard to both mathematical and psychological aspects of multimedia learning. While several studies investigated the effect of multimedia-based representations on learning outcome in general, there is still little known on how to evaluate applets with interdisciplinary criteria of multimedia learning. Also it is little known about the competencies mathematics teachers need for an effective use of multimedia-based representations in their classrooms.

Hence it is the research goal of this study to develop a test instrument to assess competencies regarding the technological pedagogical content knowledge (TPACK, cf. Koehler & Mishra, 2009) and the interdisciplinary aspects of multimedia learning in mathematics education.

Assessing mathematics teachers’ competencies in using multimedia-based mathematical representations by video-vignettes

As functional and geometrical thinking build an essential base for the understanding of mathematics and elementary functions as well as geometry also play a major role in the german curriculum of secondary schools (Kultusministerkonferenz, 2012) we decided to focus on these two mathematical contents when starting to develop the intended test instrument. These contents deeply involve the understanding of their dynamic aspects (for instance while studying covariance of functions, transformations of geometric figures or whole families of functions or geometric objects), so multimedia-based representations could be an appropriate tool in teaching functional and geometrical thinking. Functional thinking includes mainly three aspects of functions: aspect of assignment, aspect of covariance and view as a whole (cf. Vollrath, 1989). Especially for handling the aspect of covariance dynamic representations are an appropriate tool, because changes in one variable and their
effects can be directly visualized in other representations. Also for acquiring geometrical thinking, multimedia-based representations can be helpful: Geometrical thinking is based on the understanding of geometrical terms and conceptions (Ulfig & Neubrand, 2013). Young children already develop an understanding for geometrical terms, but mostly ignore the similarities (Heinze, 2002). For example they are not able to understand that a square is a special representative of rectangles. With dynamic representations it is possible to illustrate not just one example of a geometrical object, but to construct a whole class of objects by using the dynamic transformation (Kittel, 2009).

On base of our theoretical considerations it is necessary to investigate also psychological aspects beyond the mathematical ones. According to an intensive literature review, we determined eight facets of psychological aspects of multimedia learning as basis for the test instrument: relation to the content (e.g. Spanhel, 1999), efficacy of the use of multimedia (e.g. Mandl, Gruber, & Renkl, 2002), limitations of the representations (e.g. Mandl et al., 2002), misconceptions (e.g. Mayer, 2009), cognitive load (e.g. Chandler & Sweller, 1991), individual promotion of the learners (Wauters, Desmet, & van den Noortgate, 2010), mutual supplement of multiple representations (e.g. Mayer, 2009) und simplifying (mathematical) content (e.g. Kittel, 2009). Within the development of the test instrument we conducted a multistage expert-rating in order to validate, but also to empirically support a selection of two of these eight facets for purposes of reducing complexity in this first approach. This process will be described more detailed later on.

**Video-vignettes and their construction**

Since video-vignettes are assumed to be an effective way of measuring teachers’ competencies (Blomberg, Stürmer, & Seidel, 2011), we developed, for the time being, a pool of 36 video-vignettes, that show various situations during mathematics lessons using multimedia-based representations. Video-vignettes are short sequences of a classroom situation that show critical problems: to evaluate these situations the observing person needs special competencies (Rehm & Bölsterli, 2014). Figure 1 shows an example of a script for a video-vignette related to the psychological facet mutual supplement of multiple representations.

The vignettes are constructed with a closed-ended question type. Multiple statements have to be rated on a scale from one to six according to its appropriateness for the presented situation. An example of statements is shown in Figure 2.

After the development of 36 vignettes, they have been validated in a multistage expert-rating.

**Validation of the constructed video-vignettes**

First the constructed vignettes were evaluated by nine experts in a semi-standardized qualitative interview. The aim of these interviews was to assure the relevance and the clarity of the presented situations in the vignettes. Afterwards the vignettes were rated by 104 experts in a quantitative interview. The aim here was to reassure the evaluation of the qualitative interviews as well as to analyze the distribution of the answers on the scale from one to six of each statement. Moreover, the experts could give comments on each of the vignettes. The answers and the comments of the experts from the quantitative rating were analyzed regarding four criteria: focus regarding the mathematical content of secondary school, distribution of the answers to the statements, relevance for school and clarity of the vignette and comments of the experts.
Figure 1: Example of a script for a video-vignette according to the psychological facet mutual supplement of multiple representations

Based on the multi-stage expert rating and psychometric properties of the instrument we chose the most appropriate vignettes and determined the two psychological facets of multimedia learning cognitive load and mutual supplement of multimedia representations as the focus for the final test instrument. Cognitive load refers to the trichotomy from Chandler and Sweller (1991): intrinsic cognitive load, extraneous cognitive load and germane cognitive load (cf. section theoretical background). So the aim is to explore if prospective teachers can estimate the cognitive load. The mutual supplement of multimedia representations refers to the interaction between two or more forms of representations of the same issue (cf. section theoretical background; Ainsworth, 1999; Kaput, 1989). Using these interactions between different forms of representations could involve many chances, but also risks. For example, it is important to link the different representations to gain an understanding of coherence (Seufert, 2003). However, as mentioned above different forms of representations could also cause the split-attention-effect (Brünken & Leutner, 2001).
Assessment

After the reduction of the vignettes as well as the reduction of the psychological facets, we revised and adapted five vignettes for each of the psychological facets as well as six to seven items for each vignette. The formulation of the items was parallelized between the vignettes in order to assure that the important aspects of each of the psychological facets are tested.

These ten vignettes were again validated in a pilot study and as the results were promising, they were used in the final assessment. In this assessment we also included covariates to prove the discriminant validity of the test instrument: pedagogical knowledge and content knowledge. Preliminary results with 261 prospective teachers in Baden-Württemberg already show evidence for the discriminant validity of the test instrument: As expected from the TPACK-framework (Koehler & Mishra, 2009) the test score of the developed vignettes shows a weak correlation with the two constructs pedagogical knowledge \( (r = .17, p = .01) \) and content knowledge \( (r = .29, p < .001) \). Furthermore we could prove expected correlations with the educational progress of the prospective teachers \( (r = .14, p = .03) \) as well as the number of attended courses addressing the use of computers in mathematics lessons \( (r = .17, p = .03) \).

Discussion and outlook

The research goal was to develop a test instrument in order to assess the competencies mathematics secondary teachers need for an effective use of multimedia-based representations in mathematics lessons. Therefore, we considered both mathematical and psychological aspects of multimedia learning and developed a test instrument for the mathematical contents of functions and geometry as well as for the psychological facets cognitive load and mutual supplement of multiple representations. With the conducted multistage expert-rating and the preliminary results of the assessment we could confirm the validity of the test instrument.

At the moment, we conduct an assessment with the final test instrument in order to research the development of the previously described competencies during the practical phase of the studies of prospective teachers. Moreover, the test instrument will be complemented with further mathematical content: algebra and stochastics. At the current stage of the project, new vignettes are developed for these two subjects which will supplement the current test instrument. The new test instrument will
then be able to test a wide range of mathematical content knowledge combined with knowledge about the psychological aspects of multimedia learning.

Children’s drawings for word problems – design of a theory and an analysis tool

Barbara Ott
University of Education, St. Gallen, Switzerland; barbara.ott@phsg.ch

Representations are essential for mathematical understanding. In particular, graphic representations are taught as tools for solving word problems. However, not only do children often have difficulties in using them, but there is also a complete absence of research into whether or not children’s own graphic productions actually represent the key mathematical elements of word problems. My project, therefore, focuses on this gap by developing a theoretical model and an analysis tool to categorise and map the drawings. This is based on primary school children’s drawings, which have been identified as graphic representations of word problems.

Keywords: Graphic representations, visualisation, word problems, analysis tool, elementary school students.

Introduction
For doing mathematics, the use of external representations is essential. Without them it is virtually impossible to discuss or gain insight into mathematical problems (Dörfler, 2008; Hoffmann, 2005). In external representations mathematical patterns may be apparent and can be analysed. They are also important in the mathematical learning process. Bruner (1966) explains the power of external representations for learning “as its capacity, in the hands of a learner, to connect matters that, on the surface, seem quite separate” (p. 48). Accordingly, representation is quoted as a process standard in several standards and curricula (e.g. NCTM, 2000).

Within a range of external representations, graphic representations allow certain aspects of space to be mapped onto specific elements of content (Stern, Aprea & Ebner, 2003). They can be defined as a “data structure in which information is indexed by two-dimensional location” (Larkin & Simon, 1987, p. 68). Every element of a graphic representation contains information not only to do with its own location, but also nearby elements. Graphic representations, therefore, constitute a key tool for problem solving (Polya, 1967).

Nevertheless, it is often reported that children have difficulties in using graphic representations as a tool for problem solving (Fagnant & Vlassis, 2013; van Essen & Hamaker, 1990). In some studies, it is shown that the use of graphic representations can be trained (e.g. Fagnant & Vlassis, 2013; Diezmann, 2002). However, there is a lack of research into the actual extent to which children’s individual drawings represent key mathematical aspects of a given word problem. This study (Ott, 2016) aims to make a contribution to this gap.

Research interest
This research focuses on self-generated children’s drawings for word problems. It addresses the main question as to what extent these drawings represent the mathematical structure of the word problem. More specifically, two research questions are defined:

1) Which features are key in drawings for word problems?
2) How do they manifest themselves in children’s drawings for word problems?
Finally, the study aims to design an analysis tool for children’s word problem drawings, based on theory and split into various categories.

**Methods**

**Data collection**

A paper and pencil test was given to two first grade and two second grade classes in two German primary schools. 42 first graders and 35 second graders participated in the test. The average age of the first graders was 6 years and 4 months, whilst the average age of the second graders was 7 years. By pure chance, there were 35 girls and 42 boys.

The test was conducted at the end of the school year’s first half. At that time, the first and second graders could solve addition and subtraction tasks in the number ranges up to 20 and 100 respectively. The first graders had experience in drawings for equations and finding equations to match drawings. Students of one second grade class (N=19) had additional experience in drawing sketches for word problems.

![Children's drawings for the tower-item (Ott, 2016)](image)

The test consisted of six word problems based on schoolbook tasks. The level of difficulty differed, in accordance with how much the verbal texts implicitly suggested objects and hence ways of drawing (Ott, 2015, 2016). Testing took place on two successive days, three test items a day. The instructor read the items out aloud to the students, who were then requested to draw their thoughts on a plain sheet of paper, so as to be understood afterwards by the instructor. Figure 1 shows six examples of children’s drawings for the following word problem: *Once upon a time there was a king who wanted to have a tower of 11 meters in height. The tower was built over the course of several years. Every year, the workers built 2 meters. How long did it take for the tower to be built?*
Analysis

The children’s 438 individual depictions from the test have been used both to develop a theory of drawings for word problems and also an analysis tool, based on various categories. To this end, the drawings have been analysed via a combination of qualitative content analysis (Mayring, 2010) and theoretical coding (Strauss & Corbin, 1996). Developing a theory and the design of an analysis tool took place simultaneously in an iterative process according to representation theories.

Results

The analysis of the children’s drawings revealed as key either for a draft of a theory or an analysis tool the following three features: The mathematical structure, the mathematical matching and the degree of abstraction. In analysing the drawings, it is important to differentiate between these features, details of which are presented below.

Mathematical structure

Theory

A mathematical structure may be defined by set theory: An amorphous set is structured by defining relations and operations between its elements (Rinkens, 1973). This definition is used to identify both the mathematical structure of word problems and also of graphic representations.

Word problems are verbal descriptions of situations with a focus on mathematical relations (Veschedel, Greer & de Corte, 2000). They can be characterised as “descriptional” (Schnotz, 2014, p. 47) representations. Information is presented sequentially with the quantities and nouns being related to each other by verbs and prepositions. Thus, structural information is integrated into the text and the word problem is thus given a mathematical structure. Accordingly, the verbs and prepositions serve as relational symbols (Schnotz, 2014, p. 47), without which the quantities and nouns would be unrelated – this applies equally to the elements of an amorphous set. Because of the verbal construction with verbs and prepositions as relational symbols, a relationship between the quantities will be defined. Consequently, a structure is given to the quantities and nouns. In the word problem presented here, the quantities and nouns “tower”, “11 meters”, “year(s)” and “2 meters” are related by the verbs and prepositions “of”, “built” and the adverbial phrase “every year”.

For a sound graphic representation, it is necessary to identify key objects in the text, e.g. quantities, objects or people mentioned, that are relevant and necessary for the mathematical structure. To achieve this, structurally relevant objects signs (Peirce, 1965) need to be invented, which can be regarded not only as physically analogous to the objects but also symbolic. Graphic representations can be characterised as “depictional” (Schnotz, 2014, p. 47). Compared with word problems, graphic representations do not include relational symbols. Indeed, a structure is given to the signs for structurally relevant objects by mapping them to certain aspects of space. To this end, the signs for structurally relevant objects have to be set out on the sheet in such a way that the arrangement represents the word problem’s verbally described relationships. Such graphic representations have the character of diagrams (Dörfler, 2006). For instance, in Simon’s graphic representation (Figure 1) the signs for structurally relevant objects “1J”, “1 Halbes”, “2”, “1” and the rectangles are arranged in vertical columns side by side.

Analysis tool
Six categories of how the mathematical structure appears in children’s drawings for word problems are identified: A representation is

- **non-graphic** if it consists only of calculations or texts;
- **off the text** if it possesses graphic elements, but there is no link to the text with regard to the content;
- **illustrative** if it possesses graphic elements with a link to the text but no structurally relevant objects are represented;
- **object-related** if it possesses graphic elements with a link to the text and structurally relevant objects are represented although relations between them are not identifiable in the arrangement;
- **implicitly diagrammatic** if it possesses graphic elements with a link to the text, structurally relevant objects are represented and relations between them are identifiable in the arrangement; the relations are not explicitly emphasised;
- **explicitly diagrammatic** if it possesses graphic elements with a link to the text, structurally relevant objects are represented and relations between them are identifiable in the arrangement; the relations are explicitly emphasised.

![Figure 2: Analysis tool for the mathematical structure](image)

In contrast to text analysis, such as the qualitative content analysis (Mayring 2010), it is impossible to analyse units step by step in a drawing. The analysis tool introduced here, therefore, arranges the categories in a decision tree guided by key questions, which lead to category definitions. The categorisation of a child’s drawing takes place step by step in a strictly dichotomous procedure. Only if a question has to be answered with ‘no’, will the drawing be classified into the associated category. As long as questions can be answered with ‘yes’, the categorisation process is not yet finished. This way, each of the children’s drawings can be clearly categorised. In Figure 2 we can see the decision tree.

We will now categorise the children’s drawings shown in Figure 1. Dana’s solution is an example of a **non-graphic** representation. It consists of text and a calculation but no graphic elements. Ole’s
drawing is an example of a representation that is off the text. A stick figure with a speech bubble is drawn, which contains the answer. The drawing contains no link to the problem’s content. In contrast, Rike’s graphic representation with a castle and hearts contains a link to the text, because a tower as part of a castle is drawn. Gabi’s representation of a tower also comprises graphic elements with a link to the text. The tower is subdivided into 11 rectangles, which could represent the 11 meters that are structurally relevant objects. Relations are not identifiable in this representation and hence it is an example of an object-related representation. Nadine and Simon’s representations are both graphic with links to the text and structurally relevant objects, e.g. the tower. Nadine’s representation is a sequence of pictures. In each picture, one can see the height of the tower in a given year. Thus, the relations between the meters and the years are identifiable and the representation is, therefore, diagrammatic. The relation is not explicitly emphasised and the representation is, therefore, an example of an implicitly diagrammatic representation. In Simon’s drawing, the height of every tower section is shown in one tower only. Next to every section of the tower, one can find the years necessary for the work to be completed. Thus, the relation between meters and years is not only apparent but also emphasised and it is, therefore, an example of an explicitly diagrammatic representation.

Mathematical matching

Theory

In a representational system (Palmer, 1978) the correspondences between the represented and the representing “world” (p. 262) are important. In regard to the mathematical structure, this idea is used to define how a word problem is matched with a graphic representation. If there is a match, they are “informationally equivalent” (Palmer, 1978, p. 270).

We call a relation of text and drawing a mathematical matching if the word problem and the graphic representation are informationally equivalent on both object and relational levels. Accordingly, if there is a match between the quantities and nouns on the text side and the signs for the structurally relevant objects on the graphic side (object level), and if there is a match between the verbs and prepositions on the text side and the arrangement of the signs for the structurally relevant objects on the graphic side (relational level), then there exists a complete matching between the word problem and the graphic representation.

Analysis tool

The matching between word problems and graphic representations is analysed with regard to the mathematical structure. Only object-related, implicitly or explicitly diagrammatic representations are, therefore, analysed (see above). Representations of the other categories do not contain elements of a mathematical structure and accordingly there is no matching between them and the word problem.

For analysing the match between the quantities and signs for structurally relevant objects, it is useful to distinguish between the measured value and the measuring unit. Numbers can also be considered as discrete quantities (Müller & Wittmann, 1984). For analysing the match between verbs and prepositions and the arrangement of signs for structurally relevant objects, we have to consider the operations of the word problems.
The variation of match between graphic representations and word problems with regard to the measured value, the measuring unit and the operations can be scaled (Mayring, 2010). The match can be complete, partial or non-existent. If it is non-existent, the quantities or operations graphically represented are other than those given in the word problem, e.g. an addition instead of a multiplication. It is also possible, that the quantities and operations are not apparent in the graphic representation. They are without compliance. In the analysis tool the possibilities are arranged in a 3x4 matrix, where each matching can be marked with a cross. Arithmetically, 64 combinations are possible (see Figure 3a).

In Simon’s representation (see Figure 1), measured values (11 and 2) are apparent as well as measuring units (meters and years) and the operations (addition of meters and years, meters per year). In Nadine’s drawing each measured value and operation are also apparent. With regard to the measuring units, only meters are identifiable. In Gabi’s representation the operations are without compliance. With regard to the measured values, only the 11 is apparent. So far as measuring units are concerned, only the meters are identifiable in the squares.

<table>
<thead>

</tr>
</tbody>
</table>

In the analysis tool the possibilities are arranged in a 3x4 matrix, where each matching can be marked with a cross. Arithmetically, 64 combinations are possible (see Figure 3a).

Figure 3: Analysis tool for the a) mathematical matching, b) degree of abstraction

Degree of abstraction

Theory

Children’s drawings for word problems are realistic to a greater or lesser extent. For analysing this, the idea of abstraction is used, which can be defined as a focusing of attention on certain aspects (Peschek, 1988). This idea is used to define the degree of abstraction.

We characterise the degree of abstraction in a graphic representation as being the degree of focusing on representation of the word problem’s mathematical aspects (Ott, 2015). The foundations for the mathematical structure of a graphic representation are the structurally relevant objects (see above), that are important in defining the degree of abstraction, for which two indicators are identified:

1) Focus on the structurally relevant objects in the graphic representation - no objects other than the structurally relevant objects are drawn.

2) Focus on the mathematically relevant qualities of the structurally relevant objects - the signs for structurally relevant objects are not decorated and represent only the mathematically relevant qualities.
Analysis tool

Given that the degree of abstraction becomes apparent when focusing on the structurally relevant objects and their mathematically relevant qualities, only object-related, implicitly or explicitly diagrammatic representations are analysed (see above). Representations of the other categories do not contain structurally relevant objects and they are in themselves, therefore, not abstract.

Both of the indicators for the degree of abstraction can be pronounced ‘low’ or ‘high’. Consequentially, it is possible to distinguish four categories for the degree of abstraction: High-high or low-low if each indicator is identified as high or low respectively, and high-low or low-high if one indicator is identified as low and the other as high. In the analysis tool the possibilities are arranged in a 2x2 matrix (Figure 3b). Both indicators have to be regarded separately in analysing a child’s drawing, which is then classified in the category that fits both results.

In Simon’s representation (Figure 1) the focus on both structurally relevant objects and their mathematically relevant qualities are high, contrary to Nadine’s representation. Here, signs for other objects are drawn such as people and the tower decorated with battlements as a structurally relevant object. In Gabi’s representation, the focus on the structurally relevant objects is high, because only the floors of the tower are drawn, which are decorated with colour and squares.

Conclusion

This study has focused on the main question of the extent to which children’s drawings for word problems represent the actual mathematical structure. For this purpose, the mathematical structure, the mathematical matching and the degree of abstraction have been identified as substantial features of such graphic representations. Children’s drawings for word problems vary greatly in the way they are depicted. In the analysis tool, the extent of the substantial features’ occurrence in children’s drawings has been modelled, so that each drawing can be clearly categorised. The analysis tool has been tested with an inter-rater reliability of $K=0.81$. It could, therefore, be applied in further research. In the second part of the research presented here it has been used in an intervention study looking at graphic representations of word problems (Ott, 2016).

How the representations take on a key role in an inclusive educational sequence concerning fraction

Elisabetta Robotti

Università degli Studi di Torino, Dipartimento di Filosofia e Scienze dell’Educazione, Italy;
elisabetta.robotti@unito.it

The design analysis of an inclusive educational sequence concerning the teaching and learning of fractions (Robotti, et al., 2015) is the focus of this work. Referring to the principles of Universal Design for Learning, developed by the Centre for Applied Special Technology to reduce barriers in learning, we analyse the design of the educational sequence focussing on fractions and devoted to classes where students with certifications of mathematical learning disabilities (MLD) were present. From the point of view of mathematics education, we refer to the theory of semiotic mediation (Bartolini-Bussi, Mariotti, 1998) in order to clarify the cognitive role of artefacts taken into account in class activities. In particular, the use of artefacts to solve tasks produces representations that contribute to develop of mathematical meanings aimed in the teaching activity.

Keywords: Mathematical learning disabilities, Universal Design for Learning, fraction, number line, artefact.

Introduction and conceptual framework

The focus of this paper is the analysis of an inclusive educational sequence concerning the teaching and learning of fractions already described in detail in CERME9 (Robotti, et al., 2015). In the paper presented in CERME9 we discussed how, in the context of Semiotic Mediation (Bartolini, Mariotti, 2008), the choice of particular artifacts and the design of tasks related to their use, allowed students to grasp different meanings of fraction. Now, I would like to discuss why that educational sequence was "inclusive" for learners with certifications of mathematical learning disabilities (MLD) or difficulties in math or with low achievement in math. To this aim, I will refer to the theoretical framework of Universal Design for Learning (UDL) and I will analyse how the design of the activities follows the guidelines and principles of UDL in order to reduce barriers in learning. Therefore, the rationale for referring both theoretical frameworks is to consider learning difficulties in a context of math education: if the Semiotic Mediation framework allowed us to design a structured educational sequence for teaching and learning different of meanings of fraction (for this, see CERME9 proceedings), the UDL framework, allowed us to design and analyse those tasks in order to be inclusive for MLD students, students with difficulties or with low achievements. Even if there isn't consensus on definition and identification of MLD students (Karagiannakis, et al., 2014) and the inclusivity (Ianes, 2006) is not a construct used consistently across different fields (education, society...) or in different countries, in this research work, we considered as "inclusive educational activities" the educational activities, developed in the context of the class, which face to the special needs of MLD students including dyscalculic students, students with difficulties in math and students with low achievement in math. In other words, according to the UDL framework, we consider “inclusive educational activities” those that meet the needs of all students of the class. UDL is based on a set of principles and guidelines that have been elaborated to increase access to curriculum for all the students, including those with disabilities. These principles and guidelines have a general valence and they are devoted to various application contexts. In this paper we refer to the context of math
education. At the core of UDL is the belief that there are three networks in our brain that support learning: (i) The Knowledge/Recognition Networks, which are involved in identifying and interpreting sound, light, taste, smell, and touch. They are essential to learning because students are expected to comprehend a text, interpret formulas, identify cause/effect relationships, etc. UDL states that it is possible to support the knowledge/recognition networks providing Multiple Means of Representation (1° principle) to give learners various ways of acquiring information and knowledge. This principle has three supporting guidelines: provide options for Perception; provide options for Language, Mathematical expression, and symbols; provide options for Comprehension; (ii) The Strategic Networks, which are involved in planning, executing, and monitoring actions and skills. In learning, they occur, for example, to solve a problem, use an artefact, take notes and listen to a lecture. UDL states that it is possible to support the Strategic networks providing Multiple Means of Action and Expression (2° principle) to give learners alternatives for demonstrating what they know. This principle has three supporting guidelines: provide options for Physical action; provide options for Expressive skills and fluency; provide options for Executive function; (iii) The Affective Networks, which are responsible for establishing priorities and interests. UDL states that it is possible to support the Affective networks providing Multiple Means of Engagements (3° principle) to stimulate interest and motivation for learning. This principle has three supporting guidelines: provide options for Physical action Recruiting interest; provide options for Physical action Sustaining effort and persistence; provide options for Physical action Self-regulation. According to UDL frameworks, representations seem to be “the ways [to] perceive and comprehend information”, produced by visual or auditory means, or contained in a printed text. Therefore, UDL considers representations as signs of different nature (visual, auditory, kinaesthetic…) produced by different means (or artefacts). In the Theory of Semiotic Mediation, Bartolini and Martiotti state that: “[…] any representation comes to life because of a human construction that makes it possible, in other words any representation is supported by an artefact” (Bartolini, Mariotti, 2008, p. 747). Even if the difficulty in articulating an accurate definition for the term “representation” is recognized in math education, we want to stress that, in his theoretical framework Duval states the importance of connections both within and amongst different representational registers as absolutely fundamental to deep understanding of mathematics (Duval, 1999). According to this, Arcavi (2003) stresses the essential role of visual representations in the learning of mathematics and he defines “visualization, as both the product and the process of creation, interpretation and reflection upon pictures and images, …” (Arcavi, 2003, p. 215). Visualization, visual representations and more general representations were taken into account in our analysis presented in CERME 9 discussion. As described in that analysis, the teaching of the notion of fraction is a quite delicate issue, which requires insightful ways of structuring didactical activities. In that occasion, we stressed how the importance of spatial processes, performed on the base of spatial skills, can be important in mathematical performances where explicit or implicit visualization is required, as in the case of learning of fractions. Therefore, the visual non-verbal, the kinaesthetic-tactile and the auditory channels were considered as preferential for designing inclusive educational activities concerning fractions. Finally, Goldin (1992) outlined a unified model for the psychology of mathematics learning, which incorporated cognitive and affective attributes of visualization as essential components in systems of representation in mathematical problem solving processes. From the above considerations, we can observe that, even in the domain of math education, the aspects related to multiple means of representations and their relations, multiple means of action and
expression and multiple means of engagement are taken into account. For this reason, we use the three principles of UDL to analyse the design of an educational sequence about fractions whose purpose was to be inclusive (in the UDL sense), that is to say, to meet the needs of all learners of the classes, even MLD students. Moreover, we will adopt the framework of Semiotic Mediation to analyse the role of the artefacts in the educational sequence in order to reach the aimed educational goals. More in detail, we will show how the design of the different tasks, requiring actions on artefacts, can be interpreted through the three principles of the UDL to analyse the efficacy both of construction of meanings for the notion of fraction and of inclusion for MLD students.

An example of inclusive educational sequence

I will briefly recall the main activities characterising the educational sequence concerning fractions, described in details in TWG13 of CERME 9 (Robotti & al., 2015), which was carried out in 22 classes (nine 5th grade classes, six 4th grade classes, and seven 3rd grade classes) involving around 400 students, of which 20 were certified MLD students (Robotti & al., 2016): (1) Partitioning of the A4 sheet of paper (named “placemat”). (2) Partitioning of a strip of squared paper: given a certain unit of measure (number of squares) on the strip, position a fraction on that strip (1/2 or 1/3 or 1/4, ….); given different units of measure on different strips, on each strip a same fraction is represented (1/2); chosen an appropriate unit of measure on the strip, different fractions are represented on that strip (e.g., 1/3 and 1/5). (3) Placing fractions on the number line. (4) Placing coloured tags, labelled with fractions, on a “string on the wall”.

The learning difficulties concerning fractions seem to be due, among other things, to the lack of connection between different meanings of fraction (Charalambous, Pitta-Pantazi, 2005) and to the fact that only some of them are fostered (e.g. the meaning of "part/whole"), (Pantziara, Philippou, 2011). Moreover, some visual representations are favoured (such that of the pizza) even if they could hinder the learning of the different meanings of fraction (Fandiño Pinilla, 2007). The main learning difficulties identified in Italian national assessment (INVALSI tests) are related to: managing the meaning of the “equal” sign (for instance, What does it means obtaining “equal parts” of the whole?); switching from a fraction to the unit that has generated it; managing equivalent fractions; ordering fractions on a straight-line even without transform them to decimal numbers. In the following, I will discuss how principles and guidelines of UDL can be effectively used to analyse the design of the tasks, which allow overcoming these difficulties. The analysis of actions required by tasks on the artefacts, will show how the educational aims and the aims of inclusion were achieved.

The artefact “placemat”

The “placemat” is a A4 sheet of paper that, at the beginning of the sequence will be in white colour but that, in the following, will be coloured. The mathematical meanings to be mediated by the “placemat” are: 1) construction of fractional units starting from a given unit of measure (the A4 sheet of paper) by folding and cutting out the A4 sheet of paper; 2) equivalence between fractional units, by folding or cutting the fractional units in order to show the equivalence between the surfaces. This allows to overcome the difficulty related to the interpretation of “equal parts of the whole” as “congruent fractional units” instead of “equivalent fractional units” (see above); 3) sum of fractional units in order to obtain the given unit of measure (in this case, the A4 sheet of paper). This can be realized covering the A4 sheet with different fractional units. This allows to come back to the unit of
measure starting from the fractional units. According to Guideline 1 of first Principle of UDL, learning is difficult if information is imperceptible to the learner, or when information is presented in formats that require extra effort for him/her (for example, decoding the text “one half” or decoding arithmetical expressions “1/2” for a dyslexic student). To reduce barriers to learning, it is important to ensure that key information are equally perceptible to all learners. For this reason we provided the same information through different modalities (e.g., through the possibility of touching and manipulating the pieces of A4 sheet, through vision of their drawing on the notebook, through hearing or reading an arithmetical expression). In other words, through different forms of representation (Guideline 2, Principle 1). Moreover, the colour, which characterises fractional units later on, plays the role of support to long-term memory for students with learning disabilities or simply students with math impairment. Once the information are made accessible, our educational sequence aims to help students transform them into usable knowledge. As pointed out by the Guideline 3 of the first Principle of UDL, this depends upon “information processing skills” like: selecting useful information, integrating new information with prior knowledge, strategic categorization and active memorization. Individuals differ greatly in their skills in information processing, but effective design of task and presentation of information in accessible ways can provide the scaffolds necessary to ensure that all learners are able to process information. Therefore, we designed educational activities in which students have to act on the artefact, in order to produce representations (for instance, by cutting or folding different pieces of paper referring to the same fractional unit in order to show the equivalence of their surfaces or choosing appropriate fractional units to cover the A4 sheet in order to show that the sum of appropriate fractional units gives the unit of measure 1), and they have to put the obtained representations into relation. Indeed, the actions, performed by students on the artefacts, produce situated signs (representations) through which students, with the help of teacher’s mediation, construct the mathematical meanings aimed for (in that case, equivalent fractions or $2/8+3/4=1$). In order to help students remember the mathematical meanings described, the teacher asks students to: reproduce on the note-book the operations performed with the artefact; write down the content of the class discussions; write texts in which the processes developed in the activity are explicitly linked to knowledge. This allows recalling and using knowledge in the future and it provides options for expression and communication. As a matter of fact, it is well known that there is no medium of expression that is equally suited for all learners and for all kinds of communication. This means that, according to the second Principle of UDL, students with learning disabilities may excel, for example, in interpretation of drawing data (e.g., the drawing of “placemat” covered by different coloured fractional units), but they may falter when asked to read data provided in a table or in arithmetical expression (e.g. $1=2/8+3/4$).

The artefact “strip of squared paper”

The strip of squared paper is a strip with squares of 1 cm, 10 cm high and approximately 1 m long. In the strip there are some integer numbers (0, 1, 2, 3, …) and fractions are constructed. The mathematical meanings mediated by the “strip of squared paper” are: 1) Fraction as operator on a given unit of measure: once a unit of measure is considered, the teacher asks students to place on the strip a given fractional unit and then a given fraction (equal o more than 1); Comparison, by means of a perceptive strategy, of fractional units that should be positioned on different strips of paper; 3) Relationship between a fractional unit and a chosen unit of measure: considering different units of measure on different strips, the teacher asks to place the same fractional unit (for instance, $\frac{1}{2}$) on all
the strips; 4) Ordering fractional units: considering on a strip an appropriate unit of measure (given by the l.m.d. of the denominators), the teacher asks to place different fractional units. This allows students to compare them in a concrete way; 5) Equivalence between fractions: considering on a strip a given unit of measure, the teacher asks to place different fractions. Among them there are some equivalent fractions. We note that some mathematical meanings concerning fraction, such as equivalent fractions or comparison of fractions, are already presented in previous activities with the artefact “placemat”. Once again, the first principle of the UDL is used in this educational sequence providing different means of representation (that is, different artefacts through which representations can be performed). In this activity, the students produce different representations: linguistic signs associated to the name of the fraction expressed in verbal language (“One half”), in verbal visual language (the writing “One half”) and arithmetical language (“1/2”). The teacher institutionalizes the relationship between the different signs in terms of rational numbers. Thus, the construction of meaning related to the notion of rational number, is based on both the interplay between different types of semiotic representations, according to the first principle of UDL, and by different actions on artefacts producing those representations, according to the second principle of UDL. Moreover, we note that the colour, perceptive option already provided in the A4 sheet of paper, is used with the same aim also in the activities with strip of squared paper. Therefore, the fractional units constructed on the strip are coloured with the same colour of the respective fractional units constructed by A4 sheet of paper. Therefore, the colour assumes the role of a support for memory and also of an artefact, which allows students to link the meaning of fractional unit constructed with the “placemat” (fraction as a part of a whole) with the meaning of fractional unit constructed by the strip of paper (fraction as operator). Moreover, we have taken into account different strips where different units of measure have been considered and where have been represented a given fractional units. The strips are put one beside the other (proving option for physical actions, as called for by the second principle of UDL) and the relationship between unit of measure and fractional units becomes perceptively evident, reifying Guideline 1 (provide options for perception) of the first principle of the UDL. In order to link the meaning of fraction as part of a whole and as an operator to the meaning of rational number on a number line, we need to switch from the artefact “strip of squared paper” to the artefact “number line”. For this reason, the teacher asks the students to represent, on the same strip different fractional units: 1/8, 1/6, ¼, 1/3 and ½. Thus,, in order to represent all fractional units on the same strip, students need to find a suitable graphic strategy that maintains the colour without superposing different colours on the strip. They adopt coloured notches. Positioning on single strip different fractions makes the ordering of fractions exactly like that of the other perceptively evident numbers. Here the semiotic potential of the artefact “strip of squared paper” associated to the tasks proposed by the teacher becomes evident, playing a key role in fostering identification of fractions as rational number on the number line. I will show this in the following session.

The artefact “number line”

The number line is drawn by students on their note-book. It is a number line of positive numbers starting from the point 0 and it is presented as the natural "crushing" of the paper strip. Therefore, on the number line, students place fractions without transforming them into decimal numbers. The mathematical meanings supported by the “number line” and the tasks proposed are similar to those proposed in activities with the artefact "paper strip". This allows all students to find continuity both between the artifacts proposed and the construction of the aimed for mathematical meanings.
The artefact “string” on the wall

The artefact "string on the wall" consists of a string in nylon whose ends are fixed to two adjacent walls of the class (such as a wire for drying clothes). On it, students hang some tags labelled with fractions (in this case, tags are coloured accordingly with the colour used in previous activities) or natural numbers (in this case tags are white). The string simulates the number line starting from zero, which is placed at the left end and the position of the unit is made to vary dynamically sliding the corresponding labelled tag attached with a clothes’ peg. In this case, however, the positions of the other tags do not vary dynamically at the same time or automatically as a consequence of the new placement of the unit: their motion requires a specific action in order for the numbers on the line to maintain the desired mathematical relationships. Tags are made so that they can be hung in "clusters" to ensure that tags corresponding to equivalent fractions have the same position on the string. The mathematical meanings supported by the “string” are: 1) Ordering of fractional units or fractions: once the unit of measure has been defined, by positioning the tag labelled with "1", the tags labelled with fractions need to be hung in the correct position; 2) Equivalent fractions: since their tags correspond to the same position on the string, they are hanging as "clusters" and they represent classes of equivalence. Students named them "caterpillars" whose first tag (corresponding to the irreducible fraction) was called "head of the class"; 3) Density of the numerical set Q: "enlarging" the unit of measure, that is to say increasing the distance between the tag corresponding to 0 and that corresponding to 1, it is possible to hang on the strip more and more fractions. This operation, repeated many times, allows constructing a mental image connected to the idea of infinity. We note that, when tags on the strip become numerous, one needs to "enlarge" their position to make room for other tags. This action on the string is a situated sign used by the teacher to introduce the idea of density in the set Q. Therefore, the representations of fraction on the string (tags labelled with fractions), their position on the string and the action performed on the tags are in line with the first principle of the UDL according to which different forms of representation are needed in order to capture information and transform them into knowledge. The colour of tags, the position of tags on the string, the dynamic position of tag labelled with “1” on the string, recall actions and representations performed in previously activities. Once again, this allows linking different representations and actions to the same mathematical meaning, by supporting long-term memory. According to the principles of the UDL, this contributes to making mathematical meanings accessible to the students.

Discussion and concluding remarks

The first principle of UDL (Providing Multiple Means of Representation) and the related guidelines provide useful references in order to choose artefacts and define tasks which allow overcoming obstacles and difficulties in understanding some of the different meanings of fractions (part of a whole, measure and operator). In order to provide different means of representation, we considered different artefacts: the “placemat”, the strip of squared paper, the drawing number line and the “string” on the wall for “hanging out” fractions. Each of them allows students to produce different semiotic representations: pieces of paper as fractional units, coloured sections of the strip as fractions or fractional units, points on the number line, coloured tags labelled with fraction hanging on the string. We note that these representations are of different nature: physical, visual or symbolic. Thus, following the Semiotic Mediation Theory, each artefact allows students to produce situated signs (for example, the sign “enlarge” the tags’ position on the string), which will be interpreted as mathematical
signs by the teacher’s mediation (in the case above, the sign is used by the teacher to introduce the idea of density in the set Q). The aim is to single out mathematical aspects relevant to the activity and make them accessible to all students through representations; this should allow them to use those mathematical aspects in future. To reach this aim, the design of educational activity (presentation of information, choice of the artefact on which students can act, task design in large sense…) is essential to ensure that all learners have access to knowledge. We note that in our educational sequence about fractions, learners construct mathematical meanings (for instance, the meaning of equivalent fractions) acting on different artefacts (A4 sheet, strip of paper, number line and “strip on the wall”) and different representations carried out by those artefacts (fractional units of paper, coloured part of the strip, point on the line and coloured tags composing a "caterpillar"). According to the first principle of the UDL, we state that this is not yet sufficient to ensure the construction of the mathematical meaning, that is to say of usable knowledge (for example, the meaning of equivalent fractions). It is necessary that these different representations be put in relation with each other (for example, two equivalent fractions correspond to the same point on the number line or on the “strip” on the wall because they have the same surface extension as a sheet of A4 paper). Moreover, it is necessary that they be always available to learners during the whole teaching sequence. Thus, according to the second principle of the UDL (Providing Multiple Means of Action and Expression), the action performed by students on different artefacts allows to put into relation different representations associated to the same notion (such as, equivalent fraction) or associated to different meaning of fraction (such as “a part of the whole”, in the case of placemat, or “fraction as operator”, in the case of strip of paper). The third principle of the UDL (Providing multiple means for engagement) supports the engagement of students in the arithmetic activity concerning fractions. It suggests options to challenge all students, appropriately. Designing activity where a “real” situation requiring a solution was the starting point. As a matter of fact, acquiring new information must be received by the student as a necessity to deal with the challenge posed by the activity. Thus, since the narrative aspect is very important in primary school teaching, the work with the “placemat” started with a letter, sent by a pizzaiolo (pizza chef), where he asks students to realize coloured placemats for his restaurant. The need to make placemats according to the pizzaiolo’s requests was, for primary school children, a stimulus to take in information and to process them in order to get new knowledge useful for the activity's aim. To create conditions for the students’ self regulation and self assessment in the activity we asked students to work in pairs or in small groups and to compare, by the class discussion, the results of work with the other groups.

Using manipulatives in upper secondary math education
– a semiotic analysis

Marit Hvalsøe Schou
Laboratory for Coherent Education and Learning, University of Southern Denmark;
maritschou@imada.sdu.dk

The use of manipulatives in upper secondary education is not common, although they hold learning potential in contributing to students’ conceptualizing and establishing of relations. In this case study it is investigated how the concept of recursive sequences as a description of growth can be seen in the written reflections from students having engaged in activities with manipulatives like matches and LEGO® and with only minor teacher interference. The analysis of students’ answers is carried out by a combination of Radford’s Theory of Objectification and Peirce’s Theory of Signs. By interpreting the type of signs, the kind of arguing and the nature of the words used by students in various activities involving manipulatives, it is possible to acquire knowledge of the significance of the manipulatives in students’ conceptualizing.

Keywords: Upper secondary mathematics education, manipulatives, semiotics, conceptualizing, objectification.

Introduction

For centuries manipulatives have been used in mathematics education as a pedagogical means for learning at all levels. A visit to the Institute of Mathematics at the University of Göttingen, Germany reveals an entire floor display of manipulatives used in university teaching (Stewart, Mühlhausen, & Miyazaki, 1993). Today the use of manipulatives is still common in primary and lower secondary school as a way of making the teaching concrete and meaningful. On higher levels where deduction and generalisation are important issues, manipulatives are rarely seen and research on their use is scarce (Bartolini & Martignone, 2014). Previous studies show that manipulatives can help students perform algebraic reflections and actions in pattern-generalizing tasks in primary and lower secondary school by joint student-teacher interaction (Radford, 2008). Here it will be investigated how the use of manipulatives can be seen in student reflections on the concept of growth in this upper secondary education.

Theoretical framework

Generalisation depends on symbolization (Otte, 2006) and many teachers use symbolic representations extensively without connecting them to other representations thereby preventing their students the chance to explore or reflect on these relations (Steinbring, 2005). The use of manipulatives is an alternative way of bringing in abstraction and generalisation in teaching, enhancing the development of mathematical knowledge (Mitchelmore, 2002). In his Theory of Objectification, Radford (2013, p. 26) states: “Learning […] is the noticing of something that is revealed in the emerging intention projected onto the signs […] in the course of practical concrete activity […] and is hence transformed into knowledge.”

A semiotic analysis of the representations and the communication about these representations, i.e. the signs the students produce, is used to investigate the mathematical knowledge developed. Each
observation of student work is treated as a semiotic bundle, a system of signs produced by a student or a group of students while they solve a problem or discuss a mathematical question. (Arzarello, Paola, Robutti, & Sabena, 2009).

Presmeg et al. (2016) demonstrate the usefulness of Peirce’s semiotics in analyzing students’ work with representations. Peirce defines:

A sign, or representamen, is something, which stands to somebody or something in some respect or capacity. It addresses somebody, that is, creates in the mind of that person an equivalent sign, or perhaps a more developed sign. That sign which it creates I call the interpretant of the first sign. The sign stands for something, its object. [Peirce 1965, 2.228, italics in original]

A sign to Peirce thus consists of a triad (representamen – object – sign). Each of these can be interpreted in terms of his categories (of which there are three: “possibility, existence and law”). Here I use in particular two trichotomies: icon, index and symbol referring to how the sign stands for its object, and the token-type distinction (omitting quali-sign).

An icon is a sign that shares a likeness with the object it represents either as an image, a diagram or a metaphor. An image has a resemblance or a simple quality in common with the object – a drawing of a real thing; a diagram is a sign representing relations, e.g., $x^2 + y^2 = r^2$ represents the points of a circle. A metaphor represents a parallelism where the character of one sign is expressed in a law-like manner in the other, like when a symptom, fever, of illness is seen as an increased temperature at a thermometer. An index is related to the object it represents by either a causal connection or by ‘a purposeful act of connecting the signs’ like using ‘f’ as the name of a certain mathematical function. Finally a symbol is connected to its object by habit or law, e.g. designating $\pi$ to refer to the ratio between the circumference and the diameter of a circle.

The token-type distinction applies to the sign alone. A token refers to the sign itself; consider the letter ‘e’, this letter appears many times – as a token – on this page. It is also possible to refer to ‘e’ as a general – as a type, stating that ‘e’ appears a particular number of times on this page.

A thorough explanation of Peirce’s trichotomies of signs is offered in (Short, 2007) whereas mathematical examples can be found in (Otte, 2006) and (Sáenz-Ludlow & Kadunz, 2015).

The teaching design rests on the Theory of Didactical Situations, TDS (Brousseau, 2006). The epistemological foundation of TDS is that new knowledge is obtained in two steps: first as personal knowledge connaissance in working with a given problem and second as formal, scientific knowledge savoir, which can be share with and understood by others.

TDS distinguishes between didactical situations where the teacher participates, and a-didactical situations where students engage in activities on their own. Devolution, where the teacher introduces and hands over the problem, validation and institutionalisation, where the ideas and results are tested and then related to the scientific knowledge of the solution, are all didactical situations. The main focus of this case study is, however, the a-didactical situation where students interact with the milieu, which contains the tools that the students have at their disposal (symbolic or material as well as the other students in the group). An important issue in designing the milieu is to ensure that it provides feedback on how the students progress in order to solve the problem.
Within this framework the study will try to answer the question: How does the use of manipulatives in teaching reflect in students’ answers about growth, exemplified by recursive sequences?

**Method**

The case study considers one lesson (100 min.) of a ten-week teaching sequence about differential equations in an upper secondary mathematics class with 25 students. The aim of the lesson was to enhance the students’ understanding of the concept “growth” using recursive sequences. After a short devolution where the purpose of the lesson, describing the growth of certain patterns, and the milieu containing worksheets and manipulatives like matches and LEGO® were introduced, the students worked in groups of 4 for 60 min. During this period teacher intervention was very sparse. Figure 1 shows an example of an activity/worksheet. As preparation for the validation and institutionalisation the students were asked to share results, ideas and reflections with their fellow group members in a logbook prompted by questions given by the teacher. Part of the logbook writing was done in class and the rest at home using a Google Docs document shared by the group members. The empirical data consists of the logbooks and field notes from classroom observations.

The logbook entries were analysed through a qualitative content analysis (Hsieh & Shannon, 2005) for words indicating the concept of growth, like ‘grow’ and ‘rise’ (coded with underscore in the statements). In addition, words referring to the manipulatives (coded in bold) were noted.

To describe the patterns and how they evolved, the students introduced a ‘sequence of signs’. They explained each sign and how they came on to it, and they used the sign as a starting point for the next sign they introduced. In order to examine the knowledge obtained by the students during the teaching sequence, data was analysed with respect to (1) the type of sign, applying Peirce’s categories, (2) how the use of manipulatives show, according to the nature of the marked words, and (3) mathematical reasoning, according to Radford’s definition of generalizing patterns (Radford, 2008).

*The sequence of figures shown is made of matches. The first is made of 3 matches, the second of 5 matches etc. The sequence can be continued with figure no. 5, 6, 7, 8 …*

Build and describe the next figures and tell how many matches you need to build them.

Figure no. 2 has been made by adding matches to figure no. 1 in a specific way. Figure no. 2 has been made from no. 3 etc. Explain how you move from one figure to the next in the sequence. Describe the pattern for adding new matches.

Explain how this pattern affects the number of matches, you need, to go from one figure to the next in the sequence. That is how can the number of matches in one figure be found from the number of matches in the previous figure?

If you want to know how many matches you need to build figure no. 37 it is rather time consuming to build and count the number. Use the pattern you have described above to predict how many matches you need for figure no. 37.

*Figure 1: An example of an activity*

**Results**

In this section, we will look at two logbook entries and one episode observed in class that show how the use of manipulatives contributes to obtaining knowledge of growth.
Figure 2 shows the first logbook entry on the question: Choose the pattern from one of the activities and explain how the pattern developed. Use drawings/pictures/symbols describing the growth.

For a start we observed how the number of matches grew. We found that there was a rise on two matches in every step. You can almost say that in each step a new triangle is mirrored on to the right side of the figure.

<table>
<thead>
<tr>
<th>Figure no.</th>
<th>No. of matches</th>
<th>Rise in number</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

We decided to make a formula to calculate the numbers of matches in figure no. 37. As the number rises with 2 for each figure, 2 is a constant and has to be multiplied by the figure no. But then the number is one too little. Therefore we add another constant in the formula namely +1.

The formula can then be written: The number of matches in the figure = the number of matches the figure grows with \(* figure number + 1."

We also considered other ways of describing the growth after having discussed our results in class. Here we noticed the constant rise with 2. This was the constant change between the earlier and the next figure. Therefore we could write down the relations:

\[
\begin{align*}
T(1) &= 3 \\
T(2) &= T(1) + 2 \\
T(3) &= T(2) + 2 \\
T(4) &= T(3) + 2
\end{align*}
\]

**Figure 2: A logbook entry with marked words**

The semiotic bundle in figure 2 shows how the students, based on the pattern they have built of matches, introduce three signs: a table inclusive a drawing of the pattern, a ‘formula’ written in words and a list of the first four terms of the recursive sequence describing the pattern. On figure 3 one can see how any one sign evolves from a previous sign. The photo on the left shows the pattern build of matches.

**Figure 3: Signs introduced by the first group**

The students begin by describing what they notice in the pattern they have built from matches, and they draw the pattern as the first line in a table. There is no explanation on the rest of the table but
my interpretation is that this is ‘a conditioned reflex’ as the students have made many tables like this with an independent variable (figure no.) and a dependent variable (no. of matches) when working with growth as a continuous function. The table is iconic: the previous text indicates that the students partly take it diagrammatic as it describes the relation between two subsequent figures. It also works in part as an image as the drawn pattern looks like the pattern made of matches.

In the table, the students also state the difference between two subsequent figures and this number is used for producing the next sign, a ‘formula’, from which they can calculate the number of matches in figure no. 37. The students notice that the increase is constant 2, which leads them to the first term of the expression. Using Radford’s definition of pattern generalization (Radford, 2008) we see that they use naïve inductions for producing their formula. Instead of arguing for the \( y \)-intercept, they guess and test the value. The formula itself is a partial translation of the previous arguments to a semi-mathematical language. This sign is partly diagrammatic stating a relation between the figure number and the number of matches and containing the symbols ‘+’ and ‘*’. It is interesting that the students do not finish the translation to a conventional formula (e.g. \( f(x) = 2x + 1 \)) introducing indices \( f \) and \( x \). Most groups did at this stage. Instead they keep the original iconic terms ‘figure no.’ and ‘no. of matches’ closely related to the manipulatives.

Finally, after a validation and institutionalisation where the idea of explaining growth as a recursive sequence was discussed, the students decide to include this view as, not mentioning the important issue, though, that every new term is built on the previous term. They introduce an index \( T \) to stand for the number of matches but do not find a general expression using the symbol \( n \) for the figure number like \( T(n) = T(n - 1) + 2 \) seen in other logbook entries.

We see that the signs used for representing the object Growth include various kinds of icons as well as indices and symbols. In many of the icons there is a close link to the use of manipulatives i.e. the way the students obtain their ‘data’ and how they explain relations in the pattern. The manipulatives are not clearly visible in their reasoning, though. As a result of the analysis we may conclude that the understanding of growth for this group of students now includes some very concrete conceptions based on activities with manipulatives (matches), and these are pointing towards a more abstract understanding that has not yet been reached. The relations produced indicate that they take the pattern as a token. They have not yet reached the stage of considering the pattern as a type in order to produce general relations.

In some of the worksheets the use of manipulatives were not explicitly mentioned but replaced by drawings of squares, dots etc. Some groups, though, were using the manipulatives mentally, which in figure 4 is shown as a mixture of the terms ‘squares’/LEGO® blocks’ in their explanations.

\[
T(1) = 1
\]

Figure 4: Logbook entry showing the use of mentally evoked manipulatives
The group has not built this pattern physically, but in the context of other activities with manipulatives they use a mental picture made of LEGO®. Figure 5 shows the squares from the worksheet and the mentally evoked manipulatives. Like in the entry in figure 2, the text indicates that the iconic sign is partly diagrammatic as it describes the relation between two subsequent figures and at the same time works as an image as the drawn pattern looks like the pattern made of LEGO® blocks, which the students have evoked in their mind.

![Figure 5: Alternating between signs](image)

As in figure 3, this group bring in various words describing growth; several terms refer to the manipulatives thereby showing the importance of the artefacts in the learning process.

The last example does not directly refer to the manipulatives from the activities but shows how a student seizes the idea of applying a concrete artefact in explaining a mathematical concept. The episode happened during the validation of the results from the activities described above. During the discussion it became obvious that many students had great difficulties with this new and different way of looking at the concept of growth. Their prior knowledge, connected to continuous functions, seemed very persistent. During the discussion one of the students reacted:

“No, no. We talk about the growth, the change – not the actual number. Look… [she jumps up from her chair, looks around and grabs a pile of books from the neighbouring table] …If we start with, say 1 book, [she puts one book on the table] and then in the first step we put 2 books on top of it, and then in the next step 2 more books and 2 more books and so on. [For every step she places 2 books on top of the stack on the table, see figure 6]. It doesn’t matter if there are 1 or 3 or 5 books in the pile. The important thing is that it grows with two books every time. The difference is two.”

![Figure 6: The pile of books holds many interpretations of a sign on Growth.](image)

The student makes use of concrete artefacts in order to explain to her peers how to understand growth. She applies what is easily accessible in a classroom: books! As a representation of growth, the sign contain qualities of all three kinds of icons: the growing stable of books is an image, the relation of adding two more books in each step is a diagram, and by insisting on seeing the difference in each step (two more books every time) instead of the height of the stable, it becomes a metaphor. The student clearly states that this is just one way of visualizing how something grows. From the many different words used to indicate growth she demonstrates a wide understanding. It is an example of how manipulatives can be used as visualising a challenging concept rather than a starting point for general, symbolic expressions, which we saw in the logbook entries.
Discussion and conclusion

The case study demonstrates how the use of manipulatives shows in students’ answers and reflections when describing a mathematical activity, e.g. building of patterns. By using concrete artefacts they are able to describe how patterns develop and translate this description to an expression of how the number of parts in each figure of the pattern grows. In the logbook entry (figure 2) the students use an intermediate stage mixing words and symbols, not reaching the final stage expressing the formula in formal mathematical language. Other groups, not considered here, argue for an algebraic expression.

Students use various words referring to different aspects of growth. Some are everyday language e.g. sticking out, broader, bigger, grow, rise and extra; whereas others are mathematical terms like add, multiply, change, growth etc. Often the everyday language is linked with the manipulatives, and the words might not have been evoked in a purely abstract context without the artefacts present. The semiotic analysis reveals that the signs introduced by students are predominantly iconic, many of these images. (Otte, 2006) argues “[...] iconic representations and perceptions are essential to introduce anything new into mathematical discourse”, and he notices, “Mathematics teachers very often dislike iconic representations and perceptions, believing them to be confusing and not controllable with respect to their impact” (Otte, 1983). This case study shows how students benefit from the use of artefacts by bringing in numerous iconic representations.

While figure 3 shows that very simple patterns can be visualized as drawings without actual physical materials, classroom observations, not treated here, reveal that patterns in 3D demand the use of actual building blocks. In both cases students use the names of the manipulative i.e. “matches” or “LEGO®”. Even when the physical artefact is not needed, students can apply a mental image of the artefact in their mathematical reasoning.

In former research results about the use of manipulatives in lower secondary education, Radford (2008) emphasizes the importance of joined-labour between students and teacher. In this study, the students were expected to be much more self-reliant as they were soon to end their upper secondary education, hence the use of a-didactical situations. The results, though, show that even students in the last year of upper secondary school need guidance in order to make their procedures and ideas converging with the mathematics curriculum as stated in the Theory of Objectification (Radford, 2008).

There are reasons to be somewhat cautious of the results. Using Peirce’s categories of the relationship between object and sign is complicated as Presmeg, Radford, Roth, and Kadunz (2016) state: “the distinctions are subtle because they depend on the interpretation of the learner”. They continue: “the distinctions may be useful to researchers or teachers for the purpose of identifying the subtlety of a learner’s mathematical conceptions if differences in interpretation are taken into account.” Thus, there are reasons to be careful in the interpretation. Earlier work of, among others, Radford (2000) shows comparable results indicating that the result of this case study is veridical. The semiotic analysis is based on students’ statements, and it cannot always be taken for granted that students are conscious about the precise meaning of the words they use. The fact, though, that the analysis of most logbook entries share the features exemplified here indicates that the approach used in this study is rather robust with respect to the lack of carefulness in student language.
The results points towards several areas worth further investigation. In his study Radford (2008) shows how students can be led to algebraic generalisation, introducing mathematical symbols for unknown quantities. This can be taken further by studying how students make sense in already evolved algebraic expression, and whether manipulatives can be supportive. In upper secondary education students are presented with a large number of such algebraic expressions, which they are expected to manipulate and use but often fail to understand. Another interesting aspect is the significance of prior knowledge. In figure 2 we saw how the students were led to look at the relation between a figure number in the pattern and the total amount of matches in that figure resulting in a functional expression. This behaviour was even more apparent in other entries, not shown here, and could very well originate from their knowledge of continuous functions. Although prior knowledge often helps students in new contexts, it can also prevent them from going in the desired direction.

The use of artifacts and different representations by producing mathematical audio-podcasts

Christof Schreiber and Rebecca Klose
Justus Liebig University, Department of Mathematics Education, Gießen, Germany

cristof.schreiber@math.uni-giessen.de
rebecca.klose@math.uni-giessen.de

This paper focuses on the role of artifacts and different forms and modes of representation when learning mathematics at primary school level. This will be exemplified alongside the use of an interactive approach, in which mathematical audio-podcasts are produced. Audio-podcasts are a communication tool that generally focuses on oral means of representation. During the production process of mathematical audio-podcasts however, the students use different forms and modes of representation as well as produce and use different artifacts. With regard to this, field experiences will be shared.

Keywords: Mathematical audio-podcasts, artifacts, forms and modes of representation.

Artifacts and different representations

The role of artifacts for mathematical learning is of great importance. Artifacts generally encompass objects that are produced by human beings and are materially present and durable. A learning artifact in particular, refers to an object developed by students, which displays their knowledge (Kafai, 2006). Besides artifacts that are material in nature, there are virtual ones that comprise of tools of the information and communication technologies. Different artifacts support different forms of representation and have a great influence on cognitive development (Bartolini Bussi & Mariotti, 2008).

The education standards for teaching mathematics also emphasise the transfer of various modes of representations, since they enable students to communicate their mathematical ideas and understanding as well as support the modeling and interpretation of mathematical phenomena (NCTM, 2000). Kress (2010) defines ‘mode’ as

- a socially shaped and culturally given resource for making meaning. Image, writing, layout, music, gesture, speech, moving image, soundtrack and 3D objects are examples of modes used in representation and communication. [...] Modes offer different potentials for making meaning. These differing potentials have a fundamental effect on the choice(s) of mode in specific instances of communication. (p. 79)

Therefore, being able to use different modes of representation during a mathematics lesson is a central aspect and supporting competence across all school levels. The mathematical register in the classroom also comprises of the multiple semiotic modes:

- Language, mathematical expressions, and visual diagrams, as well as the gestures and actions of participants in the classroom, together construct meaning. (Schleppegrell, 2007, p. 142)

With regards to the role of written representation for mathematical learning, working with the products of students’ writings has been common practice for some time now (Morgan, 1998). In the project ‘Math-Chat’ (Schreiber, 2013b), the use of written representations is the main means in the
problem solving process and focus of the analysis. In primary school, written-based communication is often used in the case of reflections and documentations of the students’ learning processes, for example, in journals referred to as ‘journal writing’ (Borasi & Rose, 1989); and also after having solved math problems. Thus, writing is often considered “an activity that is in itself conductive to learning” (Morgan, 1998, p. 2). In this sense, it is assumed that writing might help students organise their thoughts by externalising them in a written form. This strategy of ‘writing to learn’ has to be distinguished from ‘writing to communicate’. The tool ‘writing to learn’ enables students to become more active learners by questioning and reflecting on information, whereas ‘writing to communicate’ aims to demonstrate their learning in different forms of written assignments (Meiers, 2007).

It is oral communication that generally provides the participation in mathematical discussions and conversations, aiding with the understanding of mathematical signs (Meiers, 2010). Apart from speaking and explaining, mathematical learning also requires the acquisition of skills, such as listening, questioning, defining and proving (Ontario Ministry of Education, 2006). Pertaining to mathematical interaction and communication processes, research on mathematical didactics has attributed an increasing importance to the use of gestures (e.g. Goldin-Meadow, 2003; Huth, 2014). Kendon (2004) defines ‘gesture’ as “a name for visible action when it is used as utterance or as a part of an utterance” (p. 7). Gestures that are used in accompaniment with speech represent the same components of the expressions uttered. As such, gestures and spoken language can be seen as inseparable and interdependent modes of the same language system (Huth & Schreiber, 2017).

To further explain the interwoven use of oral and written communication in a medial and conceptual manner, the linguistic model of orality and writtenness by Koch and Oesterreicher (1985) and well explained by Fetzer as the “two dimensions of orality and writtenness” (2007, p. 79; translated by the authors: „Zwei Dimensionen von Mündlichkeit und Schriftlichkeit“) is used. Koch and Oesterreicher (1985) have developed a model of communication that distinguishes between medial phonic and medial graphic communication and between communicative immediacy and communicative distance. The medial phonic and the medial graphic realisation of communication are dichotomous, whereas the conceptual realisation can be placed on a scale between the communicative immediacy and the communicative distance (Figure 4; Schreiber, 2013a).

Considering the example of a personal talk, it is not only medially phonic, as there is an emotional closeness to the dialogue partner and thus, also conceptually oral. Although writing in a diary is medially graphic, it is conceptually oral, informal and characterised by its ‘closeness’ to the reader. An administrative directive, in contrast, is medially graphic and also conceptually an example for communicative distance. In this case, the language is strictly formal.

This paper will refer to ‘forms’ of representation when pertaining to Koch and Oesterreicher’s linguistic model of orality and writtenness and ‘modes’ of representation when used according to Kress and Schleppegrell’s definitions as mentioned above.
Audio-podcasts for mathematics

Audio-Podcasts, which we use as learning artifacts in school, primarily focus on the aspect of orality, as the process of creating an audio-podcast produces an oral product. Schreiber (2013a) developed ‘PriMaPodcasts’ to serve as tool, in which oral and written forms of representation are alternated and interwoven permanently. ‘PriMaPodcast’ is the coined term for a mathematical audio-podcast produced by primary school students. The students undergo a process in which they develop specific mathematical content in stages up to a point where a version of the explanation is ready to be published on the internet (Figure 1). The different forms of representation, the medial and conceptual realisations as well as the use of artifacts will be presented by illustrating each production step below. For more information on the aims, the production steps, the audio files and the scripts, please visit our blog (www.uni-giessen.de/primapodcast-bili/). Before giving insights into the production process, three aims of the mathematical audio-podcasts will be described:

**Learning:** The exclusive use of oral representations can support learning. This can be brought forth when learners have to deal with one specific topic in depth and are required to refrain from using any written or graphical representations, thus, solely relying on oral means of communication.

**Diagnosis:** A teacher gains insight into a learner’s mathematical concept and understanding by listening to the learner’s recorded utterances. The spontaneous and planned recordings can be analysed during and after the production process.

**Research:** As mathematics is a written and graphically based science, focusing on oral representations is an interesting area for research. Therefore, using the recordings, the aim is to investigate to what extent learners use mathematical language to express their workings.

The focus of this paper will be on the last aim. This will be illustrated in the following. The production process will be depicted through excerpts from an empirical example. These consist of recordings and documentations that were produced at a bilingual school in Offenbach am Main, Germany. The selected study sample is from a dissertation project (Klose, 2015) and it consists of fourth graders that were taught mathematics bilingually (German/English) since first grade. Within the scope of the research project, the students’ task was to produce a podcast in English. The empirical examples were transcribed and analysed by means of the interaction analysis (Krummheuer & Naujok, 1999). Excerpts of the transcribed utterances and scripts will be presented and commented thereafter. All citations of the transcripts are marked in angle brackets <like this>.

**Production steps**

In step 1 (‘Unexpected Recording’), a small group of students is unexpectedly confronted with the mathematical question ‘What is symmetry?’. The students record their responses with a voice recorder. Hence, in this step, the focus is on oral communication and representation. The medial realisation of the recording is phonic and conceptually oral as seen in the following.

In this example, the students answer the questions as follows:
In this excerpt, both students express their mathematical ways of thinking by speaking out aloud. The students associate the term ‘symmetry’ with ‘symmetry lines’ as seen in ur01 and ur03. Student 1 remembers in ur01 that her mathematics teacher had mentioned symmetry in class before. Furthermore, they relate ‘symmetry’ to “forms” ur04 and “forms that what you can do in three d and in two d” ur07. As early as seen in this excerpt as well as later on, gestures are already going into action. This step not only prompts the students to think about the topic, but also supports them to clarify and organise their thoughts and reflect on specific content (Pimm, 1987).

In step 2 (‘Script I’), the students research their topic and create a script. They are free to decide the format, structure and amount of detail they wish to include. In order to gather information, they are given different resources, such as the internet, textbooks and worksheets. They also have the possibility to use concrete material. Thus, different artifacts can serve as basis for oral communication and written-graphical representation.

The students of the empirical example were inspired by the work material and referred to various approaches of line symmetry. In particular, student 2 used the geoboard and drawings (Figure 2) to support her with the activities related to line symmetry. In their script, they explain ‘symmetry’ through the approach of folding (Figure 3).

The students continue by mentioning ‘drawing’ and ‘reflecting’. The writing activity itself may be considered a tool for ‘writing to learn’. Dealing with different artifacts and resources, this writing underlies the principle of connecting what has been read, viewed, heard and experienced with what
the students have understood so far (Meiers, 2007). The medial realisation of the script is graphic and its linguistic conception is - depending on the kind of script - a rather informal written type.

In step 3 (‘Podcast - First Version’), oral representation is essential, as the students are required to read the assigned parts of the script aloud for the recording of the first podcast version. Up to this stage, the team works independently: The students make their own decisions concerning the mathematical matter and their performances without any intervention from the instructor. The medial realisation of the recording is phonic and its linguistic conception is a more formal spoken type.

fv speaker: statement:
01 Student 2: what is symmetry there are axis symmetry reflection symmetry and partition symmetry there are symmetrical shapes
02 Student 1: symmetrical shapes are shapes that you can fold in the middle and then both sides are the same
03 Student 2: you can draw symmetrical shapes with faces . vertices and edges
04 Student 1: edges are the lines and vertices are the places where they come together faces are the places in between the edges and in German we call them flächen
06 Student 2: you can make symmetrical shapes in two d and three d
07 Student 1: examples for symmetrical shapes are a square a circle a triangle a hexagon a pentagon and a trapezoid
08 Student 2: s some some shapes have got more than one m mirror line

In step 4 (‘Editorial Meeting’), the small group of students receives feedback from their peers and the instructor. They use this to reflect on their work in terms of content, style and language use. At this point, the instructor poses specific script-related questions and asks for more precise explanations. Again, different artifacts, such as the script, the audio files and objects and especially the students’ written products, support the discussion and serve as basis for better clarifications in oral communication.

In the presented empirical example, the different types of symmetry were correctly named and distinguished. For this purpose, various kinds of materials were used. By means of their drawing (Figure 2) the phrase ‘line of symmetry’ was introduced. Several locations to draw the line of symmetry were discussed. Thereby, the instructor’s focus shifted from 3D towards the symmetry of 2D shapes. Together with the other group, they reviewed and checked how many lines of symmetry a circle, quadrilaterals and different types of triangles could have.

In step 5 (‘Script II’), the students start to improve their first script in small groups. The students have the opportunity to use the same material and artifacts again. They may discuss and share their knowledge before writing down a second script. Thus, oral communication serves as basis for written representation. The writing activity of creating a second script may be linked to the strategy of ‘writing to communicate’ (Meiers, 2007). Since the second script serves as basis for the final podcast version, the learners decide on the content they wish to present to the audience. The script is medially graphic and conceptually rather an elaborated written type since the students clearly want to present their knowledge accurately and in a structured manner.

In the empirical example, the students took up most of the suggestions given during the editorial meeting as they tried to differentiate more distinctively between the different types of symmetry.
This, however, appeared to be challenging, as they focused on 3D shapes again and listed some of their properties instead of looking at 2D shapes.

In step 6 (‘PriMaPodcast’), they record a final podcast version based on the second script. This will be published on the internet. Again, written representation serves as basis for the oral form of representation. Hence, the recording is medially phonic and conceptually more of an elaborated type.

pr speaker:    statement:
01 Student 2:  what is symmetry. there are line symmetry reflection symmetry and rotation symmetry . there are symmetrical shapes
02 Student 1:  symmetrical shapes are shapes that you can fold in the middle and then both sides are the same . that’s line symmetry
03 Student 2:  rotation symmetry is when you have a symmetrical shape and you rotate it a little bit and then the shape the shape looks the same as it was before
04 Student 1:  reflection symmetry is almost the same like line symmetry but you have to put a mirror in the middle of the shape\
05 Student 1:  you can draw symmetrical shapes with faces vertices and edges
06 Student 2:  examples for symmetrical shapes are a square a circle a triangle and in three d a sphere a pieramid and a cube
07 Student 1:  you can make symmetrical shapes in two d and three d
08 Student 2:  almost all shapes have got more than one line of symmetry

As described in the production process, the students’ products can be classified into Koch and Oesterreicher’s model as follows (Figure 4):

![Diagram](image)

Figure 4: Model of writtenness and orality; (Fetzer, 2007, p. 79/ Schreiber, 2013a)

**Conclusion**

The use of artifacts and various representations in the mathematics classroom is of high relevance. The interactive approach of producing PriMaPodcasts follows this assumption by comprising various modes and forms of representation. The aim is to produce a learning artifact; a final product of oral nature. Publishing the final version on an online blog serves as an exceptional motivation for the students. In the process, they undergo various stages, in which they can expand their knowledge through discussions and learn different approaches to present them. Mathematical concepts and language competences can be strengthened as shown by the empirical example.
Field experience

So far, mathematical audio-podcasts have been used in different areas of teacher education. Firstly, we produced audio-podcasts for mathematics with students at primary school level. Besides German podcasts, some students also produced mathematical audio-podcasts in various other mother tongues (e.g. Russian and Turkish) as well as different languages of instruction (e.g. English and Spanish) in bilingual schools.

Secondly, students who are studying to become primary or secondary school teachers, created mathematical audio-podcasts. Moreover, they supervised the production of the mathematical podcasts of school students. It is important for the university students to have gone through the steps themselves prior, so as to understand the production procedure clearly. Hence, they gain a better understanding of how demanding it can be for younger learners to explain a concept without any preparation and solely using orality. The deepening of mathematical content and its reflection are another focus of the audio-podcasts. The university students become aware of the increase in knowledge and are able to internalise and reflect on already learnt content. Content knowledge ranges from secondary school mathematics to areas covered during university lectures.

Thirdly, the idea of mathematical audio-podcasts serves as research method. As part of a PhD project, the use of mathematical language in bilingual learning settings will be investigated further. The overall interest lies in the question of how bilingually taught learners use the language of mathematics in both their target languages (English and German) when asked to present mathematical content (Klose, 2015).

The role of representations in promoting the quantitative reasoning

Lurdes Serrazina¹ and Margarida Rodrigues¹

¹Escola Superior de Educação de Lisboa, UIDEF, Instituto de Educação, Universidade de Lisboa, Portugal; lurdess@eselx.ipl.pt, margaridar@eselx.ipl.pt

In this communication, we discuss the role of representations in the development of conceptual knowledge of 2nd grade students involved in additive quantitative reasoning through the analysis of the resolutions of two tasks that present transformation problems. Starting to discuss what is meant by additive quantitative reasoning and mathematical representation, we present after some empirical results in the context of a teaching experiment developed in a public school. The results show the difficulties with the inverse reasoning present in both situations proposed to students. Most students preferably use the symbolic representation, using also the written language as a way to express the meaning attributed to its resolution. The iconic representation was used only by a pair of students. Representations have assumed a dual role, that of being the means of understanding the students' thinking, and also supporting the development of their mathematical thinking.

Keywords: Mathematical representations, transformation problems, additive quantitative reasoning, inversion.

Introduction

This paper is part of the Project “Adaptive thinking and flexible computation: Critical issues” being developed by the Schools of Education of Lisboa, Setúbal and Portalegre. Its main goal is to discuss the role of representations in the development of 2nd grade students’ conceptual knowledge that is present in different levels of understanding of numerical operations/relations when they solved two tasks. These were conceived with the aim to develop quantitative additive reasoning, as a means of understanding this same reasoning. The tasks present transformation problems included in the classes of search of initial state (Vergnaud, 2009). They are the last ones of a sequence of six tasks that was applied in the context of a teaching experiment developed in a public school in Lisbon. The empirical data analysis focused on representations aims to discuss the inferences we make in the reasoning of the students but also their role in the development of students' reasoning.

Mathematical representations and quantitative reasoning

Quantitative reasoning, within the additive structure, focuses mainly on relations between quantities (Thompson, 1993), being that the problems of transformation aimed at finding the initial state have increased cognitive complexity for 2nd grade students by requiring an inverse reasoning (Vergnaud, 2009). The representations are interconnected with the reasoning given the relevance of their role in the understanding of students’ reasoning (NCTM, 2000). But, the representations also assume an important role in students’ learning, constituting cognitive means with which they develop their mathematical thinking (NCTM, 2000; Ponte & Serrazina, 2000). In a broad sense, a representation is a setting that can represent something somehow (Goldin, 2008). The term “representation” refers both to the process of representing and the result of this process. In mathematics education, representations are privileged tools for students express their mathematical ideas, still working as helpers in the construction of new knowledge (NCTM, 2000). However, a mathematical representation cannot be
understood or interpreted in isolation, since only makes sense when part of a more comprehensive and structured system in which different representations are related (Goldin & Shteingold, 2001).

According to Stylianou (2010), the way as representations are used in classroom has impact in students learning and this largely depends on the role of the teacher, using “student-generated work as a launching point for discussions” (p. 339). This idea is reinforced by Ponte and Serrazina (2000) when they say that how mathematical ideas are represented influences profoundly the way they are understood and used. For example, according to Vergnaud (2009), the inverse transformation can be represented by two symbolic representations -- the algebraic one and the arrow diagram -- considering, however, that while the algebraic representation is not suitable for children in elementary school, using the diagram representation the teacher can help students connect, immediately, the different components of the relationship, namely the direct and inverse transformations, giving meaning to the temporal motion go forward and backward.

![Figure 1: Arrow diagram (Vergnaud, 2009, p. 87)](image)

Figure 1 presents a representative diagram of subtracting 7 to the final state in the situation "John has just won 7 marbles in playing with Meredith; now he has 11 marbles; how many marbles did he have before playing?" (Vergnaud, 2009, pp. 86-87). However, while recognizing the importance of this representation, the author states that children need several examples of the inverse transformation in order to be able to effectively understand it. "Several kinds of awareness are needed: you lose what you have just won; or you win what you have just lost; you go backwards as many steps as you have gone forwards and reciprocally" (p. 87).

For Ponte and Serrazina (2000), the main forms of representation used in the primary education are: (i) the oral and written language; (ii) symbolic representations, like numbers or the signs of the four operations and the equal sign; (iii) iconic representations, like figures or graphics; and (iv) active representations, like manipulative materials or other objects. It is through the analysis of the representations used by students that the teacher can become aware of their thinking and help them in the construction of own representations in mathematical language.

NCTM (2000) also emphasizes the role of idiosyncratic representations constructed by students when they are solving problems and investigating mathematical ideas, in that it can help them in understanding and solving problems and provide "meaningful ways to record a solution method and to describe the method to others" (p. 68). Observing these representations, teachers and researchers can understand the ways of interpreting and reasoning of students.

**Methodology**

This study follows a qualitative approach within an interpretive paradigm. Its methodology of design research is part of a perspective of learning design, in order to produce local theories of teaching and learning sequences that are resources and references available to inform the practices of teachers and researchers (Gravemeijer, 2015).

The data were collected in a second grade classroom (7-8 years old), with 26 students, of a public primary school in Lisboa. The Project team defined a sequence of tasks with the aim to develop the
calculation flexibility in addition and subtraction problems. The process of tasks elaboration included previous testing of some (namely the ones focused in this paper), through clinical interviews (Hunting, 1997) with students of the same grade. It is a technique that is directed by the researcher and seeks a description of the ways of thinking of respondents. The task sequence was previously discussed and analyzed with the classroom teacher having been made minor adjustments. Classroom teacher explored the task sequence with her students (a task every week). During their schooling the empty number line had been used regularly both by the teacher and students.

The data collection was made through participant observation of the authors of this paper, which drew up field notes and supported by video recording, subsequently transcribed. The written records of the students were also collected. All these data were analyzed and triangulated. By ethical reasons, the students’ names were changed to ensure confidentiality.

In this communication we analyze two tasks (Figure 2), proposed to the students in the same class (given the similarity between them) and presented on the same sheet of paper, with space for the respective resolution.

Figure 2: Performed tasks

These were the last ones of the sequence solved by students. With the previous exploration of the other tasks, students had already worked the relationship between wins and losses over a marbles game, realizing that what a player wins, the other loses. All the tasks were first solved in pairs. In this class, after all pairs had solved the two tasks, the teacher promoted a collective discussion with whole class, from six pairs resolutions (three on each task) who presented their work on the blackboard.

Exploring the tasks

In this section we present and discuss some examples of tasks’ resolutions. Their choice was made taking into account the diversity of representations presented by the different pairs and being representative of what happened in class.

Game of marbles I

The resolution of Alexandre and Rosa shows the inversion of reasoning as a critical aspect. Thus, they took first 10 marbles for both players from the sum of 3 ("Ana won 3 marbles") with 7, not mobilizing an inverse reasoning to determine the initial number of marbles.
Alexandre's diagram (Figure 3) represents the wins and losses of marbles as they are thought by the pair of students. But, when asked by the teacher they erased all they did and made it again on their worksheets (this diagram was seen in the video records). The new representation (Figure 4) reveals the necessary inversion to find the initial number of marbles. They got it for Ana, but they seem to forget that both players had at the beginning the same number, as in Luis’ allusive representation, they retired 3 marbles from 7.

Vítor and Joana can reverse the reasoning to the case of Ana but they show a lack of understanding of the situation alluding to Luís (Figure 5).

This diagram helped the children's thinking in the sense that it respects the temporal order of the game: the initial marbles on the left and the final ones on the right side. However, they did not look again for the initial situation, that is, if Ana won, Luis has to have less at the end of the game.

Rui and António used symbolic representations presenting a number line with two curve lines that represent the inversion of addition and subtraction (Figure 6). Like the anterior pair, they reversed their reasoning to Ana but they assumed the same situation to the player Luis, stating that he won 7 marbles at the end of the game. Here the term "won" means the absolute number of marbles at the end of the game and not a quantitative difference. The distinction between the quantitative difference and the result of an arithmetical operation is a critical aspect that emerges from this resolution.
The word "because" explains the inversion used to determine the number of initial marbles, justifying it with the inverse relationship between addition and subtraction. The order in which they placed the operations shows the inverse reasoning process: first, they determined the initial number of marbles (the initial state), and after they confirmed the resultant final state with the inverse relationship.

Tiago and João used a table disposition (Figure 7), with columns for each of the two players and the lines for the different moments of the game, the top line to the beginning of the game and the bottom to the end.

It was the only pair in the class, which established the difference between the final numbers of marbles, although not required, focusing on the difference as an additive comparison of quantities. It seems that the representation used allowed them to manage two data at the same time, the quantity of marbles and the transformation after game.

Game of marbles II

Alexandre and Rosa read the problem. Immediately, Alexandre said: "Luís started with 9 and Ana started with 4." Once Alexandre had understood the previous problem when the teacher questioned their resolution, as mentioned before, here he already coped well with the unknown initial state, solving mentally the problem, through an inverse reasoning.

On the diagram's lines (Figure 8), the numbers are placed in ascending order, getting the initial number of marbles on the right for Luís and on the left for Ana. Their answer is focused on the absolute amount of marbles of Ana at the end of the game and not on the comparison.
Figure 8: Alexandre's diagram for Game of marbles II
Vítor and Joana used the line representation (Figure 9), adopting the temporal criterion as they did in the previous task, putting the initial marbles on the left and the final ones on the right side and at this time they got the right solution.

Figure 9: Vítor's diagram for Game of marbles II
Rui used an iconic representation of Ana's marbles: first, the six marbles won from Luís; then the initial 4 marbles (probably counting them until the total 10); and finally the three final marbles of Luís. He was not able to reverse his thinking in order to determine the initial marbles of Luís.

Figure 10: Rui's diagram for Game of marbles II
Tiago surrounded the numbers to assign their meaning, recording the player and the time of the game to which they relate (Figure 11) and respecting also the temporal order of the game.

Conclusion: we discover that Luís loses and Ana wins.
R: Ana won the game with 10 marbles.

Ana won
Tiago focused the additive comparison of the resultant final states, recording that "the difference is 7 at the end".

**Final remarks**

The inverse transformation is a critical aspect in solving the tasks (Vergnaud, 2009). Thus, the first representations used by Alexandre in *Game of marbles I* show a reasoning associated with prototypical situations of addition asking for final states and not initial ones. Students seem to cope more easily with this kind of transformation in the second task after having understood the inversion involved in *Game of marbles I*. For this understanding the teacher’s questions seem to have been fundamental.

An example is the case of Alexandre and, although he did not fully solve the first problem, managed to overcome the obstacle of inversion in the second task solving it mentally very fast. Despite the inherent difficulty of the inverse transformation, the productions of the students in the class reveal a widespread understanding of an aspect of inverse thinking: what a player wins, the other loses.

Students seem to have essentially privileged two forms of representation (Ponte & Serrazina, 2000): the written language and symbolic representations. Just a pair of students used the iconic representation in support of symbolic representation (Rui and António). Among the symbolic representations used, there was a predominance of horizontal dispositions of the calculations, although the use of the empty number line also had had a significant expression, helping to think about the transformations involved in problems. We should stress that empty number line had been used by these students and her teacher since the first grade. Thus, the curved lines, which represented the transformation, supported the thought around the wins and losses, as well the temporal motion. The table disposition also seems to have helped the students (Tiago and João) to structure and relate the various elements of the problem: the two players and the two time points of the game.

Analyzing student productions, we can infer different levels of quantitative additive reasoning. While most learners focused on the absolute amounts of marbles, Tiago focused on quantitative difference as a quantitative result of comparing two quantities additively to find the relative change (Thompson, 1993). So, for the majority of students, the notion of difference as an additive comparison of quantities is a problematic aspect.
The representations used by the students had a dual role. On the one hand, they were windows to interpret their reasoning. On the other hand, they were scaffolds that helped to think mathematically demanding situations, taking into account their ages. It should be stressed that the teacher’s role, making questions, not giving answers, while students were doing their work was also essential. As stated by Vergnaud (2009), the development of a conceptual field involves not only situations and schemes but also symbolic tools of representation.

Maths Welcome Pack: A multi-sensory introduction to mathematics for high school students

Giulia Bini
LSS Leonardo da Vinci, Milano Italy; giulia.bini@lsdavincimilano.eu

Keywords: Secondary school mathematics, experiential learning, multisensory learning, mathematics activities, learning motivation.

Introduction and theoretical framework: Before the box

This poster is about the experience of an “on field” project started in 2014 with a group of 28 14-y.o. students attending to the first year (9th grade) of Liceo Scientifico and a 10cm cube cardboard box containing a collection of items that led to a two weeks journey through the focal points in the act of doing mathematics, which are the new entries of the high school approach to the subject, such as proofs, their necessity in mathematics and the related use of a proper symbolic language.

It has been conceived as a starter for the study of high school mathematics, but it also proved an effective strategy to boost students’ learning motivation and long-term knowledge retention about the subject as a whole.

As Raymond Duval points out, “the goal of teaching mathematics, at primary and secondary level, is neither to train future mathematicians nor to give students tools, which can only possibly be useful to them many years later, but rather to contribute to the general development of their capacities of reasoning, analysis and visualization” (Duval, 2006, p. 105). Taking this perspective, I wanted to investigate the effectiveness of a multi-sensory approach, which is quite frequent for lower grades but isn’t a common practice for secondary mathematics teaching and learning, through the means of Arzarello’s semiotic bundle theory, widening the semiotic system horizon “to contain gestures, instruments, institutional and personal practices and, in general, extra-linguistic means of expression” (Arzarello, 2006).

The project had a double goal: from a research point of view, I aimed at focusing on the “cognitive functioning underlying the various mathematical processes” (Duval, 2006, p. 104) and exploring the efficacy of “a rich semiotic bundle with a variety of semiotic sets” (Arzarello, 2006) to foster students’ understanding of some pivotal mathematical concepts. From a didactic point of view I wanted to verify that this approach, which took its strength from “a gradually growing and multimodal cognitive environment” (Arzarello, 2006) could help students in building up long lasting memories connected to the practice of mathematics through the act of giving “personal meanings to mathematical objects” (D’Amore, 2003, p. 19).

Methodology: Inside and Outside the box

The study explores how students answered to questions and problems prompted by the 12 items in the box, during the first two weeks of the school year (approximately 10 hours of teaching). Data has been collected by the teacher through classroom observation and assessment of the assigned homework.
The content of the box, described in detail in a multimedia presentation, varied from tactile objects like the piece of string which triggered the ice-breaker kinaesthetic activity The Magic Knot (Can you tie a knot in a string without letting go of the two ends?) to a paper cut with an extract from a 1742 letter from Christian Goldbach to Leonhard Euler which lead to the unveiling of The Goldbach mystery (What is the Goldbach conjecture? And why is it a conjecture and not a theorem?).

A good example to illustrate how the notion of semiotic bundle can be used to decode the activities of students solving a mathematical problem is The mystery of the four triangles (Can you build exactly 4 equilateral triangles using six toothpicks of equal length?). Searching for the answer to this problem students came up with the wrong construction seen in fig.1.

Figure 1

Discussing this solution, they brought into play an articulate semiotic bundle made up of:

- gesture: manipulating the toothpicks to build the solution
- speech: discussing why the construction in the figure is wrong
- written signs: drawing other possible solutions
- arithmetic representation: figuring out that the slanted toothpicks in Figure 1 weren’t long enough to play as diagonals of the square
- geometric representation: figuring out that the triangles in Figure 1 couldn’t be equilateral

Expanding the semiotic bundle from gesture to arithmetic representation, they became gradually aware that the construction couldn’t be solved in two dimensional space and it eventually helped them to elaborate the correct solution.

Conclusions: Beyond the box

The described case shows how the use of a full range of different types of representation (verbal, gesture and iconic exemplification) has been a key point in the procedure of developing the meaning of the mathematical objects involved. In the following school years (14-15 and 15-16), this class group attested in two synergic ways how successful this opening experience has been: on one hand, they proved to remember vividly the content delivered through the box and on the other they become more metacognitively aware of the importance of creating a range of different representations in order to have access to a mathematical concept or problem.

Representations of fractions in mathematics education: What do students learn?

Cecilia Sveider

Linköping University, Department of Behavioural Sciences and Learning, Linköping, Sweden

cecilia.sveider@liu.se

Keywords: Representation, fraction, primary school.

Introduction

During the past years the mathematics education community as well as the educational research of teaching and learning have seen representations as a useful tool for communicating information and understanding (e.g. Lesh, Cramer, Doerr, Post, & Zawojewski, 2003; NCTM, 2000). NCTM (2000) advocates students to “create and use representations to organize, record, and communicate mathematical ideas; select, apply, and translate among mathematical representations to solve problems…” (NCTM 2000, p. 64). In the present study, ‘representations’ refers to Goldins (2002) definition that a representation can represent something else, for example, symbolic expressions, drawings, written words or diagrams. Different representations can be used to shed light onto different aspects of a complex mathematical concept or relationship (e.g. Cai, 2005; Cathcart, Pothier, Vance, & Bezuk, 2006). For example, when learning about parts of a whole, teachers and students can use a manipulative representation, as sectors of a circle or as pieces of a rectangle.

Purpose

The aim of the present study is twofold. Firstly, investigate how teachers and students use representations of fractions focusing on finding a fraction regarding either part-whole or part of set aspect. This would for instance entail examination of which type of representation, how they are used and in which order they are used. Secondly to examine what students learn in mathematics lessons, regarding representations of fractions.

Hypothesis

The hypothesis is that a more frequent use of different representations, by either teachers and or students, will enhance the students’ knowledge of fraction as part of a set or part of a whole. This is in line with what have been suggested by Cai (2005); Cathcart, Pothier, Vance, and Bezuk, (2006) concerning different representations.

Method

The collection of data consists of two parts, (a) video recordings of lessons and (b) pre- and post-tests (“RB2 or RB3 Diamant” which is part of the Swedish National Agency for Education’s test materials). Video recordings enable data to be analyzed repeatedly and seen by other researchers in order to contribute to the study. Data will be analyzed with respect to variation theory (see for instance Marton, 2015). The pre- and post-test are a measurement to document effects of using representations of fractions during the mathematics lessons. To examine group differences between pre- and posttest repeated measure ANOVA is used.
Participants
Ten primary school teachers and approximate 250 students in Sweden, New Zealand, and Singapore, respectively, will be part of the present study.

Pre-service elementary teachers’ knowledge of comparing decimals based on the anthropological theory of the didactic

Zetra Hainul Putra
University of Copenhagen, Department of Science Education, Copenhagen, Denmark
University of Riau, Faculty of Education and Teacher Training, Pekanbaru, Indonesia; zetra.putra@ind.ku.dk

In this paper, the idea of hypothetical teacher task (HTT), designed and analysed using the anthropological theory of the didactic (ATD), was presented to study pre-service elementary teachers’ (PsETs) mathematical and didactical knowledge of comparing decimals. This study is part of the author’s PhD project about PsETs’ knowledge of rational numbers. The subjects for this study were 32 fourth year PsETs from University of Riau, Indonesia. The study illustrates how HTT can be useful as an alternative method to investigate PsETs’ knowledge through praxeological reference models.

Keywords: Anthropological theory of the didactic, praxeologies, hypothetical teacher tasks, mathematical and didactical knowledge.

Introduction

The results from the Programme for International Student Assessment (PISA) in 2015 ranked the performance of Indonesian pupils 62 out of 70 countries (OECD, 2015). Most pupils were only able to solve problems directly related to the routine procedures (mostly at level 1 and 2 in the PISA framework). These results reflect how they learned mathematics at schools, and this situation raises a question about the knowledge of teachers as the main support for the success of pupils' learning: namely, how teachers’ pedagogical content knowledge (Kuntur et al., 2013) and mathematical knowledge for teaching (Hill, Rowan, & Ball, 2005) significantly affect pupils’ achievement.

Many studies have been conducted on teachers’ knowledge concerning specific mathematical topics (Ma, 1999), including international comparative studies of teachers’ knowledge (Tatto et al., 2008). Ma (1999) studied teachers’ performance about rational numbers, especially on calculations and representations of division of fractions. She evaluated teachers’ knowledge through posing two tasks: to compute and to represent meaning for the resulting mathematical sentences. Meanwhile, the Teacher Education and Development Study in Mathematics (TEDS-M) studied teachers’ knowledge through questionnaires (Tatto et al., 2008). TEDS-M used three question formats: multiple-choice, complex multiple-choice, and open constructed-response. TEDS-M argued that only the third format allows teachers to demonstrate the depth of their thinking on mathematical knowledge and mathematical teaching knowledge. However, both studies share the focus on individual teachers’ knowledge through written tests. This method is commonly used by other studies and sometimes followed by an individual interview of selected teachers.

Teachers’ knowledge can also be studied through different approaches or methods. One possible approach is to design open constructed tasks based on pupils’ difficulties and misconceptions. The tasks can be proposed to teachers both individually and collectively. The focus of this study is on
designing a model for teachers’ shared mathematical and didactical knowledge of rational numbers based on the anthropological theory of the didactic (ATD), specifically on the notion of praxeology (Chevallard, 2006). I focus on rational numbers because they constitute one of the most difficult topics for elementary and secondary teachers (Depaepe et al., 2015). Teaching this topic requires relevant knowledge of teachers to properly deal with pupils’ difficulties. I use the notion of praxeology to model teachers’ knowledge. Durand-Guerrier, Winsløw, and Yoshida (2010), and Winsløw and Durand-Guerrier (2007) have developed a tool based on this notion to investigate teachers’ specific mathematical and didactical knowledge that is known as hypothetical teacher task (HTT). In my larger study, the focus is on designing HTT about rational numbers that can investigate not only pre-service elementary teachers’ (PsETs) individual knowledge but also the collective one. This paper presents a case study of comparing decimals as a part of my PhD project about PsETs’ knowledge of rational numbers. The research questions that drive this paper are: how can HTT on comparing decimals function to study PsETs’ mathematical and didactical knowledge? What praxeologies, specifically mathematical and didactical techniques, are shared by Indonesian PsETs related to comparing decimals?

Teachers’ knowledge and the anthropological theory of the didactic (ATD)

Many studies about teachers’ knowledge refer to content knowledge and pedagogy content knowledge introduced by Shulman (1986). These notions also have influenced several later studies on mathematics teacher education (Hill, et al., 2005; Ma, 1999; Winsløw & Durand-Guerrier, 2007). Winsløw and Durand-Guerrier (2007) identified three components of teachers’ knowledge: content knowledge (mathematical techniques, theories etc.), pedagogical knowledge (concerning education, learning and teaching in general), and didactical knowledge (regarding the conditions and mechanisms of mathematics teaching and learning, often quite specific to the content taught).

To study teachers’ knowledge, ATD provides an epistemological tool to describe and analyse mathematical and didactical knowledge as human activities among others (Chevallard, 2006). In fact, ATD holds, as a central assumption, that any knowledge, including teachers’ knowledge, can be investigated in term of a praxeology. I use this notion as a framework to study teachers’ mathematical and didactical knowledge of comparing decimals.

A praxeology consists of two main interrelated components: praxis (practical block) and logos (theoretical block). Both the practical and theoretical block of a praxeology are divided into two elements. The practical block is made of a type of tasks (T) and corresponding techniques (τ) which apply to accomplish tasks of type T. An example of a type of mathematical tasks (T) is to compare two given decimal numbers. To solve this task, a technique (τ) is needed; for instance, one can change both decimals into fractions with a common denominator, and then compare numerators. The theoretical block is made of technologies (θ) and theories (Θ). A technology (θ) is a discourse used to explain and justify the techniques (τ), while a theory (Θ) explains and justifies the technology (θ). An example of technologies is an explanation of available methods to decide which of two different given decimals is greater, when the methods work or are more efficient, etc. The order structure of rational numbers is a mathematical theory (Θ) which can be used to justify and explain the technology (θ).
A praxeology is not only used to describe mathematical knowledge but also didactical knowledge (i.e. knowledge about teaching that depends on what is taught). The praxeology used to describe didactical knowledge is known as a didactical praxeology. Like a mathematical praxeology, didactical praxeology includes a type of didactical tasks, didactical techniques, didactical technologies and theories (Rodríguez, Bosch & Gascón, 2008). The didactical praxeology is thus closely related to the mathematical praxeology because didactical praxeology is about tasks related to the teaching of the mathematical praxeology. An example of a type of didactical tasks is to teach pupils how to compare two decimals. A didactical technique is to present directly a mathematical technique for comparing two decimals and then ask pupils to apply this technique for other similar mathematical tasks. A technological discourse to justify this didactical technique is an assumption that pupils might learn better if they get the correct method from the teacher. This may even derive from a more general didactic theory, favouring direct instruction in general.

**Methodology: Design of hypothetical teacher task (HTT)**

The notion of HTT was introduced by Durand-Guerrier et al. (2010) and Winsløw and Durand-Guerrier (2007) to investigate pre-service lower secondary teachers’ knowledge. HTT consists of mathematical and didactical tasks for teachers. The mathematical task is one that is problematic to pupils in the hypothetical situation, often related to some common misconceptions. Teachers have to analyse this task and provide some mathematical techniques. They work individually for this task and then share their ideas for the discussion on the didactical task. The didactical task asks, with variations depending on the situation described, what could be done to further pupils’ overcoming of particular difficulties with the mathematical task. So the didactical task strongly relates to the mathematical task.

The HTT about comparing decimals was designed based on known misconceptions related to place value (Irwin, 2001). As an example, pupils may argue that 0.15 is greater than 0.2 because 0.15 is longer than 0.2 or 15 is greater than 2. Beginning with a situation where pupils hold such views, the HTT reads as follows:

<table>
<thead>
<tr>
<th>Fifth grade pupils are asked to compare the size of 0.5 and 0.45. Some pupils answer that 0.45 is greater than 0.5, while others say that 0.5 is greater than 0.45.</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>a.</strong> Analyse the pupils’ answers. Explain your ideas to handle the situation in this class? (to be solved individually in 3 minutes)</td>
</tr>
<tr>
<td><strong>b.</strong> How do you use this situation to further the pupils’ learning? (to be discussed and solved in pairs within 5 minutes)</td>
</tr>
</tbody>
</table>

**Figure 1: HTT about comparing two decimals**

The HTT was originally written by the author in English, and then it was translated into Indonesian. Two Indonesian researchers checked the translations for consistency. The HTT was also piloted with a pair of recently graduated students from the Elementary School Teacher Education (ESTE) study program at University of Riau, Indonesia. I asked for the students’ comments and used them to revise the HTT. The data consist of PsETs’ written answers for the first question and video recording of the discussion for the second question. I transcribed the video recording for all groups
using the NVivo computer program. Then, the written answers and video transcripts were analysed based on the mathematical and didactical praxeologies, to identify the techniques produced. The subjects for the implementation of HTT were 32 (16 pairs) fourth year PsETs from the ESTE study program, and the data were collected in March 2016. All participants wrote their answers on the worksheets for the individual question a, and then they used their answers to support a common discussion for the question b. A more comprehensive analysis of these data was based on the techniques identified among individual pairs.

Praxeological reference models

In the first phase of analysis, I focus on the practical blocks (i.e. types of tasks and techniques). The mathematical task \((T_m)\) contained in the HTT (Figure 1) can be stated as follows:

\[
T_m: \text{given two different decimal numbers, } 0 < a < 1, \text{ and } 0 < b < 1, \text{ decide if } a > b \text{ or } a < b.
\]

There are many possible mathematical techniques to solve a mathematical task of type \(T_m\) which could be developed by the PsETs individually, or during their discussion. I describe some of them in the following table:

<table>
<thead>
<tr>
<th>Code of techniques</th>
<th>General description of techniques</th>
</tr>
</thead>
<tbody>
<tr>
<td>(\tau_1)</td>
<td>Change (a) and (b) into integers, multiplying by an appropriate power of ten.</td>
</tr>
<tr>
<td>(\tau_2)</td>
<td>Use lexicographical orders to compare the decimals.</td>
</tr>
<tr>
<td>(\tau_3)</td>
<td>Add 0 digits where required to get the same number of digits in both decimals.</td>
</tr>
<tr>
<td>(\tau_4)</td>
<td>Change decimals into fractions with a common denominator and compare the numerators.</td>
</tr>
<tr>
<td>(\tau_5)</td>
<td>Subtract (b) from (a) or divide (a) by (b). When the result is less than 0 (for subtraction) or less than 1 (for division), (a &lt; b), otherwise (a &gt; b).</td>
</tr>
</tbody>
</table>

Table 1: Mathematical techniques for a mathematical task of type \(T_m\)

In addition, there are several possible mathematical techniques based on diagrammatical representations and number lines. For instance, one can represent both decimals by a rectangle or a circle diagram and then compare areas or sizes \((\tau_6)\), or locate both decimals on a number line and compare the positions \((\tau_7)\). Furthermore, to each correct mathematical technique, one might associate with one or more incorrect mathematical techniques. For example, when someone multiplies both decimals with different powers of ten, one does a similar but an incorrect mathematical technique of \(\tau_1\). This mathematical technique is denoted as \(\tau_1^-\), where the minus means “incorrect variation of \(\tau_1\)”. Hence, there will be at least a similar number of incorrect mathematical techniques to the correct ones.

The question b and also part of question a contain a didactical task \((T_d)\) as follows:

\[
T_d: \text{given pupils’ answers as stated to a task of type } T_m, \text{ determine what to do as a teacher to facilitate pupils’ learning.}
\]

Most didactical techniques to solve \(T_d\) relate to the mathematical techniques proposed to solve the task of type \(T_m\). When PsETs recommend teaching pupils by simply explaining a mathematical technique, for instance \(\tau_1\), this technique is coded as \(\tau_1^*\), so similar numbers of didactical techniques can be derived from the previous mathematical techniques. In addition, some didactical techniques...
can be variants of those didactical techniques. For instance, PsETs provide pupils with similar problems, such as comparing 0.5 and 0.25, they choose these decimals because pupils might simply recognise both decimals as a half and a quarter, and may then realise their original mistake. Many other possible didactical techniques might appear during the discussion, but space does not allow me to describe them in detail here. One common didactical technique is to build the mathematical task into a real word problem. PsETs may even say that the mathematical task presented in the HTT is too abstract to pupils, so they need to present it within a more familiar situation. Such a justification furnishes a technological discourse for the didactical technique, could conceivably even invoke a didactic theory.

Results

The analysis of answers to the task of type $T_m$ was mainly based on the PsETs’ written solutions, but I also looked at the video transcripts when I found some difficulties in categorising the mathematical techniques from the written solutions. In general, almost all mathematical techniques described in the reference models appeared in PsETs’ written answers, but some techniques were more common than others. The mathematical techniques presented by PsETs are summarised in the following table:

<table>
<thead>
<tr>
<th>Mathematical Techniques</th>
<th>$\tau_1$</th>
<th>$\tau_1'$</th>
<th>$\tau_2$</th>
<th>$\tau_3$</th>
<th>$\tau_4$</th>

Table 2: A summary of PsETs’ mathematical techniques for the task of type $T_m$

The most common mathematical techniques were adding 0s to equalise the number digits after the decimal point ($\tau_3$) and changing decimals into fractions ($\tau_4$) (Table 2). But when changing decimals into fractions, five PsETs could not change 0.45 into a fraction. One PsET said during the discussion: “We can change decimals into fractions, but I do not know how to change 0.45 into a fraction”. Among six PsETs who gave a correct mathematical technique of $\tau_4$, only two PsETs changed the fractions to have a common denominator and then compared numerators, whereas the others presented both decimals into simple fractions and compared intuitively. Five PsETs also provided the mathematical technique of representing decimals on a number line, but two of them placed the numbers in incorrect positions on the number line. One of these PsETs stated on her worksheet that she agreed 0.5 was greater than 0.45, but still represented the decimal numbers incorrectly on the number line (Figure 1). Another finding was that a PsET answered that 0.5 is greater than 0.45, but she could not represent 0.45 correctly as a shaded portion of a circle. Overall, only 71% of the mathematical techniques presented by the PsETs are correct.

Figure 1: A PsET’s incorrect number line representation of decimals
The total number of didactical techniques proposed by PsETs is greater than the number of those mathematical techniques because some pairs presented more than one didactical technique during their discussion. The most common didactical technique was a direct instruction of pupils based on how PsETs themselves solved the pupils’ task of type $T_m$. For instance, eight pairs said that they would instruct pupils to add 0 after 0.5 and compare the result to 0.45 ($\tau_3^*$), and seven pairs discussed direct instruction of the mathematical technique $\tau_4$, while three of these pairs could not change 0.45 into a fraction. The didactical technique related to number line representations was also discussed by eight pairs of PsETs, but two of them placed 0.45 incorrectly in relation to 0.5. For example, the following discussion shows how two PsETs shared their incorrect mathematical techniques $\tau_4$ and $\tau_7$ in order to produce possible didactical techniques.

**PsET A:** Let’s use a number line. Here is 0, and here is 0.1; 0.2. (She explained her drawing presented in Figure 1.)

**PsET B:** And so on.

**PsET A:** So, 0.5 is greater than 0.45.

**PsET B:** How can we know that 0.5 is greater than 0.45? I thought, using your number line, that one is greater than the other.

**PsET A:** How do you think?

**PsET B:** I am confused. I change them into fractions. From fractions, they can be represented in rectangle diagrams, so we can see them. For instance, we know that 0.5 is equal to a half.

**PsET A:** Hmm.

**PsET B:** If this is 0.45, what fraction is it? Later, it is drawn. From the drawing, pupils can compare, to see which one is greater.

From the discussion, PsET B might realise that her partner placed the two decimals incorrectly on the number line, but she did not have any idea on how to fix it. Instead, she proposed to change decimals into fractions and then suggested to represent the fractions into rectangle diagrams. However, it turned out that they could not change 0.45 into a fraction or represent it by a correct rectangle diagram. They appeared to lack a general technique to convert decimals into fractions.

In addition, five pairs suggested explaining to pupils how to change decimals into percentages, but three of them were in fact unable to do so correctly. For example, one PsET presented to his partner the mathematical technique of changing decimals into fractions. He changed 0.5 into 5/100 or 500%, but no-one realised the mistake. Furthermore, some PsETs also considered presenting the mathematical task into a contextual or real life problem, providing other decimal comparison problems, or giving some technological elements, such as writing 0s after the decimal point is rarely written but may be useful. In general, twelve pairs suggested reasonable didactical techniques, most of the techniques being classified as direct instruction of mathematical techniques. Two pairs suggested both reasonable and unreasonable didactical techniques, and the other two totally could not recommend any didactical technique.
Discussion and further remarks

An important point for this study is to explore the idea of HTT as an alternative method to investigate PsETs’ mathematical and didactical knowledge of comparing decimals. This method asks PsETs to demonstrate their collective development of mathematical and didactical knowledge as they solve the task because the design of tasks involves open constructed-responses and conversations among pairs of informants. This situation challenges PsETs to produce more than a single technique for each task. They shared their mathematical knowledge to provide didactical techniques for further pupil learning through a collaborative effort (Question b). This method is quite different from a diagnostic test in which PsETs’ knowledge is measured through a single correct answer, such as multiple-choice or complex multiple-choice questions in the TEDS-M study (Tatto et al., 2008). It is also different in that teachers’ didactical logos is developed in discussion with a peer.

The most common mathematical technique shared by PsETs was to put 0s after numbers behind the comma to equalise the number of digits for both decimals ($\tau_3$). This mathematical technique can be simply applied by PsETs because it reduces the comparison to the more familiar task of comparing two integers. The technique is valid for comparing two decimal numbers in $[0,1]$, but it does not work as immediately in other cases; so it is a more limited technique than, for instance, $\tau_4$.

When PsETs discuss how they might handle the didactical task, they tend to just explain, based on their mathematical techniques, how to solve the mathematical task. In fact, when they have an inappropriate mathematical technique for the mathematical task, they then struggle to provide an appropriate didactical technique during the discussion. With subtle didactical techniques in mind, they could conceivably realise their mathematical mistake; unfortunately, this was not observed in any case.

Finally, I conclude this study with two remarks. First, the mathematical task designed in the HTT did not involve a contextual or real life situation. Such a situation could both facilitate and add to the difficulty of the HTT, and variations of this type would be interesting to investigate. The second one is related to the PsETs’ collective discussion on didactical techniques. I expected that they could resolve their difficulties in constructing didactical techniques during their discussion in pairs, but some could not do that because none of them had an adequate mathematical technique for the first part. Therefore, the such problematic HTT may become a useful subject for a classroom discussion in the teacher education program in order to overcome both the PsETs’ own mathematical misconception and construct didactical techniques for their future tasks as teachers.

The article explores how future mathematics teachers (n = 26) at the end of their master studies notice moments in a lesson deemed important by experts and looks into their knowledge-based reasoning. A reflective task was given to the students and their written observation about the videoed mathematics lesson was compared against the expert analysis of the lesson. While all students commented on at least one important moment (the median was 3.5, expert rate 6), a third of their comments about these moments was of a subjective evaluation nature. They were mostly unable to provide a theoretical justification for their opinions. On the other hand, most students were able to suggest an alternative action to what they observed in the important moments of the lesson.

Keywords: Preservice mathematics teachers, teacher noticing, knowledge-based reasoning.

One of teachers’ specific skills is the ability to notice aspects of a mathematics lesson which “matter”. There is a body of literature on (student) teachers’ noticing skills showing the pattern of their attention to various aspects of lessons and investigating how it can be developed. In our previous work, we showed that while two-year master studies do not influence the pattern of attention much, even a short video-course does (Simpson, Vondrová, & Žalská, in press). After this course, student teachers (here students) described events rather than evaluated, noticed more of pupils’ actions rather than the teacher’s and paid more attention to the mathematical aspect of teaching rather than pedagogy. In a different study, we found that students paid limited attention to what experts considered to be crucial in the observed lesson (Vondrová & Žalská, 2015).

Theoretical framework

Professional vision means seeing phenomena in a situation from the area of expertise which are different from those arising from lay viewings of the same situation (Goodwin, 1994). According to Sherin (2007), professional vision consists of selective attention (what the teacher pays attention to, or marking (Mason, 2002)) and knowledge-based reasoning (how he/she reasons about it). Professional vision in education overlaps the idea of teacher noticing: “teachers’ professional vision involves the ability to notice and interpret significant features of classroom interactions” (Sherin & van Es, 2009, p. 22).

Some studies focus on the selective attention only, others take into account knowledge-based reasoning. There is a difference in noticing if the event is only described or reasoned about. For example, Sherin and van Es (2009) introduce Stance and distinguish Describe, Evaluate (from a subjective point of view) and Interpret (from a theoretical point of view). Stockero (2008) introduces five levels of reflection: Describing, Explaining, Theorizing (references to research or
course readings to support the analysis, or substantial evidence from transcripts and/or pupil written work), Confronting (alternate explanations for events and/or considering others’ points of view), Restructuring (theorising and confronting to consider alternative instructional decisions).

It is the reflection on observation which is considered to be crucial to developing professional vision. Much of the research is focused on “video club” interventions where participants are guided to reflect on videoed lessons (e.g., Friesen, Dreher, & Kuntze, 2015; Liston & Gill, 2011; Simpson, Vondrová, & Žalská, in press; Star, Lynch, & Perova, 2011; Stockero, 2008). It has been shown that even a short video-course has an impact on noticing skills such as more specific comments, more attention to mathematical thinking and less on pedagogy, more attention to pupils and less to the teacher.

Studies on noticing mostly do not distinguish between less and more important events in a lesson to be noticed. Star, Lynch and Perova (2011, p. 120) even write:

[…] some classroom events are certainly more important than others, and it is critical that preservice teachers be able to attend to and interpret these important events. However, we believe that teachers do not have the ability to notice important events […] until after they have developed the ability to notice (even trivial) classroom features.

The authors do say that the ultimate goal is for teachers to be able to notice important classroom events and they admit that it is not clear yet “whether it is better to focus first on improving teachers’ awareness of the full range of (trivial and important) events (as was done here [in their course]) or to focus explicitly on only important events from the outset” (p. 132).

If researchers do look for important moments, they mostly find them in the mathematics of the lesson. For example, Star, Lynch and Perova (2011) identified ‘important questions’ in all observation categories, with the fewest from classroom environment and most from pedagogical choices made by the teacher, mathematical content addressed in the lesson and teacher-initiated communication. They say that “it is always more important to observe mathematical content carefully than to observe classroom environment carefully” (p. 132). In our research (Vondrová & Žalská, 2015), important moments are those which have been shown to play the key role in pupils’ learning of mathematics. Hiebert and Grouws (2007) take it for well documented that pupils learn best when they have the most opportunity to learn. This concept is defined as “circumstances that allow students to engage in and spend time on academic tasks such as working on problems, exploring situations and gathering data, listening to explanations, reading texts, or conjecturing and justifying” (Kilpatrick, Swafford, & Findell, eds., 2001, p. 333). The opportunities to learn are influenced, among others, by “the kinds of tasks [teachers] pose, the kinds of questions they ask and responses they accept, the nature of the discussion they lead” (Hiebert & Grouws, 2003, p. 379). Finally, two key features of teaching that promotes conceptual development are part of important moments for us (ibid, p. 383, 387): teachers and pupils attend explicitly to concepts; pupils struggle with important mathematics.

The above was the starting point of our expert analysis of lessons. This methodology is not unknown in research on noticing. In (Blomberg, Stürmer, & Seidel, 2011), experts prepared items for rating video clips and an expert norm value system. In (Star, Lynch, & Perova, 2011), important
features of the lesson were selected by two raters and then used as a measure for assessing the participants’ ability to notice. To validate measures to be used for assessing the ability to notice, the authors identified features of the lesson to be noticed and compared them against the video analysis made by six experienced teachers. Mitchell and Marin (2015) calculated the percent alignment between participants’ scores and the master rater scores. Stockero, Rupnow and Pascoe (2017) made an expert analysis to determine pivotal teaching moments. We used the same process in our previous research to determine so called expert mathematics specific phenomena, i.e., the events in the lesson which experts deemed important for the successful learning of mathematics (Vondrová & Žalská, 2015). We found out, among others, that future mathematics teachers paid limited attention to the expert phenomena both at the beginning and at the end of their two-year master studies.

The study has two research questions: How do future mathematics teachers notice moments, deemed important by experts, at the end of their master studies? What is their knowledge-based reasoning?

Methodology

We asked students to observe a video of a whole Czech Grade 8 mathematics lesson from TIMSS Video Study 1999. The piloting stage showed that the video included teaching practices understandable for students which they could relate to. The video is self-contained (the lesson has a clear introduction and ending, so that the knowledge of the previous lessons is not necessary) and it is quite rich in generic and subject-specific content (Blomberg, Stürmer, & Seidel, 2011) which is reasonably observable. The lesson leads to the discovery and formulation of Thales’ theorem: “For any triangle \(ABC\), it holds: a) If \(ABC\) is a right-angled triangle with hypotenuse \(AB\), vertex \(C\) lies on circle \(k\) with diameter \(AB\). b) If vertex \(C\) lies on circle \(k\) with diameter \(AB\), \(ABC\) is a right-angled triangle with hypotenuse \(AB\). Circle \(k\) is called Thales’ circle with diameter \(AB\).”

The participants are future mathematics teachers of pupils aged 12 – 19 studying a two-year master studies at our university. In their final semester in January 2016, the whole group (\(n = 32\)) was asked to watch a video of the lesson and write observations. They were to write what they “considered important and noteworthy”. They were told that there “were no correct or wrong answers” and that they should “feel free to write their honest views”. We received 26 written observations. The majority of students were in their mid-twenties and had teaching experience only from two fortnights of field placement at the primary and secondary schools.

The analysis of data was twofold. First, we used an expert analysis of the lesson in order to capture attention to important moments. Two authors of the paper, both mathematics educators, and four educators of future teachers of other subjects independently watched the lesson, repeatedly met and finally agreed on six important moments (here expert phenomena, Tab. 1). Naturally, what is considered important is rather subjective. We based our identification of such moments on the considerations from research on effective teaching presented above. By including experts from other fields, we ensured that the phenomena were really observable and not only apparent to an expert in mathematics education. In order to be coded as an expert phenomenon, the unit had to have a connection to mathematics; e.g., “The game was motivating for pupils.” is not coded as M1 (Tab. 1).
Second, to capture the participants’ knowledge-based reasoning, we modified Stockero’s (2008) levels of reflection: *Description* – a description of what can be seen in the lesson; *Explanation* – a naïve explanation of what was seen in the lesson using one’s experience as a pupil or as a teacher; *Theorising* – interpreting what was seen using a theory; *Evaluation* – evaluation from a subjective point of view; *Alteration* – suggestion of an alternative approach to what was seen; *Prediction* – elaborating possible consequences of the event seen. We did not distinguish the depth of alterations or the quality of the theory used and we did not follow if the students’ reasoning was in line with that of experts (this is something which can be done in further research).

### Table 1: Results of the expert analysis of the lesson to be observed

During the analysis, we first searched written observations for instances in which a student commented on M1 to M6. All parts commenting on the same phenomenon became one unit of analysis coded as M1, M2, etc. Thus, each written observation was assigned at most one code M1, M2, etc. We got 90 units from 26 students. Each was assigned one or more of the attributes capturing knowledge-based reasoning. An example is the unit: “The teacher accelerated the phase of the exact formulation of Thales’ theorem very much and did not give pupils enough time to independently reach a conclusion. The teacher tried too hard so that Thales’ theorem is formulated in a textbook way which, in my opinion, was for the worse.“ It was coded as Description, Evaluation, Explanation. Or the unit: “Pupils tried to formulate the theorem about the discovered property. I would first ask them to describe the property in their own words and only afterward to formulate the theorem mathematically. The pupils would not get tangled into it. The teacher puts down the theorem in an informative way, she emphasises that it is a right angled triangle. This can prevent some mistakes.” It was coded as Description, Evaluation, Alteration, Prediction. All the units were coded by two authors independently and any discrepancy was discussed until a 100% agreement was reached.

### Findings

Fig. 1 shows box and whisker plots and a bar chart of the number of expert phenomena M1 to M6 per student/written observation. The box and whisker plot on the left concerns all 90 units of analysis. Bearing in mind that we focus on knowledge-based reasoning, we discounted the units.
coded as Description only (the middle box and whisker plot, the number of units 82) and as Evaluation only, i.e., units coded at least Explanation (the box and whisker plot on the right, the number of units 59). The high median (3.5, the maximum being 6) of the number of comments on expert phenomena per student is not a surprise as the phenomena were rather visible in the lesson even to educators in other fields than mathematics. However, a third of the units (31) were of a subjective or descriptive nature only; students evaluated what they saw without any theoretical support: e.g., “I like that the teacher forces pupils to explain concepts (the game).” “The experiment leading to Thales’ theorem was nice.”

**Figure 1: The number of noticed expert phenomena M1 – M6 per student/observation**

The median for the number of *elaborated comments* on expert phenomena per student (Explanation and further) drops to nearly 2 (and there are even 2 students who have none). Tab. 2 shows the distribution of the 59 elaborated comments in terms of the phenomena noticed.

**Table 2: Distribution of elaborated comments among expert phenomena and the nature of elaboration**

The most commented on were M2 and M5. Both concern the core of the lesson – pupils experimenting to discover Thales’ circle and formulating Thales’ theorem. Fewer students (12) explicitly elaborated on the fact that the teacher also led pupils to see the inverse implication (M4). It is worth noticing that only about 58 % of students at the end of their master studies somehow
elaborated on the core activity of the lesson. Only 6 students (about 23%) elaborated on the “problems to think about” the teacher used at the end. Note that the experts deemed M6 important because the first problem the teacher posed can be answered intuitively without knowing Thales’ theorem and thus there is really nothing for pupils to “think about”. On the other hand, the second problem is too difficult for the pupils as they have just learned about the theorem and moreover, they got no time to think about it.

Finally, we will look into the nature of comments. There were very few predictions in written observations. It appears that it does not come as natural to the students to comment on what might be the consequences of what they see in the lesson. There were 9 theorising units made by 6 students and 32 alterations made by 22 students. Tab. 3 depicts the types of theorising comments and suggestions for alternatives with examples (some units include two types and thus the total in Tab. 3 does not match the total in Tab. 2). Few units included the theory explicitly. Students mostly proposed alternatives concerning subject matter, for the implementation of the task to discover the theorem. They were suggestions of rather small changes. Students also wanted to modify the teaching methods used. Many proposed a constructivist way of teaching with a bigger involvement of pupils which is in view with the approach taken in their mathematics education courses.

Table 3: Types of theorising comments and proposed alterations

Discussion and conclusions

In our previous study (Vondrová & Žalská, 2015), we found out for a different group of future mathematics teachers at the end of their master study (n = 53) that they did not notice the moments experts in mathematics education deemed important for the success of the lesson (the median for
the number of expert phenomena per student was 2, the expert rate was 7). In the present study, the success rate of the students was higher (median is 3.5, the expert rate is 6). Even though we cannot directly compare the two results as the students saw different lessons (and the choice of the lesson matters, Simpson, Vondrová, & Žalská, in press), we can tentatively suggest one possible cause for it. The expert analysis was done in cooperation with teacher educators from other fields and thus, chances are that the phenomena selected by experts are more visible than in our previous study in which the phenomena were selected by experts in mathematics education only and were rather subtle for student teachers to notice. It raises the question of explicitness of phenomena to be seen in the video (seen by experts in mathematics education, by experts in other fields, by pre-service teachers) which impacts the nature of observations and consequently their perceived quality.

All 26 students commented on at least one expert phenomenon. However, only 15 students were able to elaborate on them in a professional way. Thus, 11 students, just before entering teaching profession, did not show knowledge-based reasoning in their observations. A third of the 90 units were of a descriptive or evaluative nature. It might have several reasons. First, (and it is the limitation of any study on noticing investigating written observations), we only reason from the written work, we cannot really say that students do not have sufficient knowledge. For example, taking into account the fact that during their mathematics education courses the instructor emphasises the use of theory on examples from teaching, it is somewhat disappointing that only 6 students could use theoretical notions for the analysis of events in the lesson. Students did not theorise spontaneously. But if we asked them to justify their subjective evaluations, they might be able to use theory to do so. Second, it may give more credit to what Star, Lynch and Perova (2011) say that student teachers have to first be able to attend to the trivial features of the classroom in order to notice important moments.

On the other hand, 22 students suggested at least one alternative for events deemed important by experts. Kersting et al. (2010) claim that suggestions for instructional improvement might be a sign of expertise of practising teachers. They found that “students of teachers who included suggestions for instructional improvement that they connected to mathematical content showed greater learning gains than did students of teachers who included either general pedagogical suggestions or no suggestions at all” (p. 178). Our students suggested alternatives mainly for the core activity of the lesson seen as important by experts. However, they failed to comment on and suggest alternatives for the time of the lesson in which the teacher used two “problems to think” in an insufficient way. Also in (Vondrová & Žalská, 2015), we found an insufficient attention on the choice of tasks and its cognitive demands. This is something which should be stressed in their university studies as the choice of tasks is one of the key features of a successful mathematics lesson (Hiebert et al., 2003).

The limitation of our study is that a) we presumed that a noticed phenomenon is a recorded phenomenon which does not have to be the case and b) the phenomena seen as important by the six experts do not have to be seen as important by experienced teachers. This will be pursued further. Our study provided more insight into the knowledge-based reasoning of future mathematics teachers at the end of their master study. Unlike in most studies on noticing, it focused on features of the lessons which are considered by research as important. It shows that students need more explicit support in order to be able to connect theory and practice, namely to interpret what they see
in the lesson in terms of theory, and to notice and interpret the choice of tasks made by the teacher and the nature of their implementation in the lesson. It remains to be seen how the attention to expert phenomena will be influenced by teaching experience.

Acknowledgment

The study has been financially supported by project PROGRES Q17 Teacher preparation and teaching profession in the context of science and research.
