Key words: K-562 cells/Oxidative stress/Apoptosis/Energy substrates/Hyperglycemia/DNA damage

Aim. The study was carried out to evaluate the effect of several substrates on oxidative stress induced apoptosis and in K-562 cells.

Methods. Glucose at 5, 11 and 30 mM concentrations was tested, as well as 5 mM glutamine and 5 mM fructose. The cells were exposed to tert-butylhydroperoxide (tBH) and apoptotic cells were evaluated by flow cytometry with FITC-Annexin V and propidium iodide. The effect of glucose concentration on DNA damage was evaluated using hydrogen peroxide and electrophoretic “DNA comets” assay at 5 mM and 30 mM glucose concentrations.

Results. The exposure of cells to tBH resulted in increased number of apoptotic cells, and this effect was prevented by administration of an antioxidant – N-Acetyl cysteine. Rising concentrations of glucose added to the toxic effect of tBH; we also observed some toxic effect of fructose and no effect of glutamine. We found higher susceptibility to hydrogen peroxide induced DNA damage with 30 mM glucose concentration.

Conclusion. Hyperglycemia increases the cell’s susceptibility to oxidative stress and it also amplifies oxidative DNA damage. Glutamine – when used as a sole energetic substrate – showed no protective effect against oxidative stress.

INTRODUCTION

In the past decade considerable evidence has been shown that there is a tight link between energy metabolism of the cell, oxidative stress, and apoptosis1,2.

Glycolysis is a universal metabolic pathway providing energy by converting glucose into pyruvate. Under aerobic conditions pyruvate is oxidized to CO2 and H2O in mitochondria providing ATP by oxidative phosphorylation. Using O2 as final acceptor of electrons makes the breakdown of glucose a lot more efficient than in the case of lack of oxygen when pyruvate is converted to lactate. At the same time, however, it generates oxidative stress.

Oxidative stress is a result of overproduction of reactive oxygen species (ROS) which are produced in aerobic organisms by electron transport chain of mitochondria. The ROS are highly reactive agents readily attacking macromolecules including nucleic acids. Under physiological conditions, the complex I of the electron transport chain seems to be the major site of ROS production3,4.

Apoptosis is energy-demanding cellular death which is regulated in several ways5. Mitochondria play a key role in the signalling pathway resulting in apoptosis6. Once the cascade is activated by the cell death stimuli (e.g. TNF-α), caspases-8 and -10 are cleaved to their active forms and mitochondria release cytochrome C and Apoptosis Inducing Factor into the cytoplasm7. Released cytochrome C then activates the initiator caspase-9 which consequently activates the effector caspases-3 and -7. These effector caspases are also directly activated by the initiator caspases-8 and -10. Prolonged oxidative stress as well as DNA damage are some of the triggers of apoptosis that have been identified.

We hypothesized, that the susceptibility of the cell to oxidative stress and apoptosis is affected by the metabolic state of the cells. For this reason the ability of the cell to withstand the toxic effect of an oxidizing agent may vary significantly when different substrates are metabolised as a source of energy. In clinical practice a similar situation occurs in intensive care when a patient with varying blood glucose control and energy substrate availability is exposed to oxidative insults (e.g. ischaemia/reperfusion, hyperoxaemia, etc.).

MATERIAL AND METHODS

Cell culture and experimental condition

The K-562 commercial cell line was used in this experiment. The cells were cultured in RPMI-1640 medium supplied with 10% bovine fetal serum and 1% L-glutamine-streptomycine. They were maintained in the exponential growth phase by regular centrifugation and resuspension in fresh RPMI medium.

To avoid alteration of results by the constituents of RPMI medium the cells were centrifuged and resuspended in experimental medium for the experiment. This was prepared individually based on Krebs’ medium and con-

Flow cytometry experimental protocol
The experimental medium was supplied with either 5 or 11 or 30 mM glucose, or 5 mM fructose, or 5 mM glutamine. An 8 hrs incubation in these media was followed by 20 min exposure to 250 or 500 μM tert-butylhydroperoxide (tBH) with a control group not exposed to containing 24 mM NaHCO₃, 120 mM NaCl, 4.8 mM KCl, 1.2 mM KH₂PO₄, 1.2 mM MgSO₄, and 1.2 mM CaCl₂.

All chemicals were purchased from Sigma-Aldrich, except for FITC-Annexin purchased from Molecular Probes via Interchim dealer.
High glucose increases susceptibility to oxidative-stress-induced apoptosis and DNA damage in K-562 cells

Fig. 1. Cytometric detection of apoptosis with Annexin-FITC (FL1-H) and propidium iodide (FL3-H) - cells exposed to different concentrations of tBH; glucose 11 mM. The principle of the staining is based on high affinity of Annexin to phosphatidylserine (PhS). In normal cells, PhS is present solely on the cytoplasmic surface of the cell membrane where it cannot be accessed by Annexin. During the process of apoptosis, PhS is translocated to the outer layer of the cell membrane and the cell will become positive in Annexin staining. Propidium iodide (PI) does not pass through intact cell membrane and this is why it can be used to distinguish cells with compromised membrane. A cell positive in Annexin but negative in PI staining (lower right quadrant) can therefore be considered as apoptotic.

Fig. 2. The protective effect of N-Acetyl cysteine – percentage of viable cells (*p<0.05 vs. tBH 1000 μM) at 1, 2 and 4 mM N-Acetyl cysteine concentrations.

DNA comets experimental protocol

The experimental medium was supplied with either 5 or 30 mM glucose; the cells were incubated in these media for 16 hrs. After the incubation the cell suspension was mixed with low-melt agarose at 37 °C, spread on prepared agarose-covered glass slides and cooled to 4 °C. The slides were then exposed to 1 mM Hydrogen Peroxide (H₂O₂) for 5 min with a control group not exposed to H₂O₂. Hydrogen Peroxide was then washed off by three-fold rinsing in PBS and the cells were lysed on the slides with a solution containing 2.5 M NaCl, 100 mM EDTA, 10 mM Tris-Base, 10% DMSO and 1% Triton X-100 detergent. Subsequently electrophoresis was conducted for 30min at 25V/300mA. To visualize DNA fragments, the slides were stained with propidium iodide in a dark chamber and observed at 488 nm excitation wavelength in a fluorescence microscope (Fig. 3). Recorded images were analysed with the CometScore software available as freeware from TriTek corporation at http://autocomet.com/products_cometscore.php. “Tail moment” was used...
to imply the extent of DNA damage, as it includes both length of the tail and percentage of DNA contained in the tail. Tail moment was calculated automatically by the evaluation software.

Statistical Analysis

A two-way ANOVA was applied to determine the statistical significance of the effect of glucose and tBH concentrations on the percentage of surviving cells. The Mann-Whitney U test was used to compare the effect of different substrates and the results of the DNA comets assay. All statistical tests were performed at the 5% significance level. All the results were obtained using Statistica software, StatSoft, Inc. (2007). STATISTICA (data analysis software system), version 8.0. www.statsoft.com.

RESULTS

The results of flow cytometry measurements are presented as the percentage of viable cells (detected by flow cytometry using Annexin-FITC and PI staining) after the final incubation of the experimental protocol. There were nine separate incubations and measurements for each particular condition. We observed a clear toxic effect of tBH due to the non-normal character of the data (0–100%) variance homogeneity was violated. A Box-Cox transformation was used to normalise the variance and data analysis was repeated. The results of the analysis of the transformed data were identical.
High glucose increases susceptibility to oxidative-stress-induced apoptosis and DNA damage in K-562 cells

DISCUSSION

In this study tBH had cytotoxic, apoptosis-inducing and dose-dependent effect on K-562 cells. We proved that high glucose concentrations add to the effect of tBH. As it was prevented by N-Acetyl cysteine – an antioxidant – it is clearly related to oxidative stress. The explanation for this may be the metabolic linkage between glucose breakdown and antioxidant protection of the cell (Fig. 4). Since tBH oxidizes the -SH groups it attenuates the cell’s ability to protect against oxidative stress rather than directly inducing it. The -SH group is a key structure of action in glutathione – one of the most important mechanisms of cellular antioxidant defense. Reduced glutathione is essential for the breakdown of hydrogen peroxide via glutathione peroxidase. Once oxidized in this reaction, glutathione forms dimers and can only be restored with the reduced form of NADP. The source of reduced NADP within the cell is the pentose phosphate shuttle, an alternate metabolic pathway of glucose sharing its first step with glycolysis. The next step of the pentose phosphate shuttle is catalysed by specific enzyme glucose-6-phosphate dehydrogenase which is notably inhibited by high glucose concentrations. This is why high concentrations of glucose lead to increased glycolysis, mitochondrial metabolic activity and subsequently ROS production but at the same time they block production of NADP, thus attenuating the antioxidant protection of the cell. We suggest that in this way, high glucose concentration increases the toxic effect of an oxidizing agent. This finding is in agreement with other authors’ observations that high rate of substrate influx to mitochondria induces cell sensitivity to oxidant-induced apoptosis. The DNA damage observed in cells at high glucose concentrations can be explained in the same way as the additive effect of glucose to tBH – increased ROS production together with insufficient restoration of glutathione.

Fructose enters the glycolytic pathway down the flow at the level of triose-phosphates and therefore bypasses the first step of glycolysis – its most important regulatory mechanism. As a result, the breakdown of fructose proceeds in a fast and rather uncontrolled manner and increases mitochondrial ROS production. This is probably not substantial under otherwise stable conditions but may become critical when the cell has to challenge further oxidative insults. This is a possible explanation why fructose proved to be toxic to cells only at high levels of tBH.

Glutamine has been reported to have certain anti-oxidant and anti-apoptotic capabilities. In our experiment, however, we found no protective effect of glutamine. The reason for this might be that glutamine was used here as the only available substrate for the cells and not just added as extra treatment.

The concentration of glucose of 30 mM is quite high, and may already have considerable osmotic effect. To ensure that this effect did not falsify our results, we conducted a limited series of experiments with media containing 5 mM D-glucose and 25 mM L-glucose which is not metabolized by the cells. The results were similar to those obtained with 5 mM D-glucose only (data not shown).

CONCLUSION

We conclude, that higher glucose concentrations in culture media increase the demands of the antioxidative mechanisms and thereby make the cell more susceptible to oxidative-stress-induced apoptosis. The same effect also results in amplification of oxidative-stress-induced DNA damage in cells cultivated in high glucose media.

ACKNOWLEDGEMENT

The authors thank to Cecile Cottet and Christiane Chauvin from INSERM U844 for their willing help with flow cytometry and cell culture.

The authors claim no conflict of interests. The study was funded by INSERM; all the equipment used came from INSERM U884 laboratory.
