Abstract—This paper provides a bound on the number of numeric operations (fixed or floating point) that can safely be performed before accuracy is lost. This work has important implications for control systems with safety-critical software, as these systems are now running fast enough and long enough for their errors to impact on their functionality. Furthermore, worst-case analysis would blindly advise the replacement of existing systems that have been successfully running for years. We present here a set of formal theorems validated by the PVS proof assistant. These theorems will allow code analyzing tools to produce formal certificates of accurate behavior. For example, FAA regulations for aircraft require that the probability of an error be below $10^{-9}$ for a 10 hour flight [1].

I. INTRODUCTION

Formal proof assistants are used in areas where errors can cause loss of life or significant financial damage as well as in areas where common misunderstandings can falsify key assumptions. For this reason, formal proof assistants have been much used in floating point arithmetic [2], [3], [4], [5], [6]. Previous references just link to a few projects using proof assistants such as ACL2, HOL [7], Coq [8] and PVS [9].

All these projects deal with worst case behavior. Recent work has shown that worst case analysis is meaningless for applications that run for a long time. For example, a process adds numbers in $\pm 1$ to single precision, and therefore has a round-off error of $\pm 2^{-25}$. If this process adds $2^{25}$ items, then the accumulated error is $\pm 1$, and note that 10 hours of flight time at operating frequency of 1 kHz is approximately $2^{25}$ operations. Yet we easily agree that provided the round-off errors are not correlated, the actual accumulated error will be much smaller.

Developments in probability share many features with developments in floating point arithmetic:

1) Each result usually relies on a long list of hypotheses. No hypothesis can be removed, but slight variations induce a large number of results that look almost identical.
2) Most people that use the results are not specialists in the specific field. They want a trustworthy result but they are not proficient enough to either select the best scheme or detect minor faults that can quickly lead to huge problems.

For these reasons, we are strongly of the opinion that validation of a safety-critical software using probability should be done using an automatic proof checker. We present in Section II the model that we are using. Section III presents our formal developments in probability. The Doobs-Kolmogorov inequality provides an effective way to compute the probability that a piece of software will successfully run within an acceptable error bound.

This work is connected to continuous space Markov random walks or renewal-reward processes though these applications focus on asymptotic behavior [10], [11]. We want to precisely bound the probability of remaining within bounds for a given number of steps. This is connected to ruin probabilities [12] and the Doobs-Kolmogorov inequality for martingales [13]. In the rest of this text, we assume that the created round-off and measure errors are unbiased independent random variables or that their expectation conditional to the previous errors is zero.

II. STOCHASTIC MODEL

A. Individual round-off errors of fixed and floating point operations

We are dealing with fixed or floating point numbers. A floating point number represents $v = m \times 2^e$ where $e$ is an integer and $m$ is a fixed point number [14]. IEEE 754 standard [15] uses sign-magnitude notation for the mantissa and the first bit of the mantissa is implicit in most cases leading to the following definition where $s$ and all the $b_i$ are either 0 or 1 (bits).

$$v = (-1)^s \times 1.b_1 \cdots b_{p-1} \times 2^e$$

Some circuits such as TMS320 uses two’s complement notation for $m$ leading to the following definition [16].

$$v = (1.b_1 \cdots b_{p-1} - 2 \times s) \times 2^e$$

For both notations, we define for any representable number $x$, the unit in the last place function where $e$ is the exponent of $x$ as above. In fixed point notation, $e$ is a constant provided by the data type.

$$\text{ulp}(v) = 2^{e-p+1}$$

A variable $v$ is set either by an external sensor or by an operation. Trailing digits of numbers randomly chosen from a logarithmic distribution [17, p. 254-264] are approximately uniformly distributed [18]. So we can assume that if $v$ is a
data obtained by an accurate sensor, the difference between $v$ and the actual value $\pi$ is uniformly distributed in the range $\pm \text{ulp}(v)/2$. We can model the representation error $v - \pi$ by a random variable $X$ with expectation $\mathbb{E}(X) = 0$ and variance $\mathbb{E}(X^2) = \text{ulp}(v)^2/12$. The sensor may be less accurate leading to a larger variance but it should not be biased.

Round-off errors created by operators are discrete and they are not necessarily distributed uniformly [19]. For each operator $\odot$ implementing the real operation $\ast$, we define

$$X = V \odot W - V \ast W$$

where $V$ and $W$ are number distributed logarithmically over specified ranges. The distribution of $X$ is very specific but we verify that the expectation is $\mathbb{E}(X) = 0$ and we bound its variance $\mathbb{E}(X^2)$.

Fixed point additions do not create any additional round-off error provided its output is in the same format as its input. Reducing the format of a fixed point number creates a uniformly distributed round off error provided the input was logarithmically distributed [18].

### B. Round off errors of an accumulation loop

We will use two examples. The first one is given in listing 1. It sums data produced by a fixed point sensor $x_i$ with a measure error $X_i$.

#### Listing 1. Simple discrete integration from [20]

```c
1  a_0 = 0
2  for (i = 0; i < n; i = i + 1)
3    a_{i+1} = a_i + x_i
```

We can safely assume that $X_i$ are independent identical uniformly distributed random variables over $\pm \text{ulp}(x_i)/2$. Data are fixed point meaning that the sum $a_i + x_i$ does not introduce any rounding error and the weight of one unit in the last place does not depend on $x_i$ so we write ulp instead of ulp($x_i$). After $n$ iterations, we want the probability that the accumulated measure error have always been constrained into user specified bounds $\epsilon$. Using the Doobs-Kolmogorov inequality of Theorem 3 where $S_i = \sum_{j=1}^{i} X_j$, we have that

$$\mathbb{P}\left(\max_{1 \leq i \leq n} \{|S_i|\} \leq \epsilon \right) \leq 1 - \frac{\text{ulp}^2}{12 \epsilon^2}.$$  

The second example is given in listing 2. It solves initial value problem (IVP) ordinary differential equations (ODE) by computing an incremental slope $\Phi(t_i, h, x_i, f)$ based on the current time $t_i$, the current step size $h$, the current value of the function $x_i$ and the differential equation $x'(t) = f(t, x(t))$. The function $\Phi$ may be very simple using Euler’s explicit method or more complex using any Runge-Kutta method or any implicit method. We focus here on scalar ODEs although our analysis may apply to vectors. Line 4 assume for the sake of simplicity that $h_i$ is a constant although this is not necessary.

#### Listing 2. Solving initial value problem ordinary differential equations [21]

```c
1  for (i = 0; i < n; i = i + 1) {
2    x_{i+1} = x_i + h_i \times \Phi(t_i, x_i, h, f)
3    t_{i+1} = t_i + h_i
4    h_{i+1} = h_i
5  }
```

Our first guess was to introduce a sequence of random variables $\{X_n\}$ that models the difference introduced by round-off errors at step $i$. In most cases, $\Phi$ introduces a drift due to higher order effect of random variables and a drifted correlation between the error introduced at step $i + 1$ and errors on the previous steps. For example, the square of a rounded value $v + V$ where $v$ is the stored value and $V$ is a random variable, introduces a positive drift due to $V^2$ term that is always positive. So we model the effect of the round-off error by two terms $X_i$ and $Y_i$. We use the Doobs-Kolomogorov inequality of Theorem 3 for the sequence $\{X_n\}$ and worst case error analysis for the sequence $\{Y_n\}$ setting the following conditional expectation

$$\mathbb{E}(X_n; X_1 \cdots X_{n-1}) = 0.$$  

Random variables $X_{i+1}$ and $Y_{i+1}$ account for the round-off and propagated errors introduced by replacing

$$x_i + X_i + Y_i + h_i \times \Phi(t_i, x_i + X_i + Y_i, h, f)$$

with

$$x_i \odot h_i \odot \Phi(t_i, x_i, h, f)$$

where $\Phi$ is evaluation of $\Phi$ in computer. First order effect of round-off errors created are accounted in $X_{i+1}$. Higher order effect of round-off errors created and propagated effect of $X_i$ and $Y_i$ in $\Phi$ are accounted in $Y_{i+1}$.

$\{X_n\}$ is constructed to contain only independent random variables with no drift $\mathbb{E}(X_i) = 0$ and we only need to bound their variance $\mathbb{E}(X_i^2)$. We will do worst case analysis on $\{Y_n\}$ and we bound each $Y_i$ with interval arithmetic [22]. Software such as Fluctuat [23] is already able to distinguish between first order and higher order error terms.

### III. PROBABILITY DISTRIBUTION OF BEING SAFE

#### A. Probability

We have two main choices in presenting an account of probability: one is to take an informal approach, the second involves taking foundational matters seriously. In this paper we will consistently try to present matters informally except for Section III-B, however the reader should be aware that the PVS system underlying these results is built on the firm foundations for probability theory (using measure theory) [24], [25]. A middle way between extreme formality and an accessible level of informality is to be found in [13].

We begin by defining the distribution function of a random variable.

**Definition 1:** A random variable $X$ has distribution function $F$, if $\mathbb{P}(X \leq x) = F(x)$.
As we will be studying continuous random variables, these are defined as follows:

**Definition 2:** A random variable $X$ is continuous if its distribution function can be expressed as

$$F(x) = \int_{-\infty}^{x} f(x) dx$$

for some integrable function $f : \mathbb{R} \rightarrow [0, \infty)$. We call the function $f$ the probability density function for the random variable $X$.

As an example of a continuous random variable, consider the temperature $T$ at a certain point in an industrial process. Even if an attempt is being made to hold this temperature constant, there will be minor fluctuations, and these can be modeled mathematically by assuming that $T$ is a continuous random variable.

The other concept we will need is that of dependent and independent random variables. Suppose we model the outcomes of the tossing of two coins $C_1$ and $C_2$ by random variables. Provided there is nothing underhand going on, we would expect the result of tossing the first coin to have no effect on the result of the second coin, and vice versa. If this is the case, then we say that $C_1$ and $C_2$ are independent. Consider an alternative scenario in which having tossed the coin $C_1$ and discovered that it has come up “heads”, and we now define the random variable $C_2$ to be: the outcome: “the downward facing side of the coin $C_1$ is tails”. In this case the random variables $C_1$ and $C_2$ are dependent.

The other idea we must address is that of conditional probability.

**Definition 3:** We define the probability of “$A$ given $B$” (written $\mathbb{P}(A; B)$) as:

$$\mathbb{P}(A; B) = \frac{\mathbb{P}(A \cap B)}{\mathbb{P}(B)}$$

whenever $\mathbb{P}(B) > 0$.

As an example: if event $A$ is “I am carrying an umbrella” and event $B$ is “it is raining”, then $\Pr(A; B)$ is the probability that “I am carrying an umbrella given that it is raining”. Note that although in general $\mathbb{P}(A; B) \neq \mathbb{P}(B; A)$, in this particular case, if you live in Perpignan or Manchester, then on most days: $\mathbb{P}(A; B) = \mathbb{P}(B; A)$, though for rather different reasons.

**B. A Formal Development of probability**

**Definition 4:** A $\sigma$-algebra over a type $T$, is a subset of the power-set of $T$, which includes the empty set $\{\}$, and is closed under the operations of complement, countable union and countable intersection.

If $T$ is countable – as it is for discrete random variables – then we may take $\sigma = \wp(T)$; if the set $T$ is the reals – as it is for continuous random variables – then we make $\sigma = B$: the Borel sets.

**Definition 5:** A Measurable Space $(T, \sigma)$ is a set (or in PVS a type) $T$, and a $\sigma$-algebra over $T$.

**Definition 6:** A function $\mu : \sigma \rightarrow \mathbb{R}_{\geq 0}$ is a Measure over the $\sigma$-algebra $\sigma$, when $\mu(\{\}) = 0$, and for a sequence of disjoint elements $\{E_n\}$ of $\sigma$:

$$\mu \left( \bigcup_{n=0}^{\infty} E_n \right) = \sum_{n=0}^{\infty} \mu(E_n).$$

**Definition 7:** A Measure Space $(T, \sigma, \mu)$ is a measurable space $(T, \sigma)$ equipped with a measure $\mu$.

**Definition 8:** A Probability Space $(T, \sigma, \mathbb{P})$ is a measure space $(T, \sigma, \mu)$ in which the measure $\mathbb{P}$ is finite for any set in $\sigma$, and in which:

$$\mathbb{P}(X^c) = 1 - \mathbb{P}(X).$$

The PVS development of probability spaces in Figure 1, takes three parameters: $T$, the sample space, $S$, a $\sigma$-algebra of permitted events, and, $\mathbb{P}$, a probability measure, which assigns to each permitted event in $S$, a probability between 0 and 1. Properties of probability that are independent of the particular details of $T$, $S$ and $\mathbb{P}$ are then provided in this file.

If we wished to discuss continuous random variables then we would partially instantiate this PVS file with $T = \text{real}$, and $S = \text{borel_set}$. If we go further and also specify $\mathbb{P}$, we will have described the random variable distributions as well. Of particular interest later is the fact that the sum of two random variables is itself a random variable, and consequently any finite sum of random variables will be a random variable.

**Definition 9:** If $(T_1, \sigma_1, \mathbb{P}_1)$ and $(T_2, \sigma_2, \mathbb{P}_2)$ are probability spaces then we can construct a product probability space $(T_3, \sigma_3, \mathbb{P}_3)$, where:

$$T_3 = T_1 \times T_2$$

$$\sigma_3 = \sigma(\sigma_1 \times \sigma_2)$$

$$\mathbb{P}_3'(a, b) = \mathbb{P}_1(a)\mathbb{P}_2(b)$$

where $\mathbb{P}_3$ is the extension of $\mathbb{P}_3'$ that has the whole of $\sigma_3$ as its domain.

Note that the product probability $\mathbb{P}_3$ has the effect of declaring that the experiments carried out in probability spaces $(T_1, \sigma_1, \mathbb{P}_1)$ and $(T_2, \sigma_2, \mathbb{P}_2)$ are independent. Obviously, the process of forming products can be extended to any finite product of finitely many probability spaces. Currently, it is not clear whether PVS is powerful enough to capture the notion of a countably infinite sequence of random variables $\{X_n\}_{n=1}^{\infty}$; fortunately, in this work we don’t currently require this result.

In Figure 2, we define the conditional probability $\mathbb{P}(A; B)$ (written $\mathbb{P}(A, B)$ as PVS will not permit the use of “:” as an operator). We take the opportunity to prove Bayes’ Theorem along the way.

**C. Continuous Uniform Random Variables**

If $X$ is a continuous random variable distributed uniformly over the interval $[a, b]$, then informally it takes any value within the interval $[a, b]$ with equal probability.

To make this more formal, we define the characteristic function of a set $S$ as the function $\chi_S$, which takes the values 1 or 0 depending on whether it is applied to a member of $S$.

Fig. 1. Abbreviated probability space file in PVS
### Conditional Probability File in PVS

**Definition 10:**

\[ \chi_S(x) = \begin{cases} 
1 & x \in S \\
0 & x \notin S
\end{cases} \]

Now the probability density function \( f \) of the uniform random variable over the closed interval \([a, b]\) is \( \frac{1}{b-a} \chi_{[a,b]} \). From this we can calculate the distribution function:

\[ F(x) = \int_{-\infty}^{x} f(x) \, dx, \]

from which we can calculate the probability

\[ \mathbb{P}(x < X \leq y) = F(y) - F(x). \]

In the case where \( X \) is distributed \( U[0,1] \), and because \( f \) is a probability distribution, we have

\[ \int_{-\infty}^{\infty} f(x) \chi_{[a,b]}(x) \, dx = F(x) - F(a) \chi_{[a,b]}(x) + (F(b) - F(a)) \chi_{(b,\infty)}(x). \]

We also observe that if \( X \) is distributed \( U[a,b] \), then \( \mathbb{E}(X) = \frac{a+b}{2} \), and \( \text{Var}(X) = \frac{(a-b)^2}{12} \). So, with \( a = 0 \), \( b = 1 \) we get:

\[ \mu = \frac{1}{2}, \quad \sigma^2 = \frac{1}{12}. \]

### D. Sums of Continuous Random Variables

**Definition 11:** If we have a sequence of continuous random variables \( \{X_n\} \), then we define their partial sums as a sequence of continuous random variables \( \{S_n\} \) with the property

\[ S_n = \sum_{i=1}^{n} X_i. \]

**Theorem 1:** If continuous random variables \( X \) and \( Y \) have joint probability density functions \( f \), then \( Z = X + Y \) has probability density function:

\[ f_Z(z) = \int_{-\infty}^{\infty} f(x, z-x) \, dx. \]

In the special case where \( X \) and \( Y \) are independent, then (because the joint probability density function \( f(x,y) \) can be expressed as the product \( f_X(x) f_Y(y) \)) we have the Continuous Convolution Theorem:

**Theorem 2:** If continuous random variables \( X \) and \( Y \) are independent and have probability density functions \( f_X \) and \( f_Y \) respectively, then \( Z = X + Y \) has probability density function:

\[ f_Z(z) = \int_{-\infty}^{\infty} f_X(x) f_Y(z-x) \, dx = \int_{-\infty}^{\infty} f_X(z-x) f_Y(x) \, dx. \]

### E. Reliability of Long Calculations

What we are actually interested in is whether a series of calculations might accumulate a sufficiently large error to become meaningless. In the language we have developed, we are asking what is the probability that all calculations of length \( n \) is correct:

\[ \mathbb{P}\left( \max_{1 \leq i \leq n} |S_i| \leq \epsilon \right). \]

Because they have nice convergence properties, we are especially interested in **martingales**

**Definition 12:** A sequence \( \{S_n\} \) is a martingale with respect to the sequence \( \{X_n\} \), if for all \( n \):

1. \( \mathbb{E}(|S_n|) < \infty \); and
2. \( \mathbb{E}(S_{n+1}; X_1, X_2, \ldots, X_n) = S_n \)
We first observe that the sequence \( S_n = \sum_{i=1}^{n} X_i \) (as previously defined) is a martingale with respect to the sequence \( \{X_n\} \).

**Lemma 1:** The sequence \( \{S_n\} \), where \( S_n = \sum_{i=1}^{n} X_i \), and each \( X_n \) is an independent random variable with \( \mathbb{E}(X_n) = 0 \), is martingale with respect to the sequence \( \{X_n\} \).

Alternatively as could be needed for program 2:

**Lemma 2:** The sequence \( \{S_n\} \), where \( S_n = \sum_{i=1}^{n} X_i \), and \( \{X_n\} \) satisfies for all \( i \)

\[
\mathbb{E}(X_i) = 0
\]

\[
\mathbb{E}(X_i; X_1, \ldots, X_{i-1}) = 0,
\]

the sequence \( \{S_n\} \) is martingale with respect to the sequence \( \{X_n\} \).

We now make use of the Doobs-Kolmogorov Inequality presented Figure 3. The statement of Theorem 3 is deceptively simple. The key as the astute reader will observe is that we have a restricted form of the Doobs-Kolmogorov Inequality in which the sample spaces of the underlying sequence of random variables are identical. This is an artifact of the PVS type system which would require us to prove multiple version of the theorem at each tuple of instantiated types.

Although the type system used in PVS is extraordinarily flexible, it is not as malleable as that used by professional mathematicians. To capture mathematics in its entirety using a theorem prover, we would need to dispense with any form of type checking. For its intended use as an aide to proving programs correct, this would fatally weaken PVS as a useful tool. In addition, in many practice areas of mathematics, the full generality of categorical constructs is an unnecessary luxury, albeit one with a seductive, siren-like, appeal.

**Theorem 3 (Doobs-Kolmogorov Inequality):** If \( \{S_n\} \) is a martingale with respect to \( \{X_n\} \) then, provided that \( \epsilon > 0 \):

\[
\mathbb{P} \left( \max_{1 \leq i \leq n} |S_i| \geq \epsilon \right) \leq \frac{1}{\epsilon^2} \mathbb{E}(S_n^2)
\]

In our particular case where each \( X_i \) is an independent random variable with \( \mathbb{E}(X_i) = 0 \), and \( \text{Var}(X_i) = \sigma_i^2 \), we observe that

\[
\mathbb{P} \left( \max_{1 \leq i \leq n} |S_i| \leq \epsilon \right) \geq 1 - \frac{1}{\epsilon^2} \sum_{i=1}^{n} \sigma_i^2
\]

The short conclusion is therefore that eventually errors will accumulate and overwhelm the accuracy of any numerical software. However, if \( \epsilon \) is large enough and each of the \( \sigma_i^2 \) are small enough, then the number of iterations required for this to occur will be high enough to be of no practical significance. Crucially, the results hinge critically on the errors \( \{X_n\} \) being independent.

**IV. Future work**

This work will be continued in two directions. The first direction is to modify Fluctuat to generate theorems that can be checked automatically by PVS using ProofLite as proposed in [5], [6]. This work will be carried in collaboration with the developers of Fluctuat. The software will conservatively estimate the final effect of the error introduces by each individual floating point operations and compute upper bounds of their variances.

The second direction is to develop and check accurate proofs about the round-off errors of individual equations. A uniformly distributed random variable whose variance depends only on the operation and the computed result might provide a too pessimistic bound. For example the floating point addition of a large number with a small number absorbs the small number meaning that the round-off error may be far below half an ulp of the computed result.

Two’s complement operation of TMS320 circuit can either round or truncate the result. If truncation is used, it introduces a drift and Doobs-Kolmogorov inequality for martingales cannot be used. Should we wish to extend this work to account for drifts (non-zero means for the random variables \( \{X_n\} \)), then we anticipate making use of Wald Identity. Such developments will also be necessary to address higher order error terms that introduce a drift.

This library and future work will be included into NASA Langley PVS library as soon as it becomes stable.

We saw with the example of listing 2 that inductions on the variances of the random variables can be crudely bounded. Yet, we may expect tighter results if we use tools that are able to infer inductions and solve them mathematically but this domain is far from the authors’ research areas.

**V. Conclusions**

To the best of our knowledge this paper presents the first application of the Doobs-Kolmogorov Inequality to software reliability and the first generic formal development able to handle continuous, discrete and non-continuous non-discrete random variable in higher order logic proof assistants. In addition, we have demonstrated a slightly weaker version of this result in PVS. We claim that the utility of this weaker result is not unduly restrictive, when compared to the general result. The major restriction lies in the fact that we have to demonstrate that a sequence of overall errors is martingale with respect to the sequence of individual errors. We have been forced to make simplifications to the mathematical model of our software to ensure that this is the case. In particular, we have been forced to insist that our individual errors have no drift, and are independent.

We have been surprised that the limit on the reliability of a piece of numeric software could be expressed so succinctly. Notice that even with a high tolerance of error, and with independent errors, we will still eventually fail. Our results permit the development of safe upper limits on the number of operations that a piece of numeric software should be permitted to undertake.

It is worth pointing out that violating our assumptions (independence of errors, and zero drift) would lead to worse

---

1A weak form of type consistency is used in category theory, but this is so weak that we can introduce the Russel Paradox.

2http://research.nianet.org/~munoz/ProofLite/.

results, so one should treat the limits we have deduced with caution, should these assumptions not be met.

ACKNOWLEDGMENT

This work has been partially funded by CNRS PICS 2533 and was partially done while one of the authors was an invited professor at the University of Perpignan Via Domitia. The authors would like to thanks Philippe Langlois and Jean-Marc Vincent for fruitful informal discussions on this work.
