(Dated: January 18, 2007)

We present novel experimental results demonstrating the coherence properties of the nonlinear emission from semiconductor microcavities in the strong coupling regime, recently interpreted by parametric polariton four-wave mixing. We use a geometry corresponding to degenerate four-wave mixing. In addition to the predicted threshold dependence of the emission on the pump power and spectral blue shift, we observe a phase dependence of the amplification which is a signature of a coherent polariton wave mixing process.

In high finesse semiconductor microcavities with embedded quantum wells, the photon and exciton confinement and the large excitonic oscillator strength make it possible to reach the strong coupling regime or normal mode coupling. As a result, the degeneracy at resonance between the exciton mode and the photon mode is lifted and the so-called vacuum Rabi splitting takes place. The resulting two-dimensional eigenstates, called cavity polaritons, are mixed photon-exciton states that have a number of attractive features. They are considered as potential candidates for Bose-Einstein condensation because of the occurrence of strong polariton-polariton scattering into the small $k_{||}$ states. The purpose of this paper is to report on novel properties of cavity polaritons in the nonlinear regime, that are a direct proof of the coherent nature of the polariton-polariton interaction.

The emission intensity of these systems has been shown to undergo a giant amplification when the intensity of the driving field is increased above some threshold, both under non resonant and resonant laser excitation. Several mechanisms were proposed to explain this behavior, including stimulated exciton phonon scattering and stimulated exciton exciton scattering, raising a lot of controversy. In particular, experiments using a resonant pump at a specific angle and measuring the amplified emission or the gain on a probe laser at normal incidence, are in good agreement with a recent theoretical model based upon coherent polariton four-wave mixing. A strong amplification is observed when the angle is chosen in order to ensure energy and in-plane momentum conservation for the process where two pump polaritons (with momentum $k_{P||}$) are converted into a signal polariton ($k_{||} = 0$) and an idler polariton ($k_{=} = 2k_{||}$).

The experiments involving resonant excitation have been performed in a non-degenerate configuration, in which the signal, idler and pump beams have different energies and momenta. An alternative configuration ensures the double energy and momentum resonance: it is the one where $k_{P||} = 0$, with $k_{signal||} = k_{idler||} = 0$, the energy of the pump laser being resonant with the polariton energy. In this paper, we present experimental results obtained in this configuration. The amplified emission, which now contains both signal and idler, is observed in the direction of the reflected pump beam. The “degenerate” configuration allows us to highlight new features of the polariton parametric interaction. To analyze the characteristics of the emission in detail, a highly sensitive homodyne detection is used. As in the non-degenerate case, a marked threshold is observed when the pump intensity is increased and the associated shift is found to be in agreement with ref. Degenerate four-wave mixing has been studied by several authors in semiconductor microcavities, however in different regimes where the giant amplification on the lower polariton branch did not occur.

Moreover, it is well known that in this geometry optical parametric amplification is phase sensitive. Using a single mode cw laser as a pump, we have been able to investigate for the first time the phase dependence of the giant emission. If it was due to stimulation by the lower polariton occupation number, a phase insensitive amplification would be observed, as in a laser-like amplifier. We have observed that the amplification depends strongly on the phase of the pump laser. This result brings in a crucial argument in favor of the interpretation of the amplified emission as originating primarily from coherent polariton four-wave mixing in the case of resonant pumping. Let us note that the case of non resonant pumping where there is no phase reference in the system corresponds to a very different problem which requires a specific approach.

We use high finesse GaAs/AlAs microcavity samples containing either one or two InGaAs quantum wells...
FIG. 1: Experimental set-up. It can be used in two different configurations: (a) Without beamsplitter (BS1): The polarizing beamsplitter (PBS) and the quarter wave plate ($\lambda/4$) form an optical circulator that direct all the circularly polarized light coming from the microcavity towards the detection system. The 50/50 beamsplitter (BS) splits the beam into two equal parts which fall on two photodetectors. The sum of the two photocurrents gives the beat signal between the emission and the laser. The difference between the photodiode currents yields the shot noise. (b) With beamsplitter (BS1): an independent local oscillator is split off by the beamsplitter (BS1) and mixed with the beam emerging from the microcavity on (BS2). In this case, the beat signal between the emitted light and the local oscillator is obtained by taking the difference between the two photocurrents. The shot noise background is measured by blocking the beam emerging from the cavity.

with low indium content. The samples are described respectively in refs. 5 (sample 1) and 18 (sample 2). These high quality samples exhibit very narrow polariton linewidth, on the order of 100-200 $\mu$eV (half-width at half-maximum) at 4 K. The microcavities are wedged, allowing one to change the cavity thickness by moving the laser excitation spot on the samples. The beam of a single mode cw Ti:sapphire laser with a linewidth of the order of 1 MHz is focused onto the sample at normal incidence. The laser light is circularly polarized. The laser spot has a diameter of 80 $\mu$m.

First the positions of the two polariton branches are determined by studying the reflection of the driving laser at very low intensity ($I \lesssim 1$ mW, corresponding to 10W/cm$^2$). For sample 2, this yields the diagram shown in Fig. 3, where the energies of the reflectivity minima have been plotted as a function of their positions on the sample. A similar diagram has been obtained for sample 1, with a smaller vacuum Rabi splitting.

The light emitted by the microcavity is detected in the direction normal to the sample by means of a homodyne detection system 14, 24. For this purpose the emitted light is mixed with a local oscillator on a photodetector (Fig. 1). The emitted light of interest co-propagates with the laser beam and has the same very small divergence angle (\( \approx 0.4^\circ \)), ensuring the $k_{\parallel}$ conservation. An additional laser beam, the local oscillator, is mixed with the pump and signal beam on a beamsplitter. The beams coming from the beamsplitter are focused on two photodetectors. The frequency spectrum of the photocurrents is analyzed with an RF spectrum analyzer. The reflected laser and the light scattered at the laser frequency yield a large peak at zero frequency which is filtered out. The signal given by the spectrum analyzer can be shown 24 to be proportional to the beat signal between the local oscillator and the light emitted by the sample, i.e. luminescence. For an incoherent emission, the spectrum analyzer measures a broad signal, that appears on top of the background quantum noise (shot noise).

In a first set of experiments, the local oscillator is the laser beam reflected by the microcavity. The phase difference between the detected signal and the local oscillator is fixed, since the emitted light and the reflected laser follow exactly the same path. This scheme is well adapted to investigate the amplification threshold and the line shift. In a second set of experiments, we have used an independent local oscillator beam, split off from the pump laser. One of the mirrors on the path of the local oscillator is mounted on a piezoceramic, which allows us to vary its phase relative to the signal beam. This provides a tool to explore all the quadrature components for the emitted light. Let us stress that without homodyne detection the emitted light would be extremely difficult to distinguish from the scattered and reflected laser light.

We first describe the results concerning the emission threshold and the line shift, using the first experimental scheme. In order to study the emission resonances we had to use a specific method. The possible frequency scan of the detection system on each side of the laser line is of the order of a few tens of MHz, that is in the 100 neV range, much smaller than a typical photoluminescence spectrum. To investigate the emission, the frequency of the spectrum analyzer is kept fixed, while either the laser frequency or the position on the sample is scanned. Therefore, the detected polaritons have an energy extremely close to the ones excited by the pump laser. The emission lineshape obtained with the homo-

FIG. 2: Energy diagram of the polariton branches as a function of position on sample 2. Inset: emission resonance obtained when the laser position is scanned on sample 2 around point (1) with fixed pump laser wavelength and $I_{\text{pump}} = 0.7 \text{mW}$. Here and in the following figures, the analysis frequency of the spectrum analyzer is fixed at 7 MHz.
Above threshold, the emitted intensity increases very fast driving laser, as is expected from thermal luminescence. The intensity has linear dependence on the intensity of the sample 2 (points (1) and (2) in Fig. 2), corresponding for two different positions on the lower polariton branch the maximum intensity versus the pump laser intensity. Figure 3 shows the height and position of the emission resonance as a function of the driving laser intensity. We find that the emission varies linearly with the intensity of the driving laser below threshold. The curves shift to the left of the unperturbed lower branch resonance in Fig. 2, which is equivalent to a blue shift in energy. The sign of the shift is consistent with a non-linearity coming from polariton-polariton scattering, which is repulsive. The measured value of the shift at threshold for point (1) in the level diagram is 0.24 meV, in good agreement with the value of about twice the polariton linewidth $2\gamma = 0.29$ meV predicted by ref. [3]. The linewidth (HWHM) $\gamma$ was measured independently using the reflectivity resonances. These results are consistent with those of previous experiments, obtained in the non-degenerate geometry.

In the case of degenerate operation, with the signal and idler having the same energies and wavevectors, the parametric amplifier is expected to be phase-dependent. Using homodyne detection, we are able to explore this property, in contrast to other authors. As in the experiment performed in ref. [3], thermally excited polaritons constitute the probe that seeds the parametric process and that is amplified through interaction with the pumped polaritons. Having no average phase, the former can be considered as a superposition of random polariton fields with equal mean amplitudes and phases spread over $2\pi$. For each value of the local oscillator phase, the emission having a specific phase is singled out by the homodyne detection. Scanning the local oscillator phase allows us to identify whether some quadrature components are amplified in a preferential way.

Well below threshold, as expected, all quadrature components are equivalent. Starting a little below threshold, one observes an oscillation of the homodyne signal as a function of the local oscillator phase. A typical recording is shown in Fig. 4 (inset), at zero cavity-exciton detuning for sample 1. This clearly demonstrates the phase dependence of the polariton field typical of degenerate parametric amplification [10]. The polariton-polariton interaction that is at the origin of the observed amplification is a coherent one, which can be identified with polariton four-wave mixing. Indeed, the Hamiltonian annihilating two pump polaritons $a_p$ and creating two identical signal photons $a_s$ is of the form $V a_p^\dagger a_p a_s^\dagger a_s^\dagger$, with $V$ the interaction energy. Then the semi-classical evolution equation for $\langle a_s \rangle$ contains a gain term proportional to $\langle a_s^2 \rangle \langle a_p \rangle$, which implies a well defined phase relationship between the pump field and the amplified polariton quadrature. An amplification originating from population effects, as in a laser, would be phase independent.

The amplitude of the oscillation grows rapidly with the pump field above threshold. In Fig. 3, we show the maxima and minima of the oscillations as a function of the driving laser power for sample 1, obtained at fixed laser frequency and by shifting the sample in order to compensate for the energy shift (the threshold is different from the one obtained with sample 2 for a similar position, but the overall behaviors are very much the same.

![Graph: Emission intensity as a function of pump laser intensity for positions (1) and (2) on the lower polariton branch shown in Fig. 2. $I_t$ is the threshold driving laser intensity. The laser frequency is fixed and the position on the sample is adjusted to maximize the signal.](image)
The oscillation period is varied for a driving laser power of 3 mW. The detection signal (arbitrary units) when the phase of the local oscillator is varied, for a driving laser power of 3 mW. The oscillation minima go well below the level of thermal emission. Inset: homodyne detection signal (arbitrary units) when the phase of the local oscillator is varied, for a driving laser power of 3 mW. The oscillation period is π rather than 2π because the probe is constituted by an ensemble of random fields in which phases ϕ and ϕ + π are equivalent.
