Abstract – This paper presents the numerical resolution of non-linear yield stress phenomena by using a new mixed anisotropic auto-adaptive finite element method. The Poiseuille flow of a Bingham fluid with slip yield boundary condition at the wall is considered. Despite its practical interest, for instance for pipeline flows of yield stress fluids such as concrete and cements, this problem was not yet addressed to our knowledge. The case of a pipe with a square section has been investigated into details. The computations cover the full range of the two main dimensionless numbers and exhibit complex flow patterns: all the different flow regimes are completely identified.

Keywords – viscoplasticity; Bingham fluid; slip at the wall; limit load analysis; variational inequalities; adaptive mesh; mixed finite element methods.

1. Introduction

The flow of a viscoplastic fluid in a straight pipe with constant cross-section and \textit{with no-slip} condition at the wall has been considered several times in the literature. In the 60’s, an extensive mathematical study was presented by Mossolov and Miasnikov \cite{1,2,3}. These authors have presented impressive results on the existence and shape of rigid zones in the flow. In particular, they were the first to characterize the critical value of the yield stress above which the flow stops. See also Huilgol \cite{4} for a recent application of this approach to several pipe shapes with symmetric cross-section. Next, Duvaut and Lions \cite{5} clarified the the problem of existence and uniqueness of a solution and renewed the mathematical study by using the powerful tools of variational inequalities. They recovered some properties already established by Mossolov and Miasnikov, and found new interesting properties.

September 20, 2007
The numerical study of this flow problem was first considered in 1972 by M. Fortin [6]. More recently, the regularized model of Bercovier and Engelman [7] has been used by Taylor and Wilson [8] to study the case of a square cross-section. The augmented Lagrangian algorithm from M. Fortin and Glowinski [9] has been used by Huilgol and Panizza [10] to solve the case of an annulus and of an L-shaped cross-section, with the Bingham rheology. More recently, Huilgol and You [11] have derived the algorithm for two other viscoplastic rheologies (Casson and Herschel-Bulkley).

In 2001, Saramito and Roquet revisited the classical fully developed Poiseuille flow of a Bingham yield stress fluid in pipe [12] with non-circular cross-section. Addressing the case of a square cross-section, they pointed out the lack of precision of the previous numerical computations, that were not able to compute accurately the yield surfaces that separate the shear region from the central plug and the dead zones. They proposed a new mixed anisotropic auto-adaptive finite element method coupled to the augmented Lagrangian algorithm. The mesh refinement is expected to capture accurately the free boundaries of the rigid zones. Based on a priori error estimate on adapted meshes, Roquet et al. [13] performed the numerical analysis of the method and showed that it converges with an optimal global order of accuracy. Finally, the extension of this approach to more general flows of a Bingham fluid is addressed in [14] where the authors considered the flow around a cylinder.

In practical viscoplastic flow problems such as concrete pumping (see e.g. [15,16]), it appears that a no-slip boundary condition is not a satisfactory model. The fluid slips when the tangential stress exceeds a critical value, and, otherwise the fluid sticks at the wall. This critical value may be considered as an intrinsic characteristic of the material: in the following, it will be called the yield-force of the fluid. In [15], Weber describes this yield-force slip phenomenon. It has already been used for the flow of a Newtonian fluid with such slip law by A. Fortin et al. [17] for the sudden contraction geometry and next by Roquet and Saramito [18] for the straight pipe flow with a square cross-section. This simple law can be extended, as mentioned by Fortin et al. [17] or Ionescu and Vernescu [19]. In the context of solid mechanics and contact problems, Coulomb type friction has been studied by many authors. Refer e.g. to Haslinger et al. [20, p. 377] for the numerical analysis and to Kikuchi and Oden [21] for the finite element approximation. In this case, the slip yield stress is no more a constant, and should be replaced by a quantity that depends upon the pressure at the boundary. Nevertheless, previous works do not study the stick-slip transition. In this paper, since our purpose is to study a new numerical algorithm for the stick-slip transition capturing, we suppose that the slip yield stress is a constant.

The aim of this paper is to extend the technique presented in Saramito and Roquet [12,18] in order to apply it to the flow of a Bingham fluid in a straight pipe with constant cross-section with the stick-slip law at the wall. In section 2, all the governing laws of the flow model are presented, ending with the non-dimensional formulation of the flow of a Bingham fluid with the stick-slip law in a straight pipe. In the third section, the numerical method is described. The last section presents all the numerical results and the discussion. The role of the two dimensionless numbers associated to the yield parameters of the flow structure are investigated in details. The computations cover the full range of the two main dimensionless numbers and exhibit complex flow patterns: all the different flow regimes are completely identified.

2. Problem statement

The general equations for the flow of a Bingham fluid with the stick-slip law is given first. Then, it is specialized for the case of a straight pipe with constant cross-section.
2.1. Constitutive equation and conservation laws

Let $\sigma_{\text{tot}}$ denote the total Cauchy stress tensor:

$$\sigma_{\text{tot}} = -p I + \sigma,$$  

where $\sigma$ denotes its deviatoric part, and $p$ the pressure. In this paper, the fluid is supposed to be viscoplastic, and the relation between $\sigma$ and $D(u)$ is given by the Bingham model [22, 23]:

$$\begin{cases}
\sigma = 2\eta D(u) + \sigma_0 \frac{D(u)}{|D(u)|} & \text{when } D(u) \neq 0 \\
|\sigma| \leq \sigma_0 & \text{when } D(u) = 0
\end{cases}$$

(2)

here $\sigma_0 \geq 0$ is the yield stress, $\eta > 0$ is the constant viscosity, $u$ is the velocity field and $D(u) = (\nabla u + \nabla u^T)/2$. For any tensor $\tau = (\tau_{ij})$, the notation $|\tau|$ represents the matrix norm:

$$|\tau| = \left( \frac{\tau : \tau}{2} \right)^{1/2} = \frac{1}{\sqrt{2}} \left( \sum_{i,j} \tau_{ij} \right)^{1/2}$$

(3)

The constitutive equation (2) writes equivalently:

$$D(u) = \begin{cases}
\left( 1 - \frac{\sigma_0}{|\sigma|} \right) \frac{\sigma}{2\eta} & \text{when } |\sigma| > \sigma_0 \\
0 & \text{otherwise}
\end{cases}$$

(4)

The slip boundary condition reads:

$$u_t = \begin{cases}
-\left( 1 - \frac{s_0}{|\sigma_{\text{nt}}|} \right) \frac{\sigma_{\text{nt}}}{c_f} & \text{when } |\sigma_{\text{nt}}| > s_0, \\
0 & \text{otherwise},
\end{cases}$$

(5)

where $s_0 \geq 0$ the slip yield stress and $c_f > 0$ the friction dissipation coefficient. The notations $u_t$ and $\sigma_{\text{nt}}$ are defined by

$$u_t = u - (u.n) n,$$

$$\sigma_{\text{nt}} = \sigma.n - (\sigma_{\text{nn}}) n,$$

(6)

where $\sigma_{\text{nn}} = (\sigma.n).n$ and $n$ is the unit outward normal vector. For any vector field $v$, the notation $|.|$ represents the vector norm $|v| = (v.v)^{1/2}$. Notice that the vector field $\sigma_{\text{nt}}$ is tangent to the boundary and that $\sigma_{\text{nn}}$ is a scalar field defined on the boundary. Observe the analogy of structure between the slip law (5) and the Bingham constitutive equation (4). The slip relation can be also written as:

$$\begin{cases}
\sigma_{\text{nt}} = -c_f u_t - s_0 \frac{u_t}{|u_t|}, & \text{when } |u_t| \neq 0, \\
|\sigma_{\text{nt}}| \leq s_0, & \text{when } |u_t| = 0
\end{cases}$$

(7)

Again, observe the analogy between (7) and (2). The boundary condition is complemented by a condition expressing that the fluid does not cross the boundary:

$$u.n = 0.$$  

(8)

We remark that for $s_0 = 0$, one obtains the classical linear slip boundary condition: the fluid slips for any non-vanishing shear stress $\sigma_{\text{nt}}$. For $s_0 > 0$, boundary parts where the fluid sticks can be observed. As $s_0$
becomes larger, these stick regions develop. The system of equations is closed by conservation laws. The conservation of momentum is:

$$\rho \left( \frac{\partial u}{\partial t} + u \cdot \nabla u \right) - \text{div } \sigma + \nabla p = 0,$$

where $\rho$ is the constant density. Since the fluid is supposed to be incompressible, the mass conservation leads to:

$$\text{div } u = 0.$$  \hspace{1cm} (10)

2.2. The pipe flow problem

We consider the fully developed flow in a prismatic tube (see Fig 1). Let $(Oz)$ be the axis of the tube and $(Oxy)$ the plane of the bounded cross-section $\Omega \subset \mathbb{R}^2$. The pressure gradient is written as $\nabla p = (0, 0, -f)$ in $\Omega$, where $f > 0$ is the constant applied force density.

The velocity is written as $u = (0, 0, u)$, where the third component $u$ along the $(Oz)$ axis depends only upon $x$ and $y$, and is independent of $t$ and $z$. The problem can be written as a two-dimensional one, and the stress tensor $\sigma$ is equivalent to a two shear stress component vector: $\sigma = (\sigma_{xz}, \sigma_{yz})$. We also use the following notations:

$$\nabla u = \left( \frac{\partial u}{\partial x}, \frac{\partial u}{\partial y} \right)$$  \hspace{1cm} (11)

$$\text{div } \sigma = \frac{\partial \sigma_{xz}}{\partial x} + \frac{\partial \sigma_{yz}}{\partial y}$$  \hspace{1cm} (12)

$$|\sigma| = (\sigma_{xz}^2 + \sigma_{yz}^2)^{1/2}$$  \hspace{1cm} (13)

Finally, the problem of the flow of a Bingham fluid in a pipe with slip at the wall can be summarized as:

$(P)$: find $\sigma$ and $u$ defined in $\Omega$ such that

$$\text{div } \sigma = -f \text{ in } \Omega,$$

$$\max \left( 0, 1 - \frac{\sigma_0}{|\sigma|} \right) \sigma - \eta \nabla u = 0 \text{ in } \Omega,$$

$$\max \left( 0, 1 - \frac{s_0}{|\sigma|} \right) \sigma \cdot n + c_f u = 0 \text{ on } \partial \Omega,$$

where $n$ is the unit outward normal vector on the boundary $\partial \Omega$ of the cross-section $\Omega$. Here (14) expresses the conservation of momentum, (15) the constitutive equation and (16) the slip boundary condition.

Let $L$ be a characteristic length of the cross-section $\Omega$, e.g. the half-length of an edge of a square cross-section. A characteristic velocity is given by $U = \frac{L^2 f}{\eta}$. The Bingham dimensionless number $Bi$ is defined by the ratio of yield stress $\sigma_0$ by the representative stress $\Sigma$:

$$Bi = \frac{\sigma_0}{Lf}.$$  \hspace{1cm} (17)

The slip yield dimensionless number $S$ is defined as the ratio of the slip yield stress $s_0$ to a characteristic stress $\Sigma = \eta U/L = Lf$:

$$S = \frac{s_0}{Lf}.$$  \hspace{1cm} (18)
The friction dimensionless number $C_f$ is defined by
\[ C_f = \frac{c_f U}{\Sigma} = \frac{c_f L}{\eta}. \] (19)

The three dimensionless numbers $Bi$, $S$, and $C_f$ characterize the problem. In order to focus on the non-linear phenomena only, the $C_f$ coefficient is chosen equal to the unity for all numerical experiments. In this paper, we explore the problem related to the variation of both $Bi$ and $S$. For the kind of flow presented here, the relevant values of the dimensionless numbers $Bi$ and $S$ are expected to be in a finite range, with an upper bound that may depend on the shape of the cross-section. This is due to the existence of critical values of $Bi$ and $S$ above which the non-linear effects do not change the stick-slip transition and the evolution of rigid zones (see for example [12] for $Bi$ only and [18] for $S$ only). One objective of this article is the determination of such critical values.

3. Numerical method

The augmented Lagrangian method, applied to problem (14)-(15), is briefly introduced in this paragraph. Then, the delicate problem of the choice of a finite element approximation is carefully treated.

3.1. Augmented Lagrangian algorithm

Let $H^1(\Omega)$ denote the classical functional Sobolev space [24] and $J$ the convex functional defined for all $v \in H^1(\Omega)$ by
\[ J(v) = \frac{\eta}{2} \int_\Omega |\nabla v|^2 \, dx + \frac{c_f}{2} \int_{\partial\Omega} |\gamma v|^2 \, ds + \sigma_0 \int_\Omega |\nabla v| \, dx + s_0 \int_{\partial\Omega} |\gamma| \, ds - \int_\Omega f v \, dx \] (20)
where $ds$ is a measure on $\partial\Omega$ and $\gamma$ is the trace operator from $H^1(\Omega)$ to $H^{1/2}(\partial\Omega)$, i.e. $\gamma v$ is the restriction $v_{|\partial\Omega}$ of $v$ on $\partial\Omega$.

Using variational inequality methods (see e.g. Glowinski et al. [25]) we show that the solution $u$ of problem $(P)$ is the minimum of $J$ on $H^1(\Omega)$:
\[ \min_{v \in H^1(\Omega)} J(v). \] (21)

Let us introduce two additional variables:
\[ d = \nabla u \in L^2(\Omega)^2, \]
\[ \xi = \gamma u \in H^{1/2}(\partial\Omega). \] (22)

These additional constraints are handled by using two corresponding Lagrangian multipliers. The first one, associated with the constraint (22) coincides with the shear stress vector $\sigma \in L^2(\Omega)^2$ and is still denoted by $\sigma$. The second Lagrangian multiplier $\lambda \in L^2(\partial\Omega)$, associated with the constraint (23), coincides with the shear stress $-\sigma \cdot n$ at the boundary. The Lagrangian $L$ is defined for all $(u, d, \xi) \in H^1(\Omega) \times L^2(\Omega)^2 \times L^2(\Omega)$ and $(\sigma, \lambda) \in L^2(\Omega)^2 \times L^2(\partial\Omega)$ by
\[ \mathcal{L}(\nu, \mathbf{d}, \zeta); (\sigma, \lambda) = \frac{\eta}{2} \int_{\Omega} |\mathbf{d}|^2 \, dx + s_0 \int_{\partial \Omega} |\zeta|^2 \, ds + \int_{\Omega} \sigma \cdot (\nabla \nu - \mathbf{d}) \, dx \]
\[ + \frac{\epsilon_f}{2} \int_{\partial \Omega} |\xi|^2 \, ds + s_0 \int_{\partial \Omega} |\zeta|^2 \, ds + \int_{\partial \Omega} \lambda (\gamma \nu - \xi) \, ds. \]

For all \( a > 0 \), the augmented Lagrangian
\[ \mathcal{L}_a((\nu, \mathbf{d}, \zeta); (\sigma, \lambda)) = \mathcal{L}((\nu, \mathbf{d}, \zeta); (\sigma, \lambda)) + \frac{a}{2} \int_{\Omega} |\mathbf{d} - \nabla \nu|^2 \, dx + \frac{a}{2} \int_{\partial \Omega} (\xi - \gamma \nu)^2 \, ds \]
is quadratic and positive-definite with respect to \( \mathbf{u} \). This implies that, with \((\sigma, \lambda)\) and \((\mathbf{d}, \zeta)\) fixed, \( \mathcal{L}_a \) can be minimized with respect to \( \nu \) on \( H^1(\Omega) \), whereas this operation is in practice impossible for \( a = 0 \). This transformation proves to be helpful since we can solve the saddle-point problem of \( \mathcal{L}_a \), which coincides with that of \( \mathcal{L} \), by an appropriate algorithm proposed in [9]:

**Algorithm (Uzawa)**

**Initialization:** \( n = 0 \)

Let \((\sigma^0, \lambda^0)\) and \((\mathbf{d}^0, \zeta^0)\) be arbitrarily chosen in \( L^2(\Omega)^2 \times L^2(\partial \Omega) \).

**Loop:** \( n \geq 0 \)

- **Step 1:** Suppose \((\sigma^n, \lambda^n)\) and \((\mathbf{d}^n, \zeta^n)\) are known and find \( u^{n+1} \in H^1(\Omega) \) such that
  \[ -a \Delta u^{n+1} = f + \text{div} (\sigma^n - a \mathbf{d}^n) \text{ in } \Omega, \]
  \[ \frac{\partial u^{n+1}}{\partial n} + u^{n+1} = \mathbf{d}^n \cdot \mathbf{n} + \zeta^n - \frac{1}{a} (\lambda^n + \sigma^n \cdot \mathbf{n}) \text{ on } \partial \Omega. \]

- **Step 2:** compute explicitly in \( \Omega \):
  \[ \mathbf{d}^{n+1} := \begin{cases} \left( 1 - \frac{\sigma_0}{|\sigma^n + a \nabla u^{n+1}|} \right) \frac{\sigma^n + a \nabla u^{n+1}}{\eta + a}, & \text{when } |\sigma^n + a \nabla u^{n+1}| > \sigma_0, \\ 0, & \text{otherwise.} \end{cases} \]

  and on \( \partial \Omega \):
  \[ \zeta^{n+1} := \begin{cases} \left( 1 - \frac{s_0}{|\lambda^n + a \gamma u^{n+1}|} \right) \frac{\lambda^n + a \gamma u^{n+1}}{\epsilon_f + a}, & \text{if } |\lambda^n + a \gamma u^{n+1}| > \sigma_0, \\ 0, & \text{otherwise.} \end{cases} \]

- **Step 3:** compute explicitly:
  \[ \sigma^{n+1} := \sigma^n + a (\nabla u^{n+1} - \mathbf{d}^{n+1}) \text{ in } \Omega, \]
  \[ \lambda^{n+1} := \lambda^n + a (\gamma u^{n+1} - \zeta^{n+1}) \text{ on } \partial \Omega. \]

**End Loop**

The advantage of this algorithm is that it transforms the global non-differentiable problem (21) into a family of completely standard problems (27)-(28) and local explicit computations (29)-(30), coordinated via the Lagrange multipliers in (31)-(32). The sequence \((u^n, \mathbf{d}^n, \zeta^n, \sigma^n, \lambda^n)\) converges for all \( a > 0 \) to \((u, \mathbf{d}, \zeta, \sigma, \lambda)\) where \( u \in H^1(\Omega) \) is the solution to (21) and \( \mathbf{d} = \nabla u, \zeta = u_{|\partial \Omega}, \sigma \) is the shear stress and \( \lambda = -\sigma \cdot \mathbf{n} \) on \( \partial \Omega \).
3.2. Finite element approximation

Let $A$ and $B$ be the two bilinear forms defined by:

\[
A((u, d, \xi); (v, \delta, \zeta)) = (\eta + a) \int_{\Omega} d \delta \, dx + (e_j + a) \int_{\partial \Omega} \gamma u \gamma v \, ds \\
+ a \int_{\Omega} \langle \nabla u, \nabla v - d \delta, \nabla v \rangle \, dx + a \int_{\partial \Omega} (\gamma u \gamma v - \gamma u \zeta - \xi \gamma v) \, ds,
\]

\[
B((v, \delta, \zeta); (\tau, \mu)) = \int_{\Omega} \tau (\nabla v - \delta) \, dx + \int_{\partial \Omega} \mu (\gamma v - \zeta) \, ds.
\]

and $j$ be the following function:

\[
j(\delta, \zeta) = \sigma_0 \int_{\Omega} |\delta| \, dx + s_0 \int_{\partial \Omega} |\zeta| \, ds
\]

The saddle point of $L_a$ is characterized as the solution of a problem expressed by the following variational inequalities:

(VI): find $(u, d, \xi) \in H^1(\Omega) \times L^2(\Omega)^2 \times L^2(\partial \Omega)$ and $(\sigma, \lambda) \in L^2(\Omega)^2 \times L^2(\partial \Omega)$ such that:

\[
j(\delta, \zeta) - j(d, \xi) + A((u, d, \xi); (v, \delta, \zeta)) + B((v, \delta, \zeta); (\sigma, \lambda)) \geq \int_{\Omega} f \, v \, dx,
\]

\[
B((u, d, \xi); (\tau, \mu)) = 0
\]

for all $(v, \delta, \zeta) \in H^1(\Omega) \times L^2(\Omega)^2 \times L^2(\partial \Omega)$ and $(\tau, \lambda) \in L^2(\Omega)^2 \times L^2(\partial \Omega)$.

Let $V_h \subset H^1(\Omega)$, be a finite dimensional space and let $D_h = \nabla V_h$ and $\Xi_h = \gamma V_h$. The finite dimensional version of the variational inequalities is simply obtained by replacing functional spaces by their finite dimensional counterparts:

(VI)$_h$: find $(u_h, d_h, \xi_h) \in V_h \times D_h \times \Xi_h$ and $(\sigma_h, \lambda_h) \in D_h \times \Xi_h$ such that:

\[
j(\delta, \zeta) - j(d, \xi) + A((u, d, \xi); (v, \delta, \zeta)) + B((v, \delta, \zeta); (\sigma, \lambda)) \geq \int_{\Omega} f \, v \, dx,
\]

\[
B((u, d, \xi); (\tau, \mu)) = 0
\]

for all $(v, \delta, \zeta) \in V_h \times D_h \times \Xi_h$ and $(\tau, \lambda) \in D_h \times \Xi_h$. Let $\mathcal{T}_h$ be a finite element mesh made up of triangles and let $\partial \Omega_h$ denote the corresponding mesh of the boundary $\partial \Omega$, consisting in segments. We define $V_h$ as the space of continuous piecewise polynomials of order $k \geq 1$, relative to $\mathcal{T}_h$:

\[
V_h = \{ v \in H^1(\Omega); v_{|K} \in P_k, \forall K \in \mathcal{T}_h \}.
\]

Thus, $D_h = \nabla V_h$ is the set of discontinuous piecewise polynomials of order $k - 1$, relative to $\mathcal{T}_h$:

\[
D_h = \{ \delta \in L^2(\Omega)^2; \delta_{|K} \in (P_{k-1})^2, \forall K \in \mathcal{T}_h \}.
\]

Conversely, $X_{i_h} = \gamma V_h$ is the set of continuous piecewise polynomial functions defined on the mesh boundary $\partial \mathcal{T}_h$

\[
\Xi_h = \Lambda_h = \{ \mu \in L^2(\partial \Omega) \cap C^0(\partial \Omega); \mu_{|S} \in P_k, \forall S \in \partial \mathcal{T}_h \}.
\]

Numerical experiments presented in this paper use piecewise linear polynomials, i.e. $k = 1$. 

7
3.3. Mesh adaptation

The mesh adaptation procedure has already been described in [12,13,14,18] for a Bingham fluid flow problem and in [18] for a stick-slip transition of a Newtonian fluid flow problem. Thus, only the main steps are presented in this paragraph.

A way to adapt the mesh to the computation of a governing field is to equi-distribute its error of interpolation, i.e. to make it constant over all triangles and in all directions. Solving a problem using a mesh adaptation is an iterative process, which involves three main steps:

1. Starting from an initial mesh $T_0$, the problem is solved using the augmented Lagrangian algorithm, yielding a solution $u^{(0)}$ associated with the mesh $T_0$.

2. Let $\varphi^{(0)} = |\nabla u^{(0)}|$ be the governing field. This field emphasizes regions where the solution has high derivatives, so that the mesh generator refines these regions.

3. Starting from the governing field $\varphi^{(0)}$ on the mesh $T_0$, an anisotropic adaptive mesh generator (see Borouchaki et al. [26], Hecht [27]) generates a totally new mesh, denoted by $T_1$.

Then, $T_1$ is used to solve the problem, and so on, until the solution obtained reaches an accurate localization of the stick-slip transition point. This method is based on the fact that high second derivatives of the velocity develop at the neighborhood of the stick-slip transition point, and thus the mesh generator refines this neighborhood. The singular behavior of the second derivative of the velocity at the neighborhood of the transition point will be analyzed in detail in the next section. The software is based on a finite element library released by the authors [28,29].

In order to reduce the computational cost in the square cross-section, we exploit the symmetries of the solutions with respect to the $Ox$, $Oy$ and the $x = y$ axis. Thus the domain of computation reduces to a triangle (see Fig. 2). Fig. 3 shows the mesh after 15 adaptation loops and for yield numbers $Bi = 0$ and $S = 0.385$, as defined in (17) and (18). The stick-slip transition point is close to the upper corner $x = y = 1$, and the stick region is small. Observe that the mesh adaptation process is able to capture the stick-slip transition point.

4. Numerical experiments and identification of the flow regimes

4.1. Flow features and terminology

The schematic view of the solution is represented on Fig. 4 and, for convenience, we introduce a specific terminology explained by Fig. 4.a. There are two types of rigid zones: the dead zones, located in the corners of the cross-section, associated with $u = 0$, and the plug, in the center of the cross-section, associated with a constant velocity. These rigid zones are separated by a deforming zone where the velocity varies gradually. The rigid zones are separated from the deforming zone by two surfaces: the dead zone boundary and the plug boundary. At the boundary of the cross-section, there is a stick region, where $u_{\partial \Omega} = 0$ and a slip region where the velocity is not zero. Finally, the transition point separates the stick and the slip regions.

In this section, the extension of the rigid zones and of the slip region are studied, using lengths shown on Fig. 4.b. Along the diagonal of the cross-section, $\xi_b$ is the distance from the center of the square to the boundary of central plug, and $\xi_m$ is the distance between the center of the square and the boundary of
the dead zones. Along an edge of the square cross-section, \( y_T \) is half the extension of the slip region, and \( y_m \) is the distance between the center of the edge and the boundary of the dead zones.

The case \( S = +\infty \), corresponding to a Bingham fluid flow that sticks at the wall, has been already studied in detail in [12] while the case \( Bi = 0 \), corresponding to a Newtonian fluid that may slip at the wall, has been studied in [18]. Thus, the present paper focuses on the cases where non-linear behaviours occur both inside the flow and at the boundary.

4.2. Flow with a fixed slip condition

When the value of the dimensionless parameter \( S \) is fixed, and \( Bi \) varies, the evolution of the velocity profiles and the rigid zones can be observed. In the particular case when \( S = +\infty \), the fluid sticks at the wall and we know that there exists a particular value \( Bi_B > 0 \) such that the flow stops when \( Bi \geq Bi_B \). This result has been proved for a general tube cross-section \( \Omega \) in [5] and the value \( Bi_B = \frac{2}{\sqrt{\pi}} \) has been obtained analytically in [1] for a square cross-section and by a numerical method in [12].

The presence of a slip condition modifies this behaviour: the results depend upon the value of \( S \). There exists a particular value \( Bi_T \) such that the flow is a rigid translation motion when \( Bi \geq Bi_T \). The translation velocity \( U_T \) could be zero in some cases, and then the flow stops.

The value of \( Bi_T \) depends upon the dimensionless parameter \( S \). When \( S \) is small enough, the flow tends, when \( Bi \) increases, to a rigid translation and fully slips at the wall. Conversely, when \( S \) is large enough, the flow tends, when \( Bi \) increases, to stop.

4.2.1. Convergence to the cessation of flow

In this paragraph, let us fix \( S = 0 \).

First, observe on Fig. 5.a the velocity profiles at the wall versus the \( y \) coordinate for various values of \( Bi \). All curves decrease with \( Bi \). Each curve reaches a maximum with an horizontal tangent at the center of the boundary cross-section, associated with \( y = 0 \). For each \( Bi \geq 0 \), we observe that there exists a point \( y_T \) that separates the slip and the stick region: when \( y \geq y_T \) the fluid sticks. Notice that the tangent in \( y = y_T \) is not horizontal and thus, the velocity gradient is discontinuous along the boundary of the cross-section.

For each fixed \( y \), the velocity at the wall is a decreasing function of \( Bi \). Fig. 5.b shows the maximal wall velocity \( u_{max,\Omega} \), reached at \( y = 0 \), as a function of \( Bi \) for \( S = 0 \). We observe that when \( Bi \) is larger than a critical value, denoted by \( Bi_A \approx 0.36 \), the velocity at the wall is zero all along the wall: the fluid sticks.

The position \( y_T \) of the transition point between the slip and the stick region is represented on Fig. 5.c as a function of \( Bi \). This representation shows that \( y_T \) is a decreasing function that vanishes for \( Bi = Bi_A \).

We have shown the following properties:
- There exists a value \( Bi_A \) such that when \( Bi < Bi_A \) the material slips in the central region of the wall and sticks close to the corner. When \( Bi > Bi_A \), the fluid fully sticks at the wall.
- The velocity at the wall decreases with \( Bi \) at each point of the wall.
- The stick region develops with increasing \( Bi \) until the total adhesion at the wall is reached at \( Bi = Bi_A \).
We now examine the solution inside the flow domain: let us consider the velocity along the axis and the development of rigid zones.

Fig. 6.a shows the velocity profiles along the horizontal axis $y = 0$ for different values of $Bi$. We observe decreasing and concave curves that reach a maximum at the center of the flow $x = 0$. The velocity is decreasing with $Bi$ at each position $x$. Moreover, at the center $x = 0$, the profiles exhibit a plateau that grows with $Bi$: it is associated with the development of a central plug flow region.

Fig. 6.b shows the velocity profiles along the diagonal axis of symmetry: notice that the material sticks at the wall before the plug reaches the wall. Also observe that in the corners of the square cross-section, i.e. at the vicinity of $\xi = \sqrt{2}$, the velocity vanishes: the material sticks at the wall and develops a dead zone. The size of the dead zone depends upon $Bi$.

The velocity of the plug region is also the maximum velocity $u_{\text{max},\Omega}$ in the pipe cross-section: it is represented versus $Bi$ on Fig. 7.a. Observe that $u_{\text{max},\Omega}$ is a decreasing function of $Bi$ and that it vanishes for $Bi = Bi_T \approx 0.53$. The value $Bi_T \approx 0.53$ is a critical value when the flow stops. This value $Bi_T \approx 0.53$ is obtained numerically and it coincides with the explicitly known critical value for the cessation of flow associated with adhesion at the wall [12]:

$$Bi_T = \frac{2}{2 + \sqrt{\pi}} \approx 0.5301589$$

This observation is consistent with the fact that the material sticks to the wall when $Bi \in \left[ Bi_A; Bi_T \right]$. Let us now observe the flow rate as a function of $Bi$, on Fig. 7.b. The curve first linearly decreases and then smoothly tends to 0, corresponding to the blocking configuration at $Bi = Bi_T$.

Fig. 8 represents the development of rigid zones for $S = 0.6$ versus $Bi$ and the associated adapted meshes. The development of rigid zones for $S = 0.6$ is similar to the case when the material sticks at the wall, that was previously presented in a separate work [12]: a central plug zone, convex and quasi-circular, develops. Its area increases with $Bi$ and its boundary flattens when approaching the wall. Simultaneously, concave dead zones appear and develop in the corners of the square cross-section. In this situation, the width of the deforming zone decreases and progressively reduces to a thin band around the central plug. Finally, the flow stops completely when the central plug simultaneously merges with the dead zones and reaches the wall.

The distance $\xi_b$ between the center of the cross-section and the boundary of the plug is displayed on Fig. 9, as well as the distance $\xi_m$ between the center of the square and the boundary of the dead zone. The distances are measured along the diagonal axis. The size variation of the rigid zones is similar to the one observed for a total adhesion.

The location $y_m$ of the dead zone boundary is compared to $y_T$ on Fig. 10, with $Bi$. Both curves decrease and first keep a constant distance to each other, then, in the vicinity of $Bi_A$, $y_T$ quickly falls to 0, while $y_m$ decreases to $y_m(Bi_T)$. It seems that $y_m(Bi_T) \approx y_T(0)$: along a side of the cross-section, the maximum extension of the dead zone and the minimum extension of the stick region seem to be the same. The variations of $y_m$ and $y_T$ mean that adhesion occurs on a part of the wall that is larger than the part covered by the rigid zones.

As a conclusion for this case $S = 0.6$, three distinct flow regimes have been identified:

(i) adhesion in the corner and slip at the wall for $Bi \in [0; Bi_A]$,
(ii) adhesion everywhere for $Bi \in [Bi_A; Bi_T]$,
(iii) blocking for $Bi > Bi_T$,

in the first two regimes, a quasi-circular central plug develops, as well as concave dead zones in the corners.
All the rigid zones are separated by a deforming layer: the greater $Bi$, the thinner the layer.

4.2.2. \textit{Convergence to a block translation}

Let us fix here $S = 0.45$ and compare the results to the previous case where $S$ was equal to 0.6.

Let us begin with the behaviour inside the flow domain, considering Fig. 11. The velocity profiles are represented along the horizontal symmetry axis, for some $Bi$. Moreover, a plateau develops for $Bi > 0$ and fills the width of the domain for $Bi > Bi_C$, with $Bi_C \approx 0.5$. This corresponds to a central plug which reaches the wall for $Bi = Bi_C$. On Fig. 11.b, the velocity profiles are displayed on the diagonal axis. A plateau is developing as well, with increasing length; for increasing $Bi$. Let us in particular consider the velocity near the corners ($\xi = \sqrt{2}$): for $Bi = 0.2$, the velocity is 0, however when increasing $Bi$ the velocity becomes positive. This means that dead zones may appear for small $Bi$ but vanish when $Bi$ increases. This leads us to the following detailed analysis of the development of the rigid zones.

On Fig. 12, a circular plug is developing when $Bi$ increases. The plug touches the wall and goes on growing while slipping on the wall when $Bi$ is increased. For $Bi > Bi_T \approx 0.71$, the plug fills the whole cross-section. The contact between the plug and the wall is the first main difference with the behaviour observed in section 4.2.1.

On the zoom Fig. 13, the area of the dead zones in the corners increases with $Bi$, as usual. However, when $Bi$ reaches a particular value and then goes beyond, the rigid zones vanish. This is the second main difference with the section 4.2.1. In addition, another important difference is the size of the dead zones, as they remain here very small (the zoom shows the corner for $0.98 \leq y \leq 1$).

The plug velocity is given as a function of $Bi$ on Fig. 14.a. The velocity decreases and smoothly tends to a constant value $U_T = 0.05$ at $Bi = Bi_T$. For $Bi > Bi_T$, the flow is therefore a unique rigid block translating with velocity\(^1\) $U_T = 0.05$. This convergence to a slipping block is the third main difference with the cessation of flow case of section 4.2.1.

The flow rate is represented on Fig. 14.b, it is a decreasing function of $Bi$, it seems to smoothly tend to $U_T \approx 0.05$ at $Bi = Bi_T$.

In order to compare the evolution of the size of the rigid zones, two distances along the diagonal axis are represented as functions of $Bi$ on Fig. 15: the distance $\xi_b$ between the center and the boundary of the plug, and the distance $\xi_m$ between the center of the square and the boundary of the dead zone. The curve\(^2\) $(Bi; \xi_b(Bi))$ seems straight, this means that the plug size increases until the cessation of flow regime is reached. In the other hand, the curve $(Bi; \xi_m(Bi))$ on Fig. 15.b has a minimum at $Bi \approx 0.22$ because small dead zones appear, with first increasing size, but finally with decreasing size, until they vanish at $Bi \approx 0.37$.

Let us now consider the velocity profiles at the wall on Fig. 16.a. For an increasing $Bi$, the velocity decreases at the center while it increases near the corner. A plateau begins to grow from the center of the wall for $Bi > Bi_C$, this is because the central plug comes into contact with the wall at $Bi = Bi_C$. The part of the wall where the velocity is constant (contact region between plug and wall) becomes larger and finally is the entire wall for $Bi = Bi_T$. For $Bi \geq Bi_T$, $u = U_T \approx 0.05$, because all the fluid in the pipe is then translating as a single block at the velocity $U_T$.

---

\(^1\) Theoretical developments about $U_T$ are presented in appendix.

\(^2\) For a real function $f$ defined for $x \geq 0$, the notation $(x; f(x))$ is used here as a shortcut to denote the curve defined by the set of points $\{(x, f(x)) : x \geq 0\}$. 

11
The maximum velocity at the center of the wall, denoted \( u_{max,\partial} \), is the velocity of the central plug for \( Bi \geq Bi_C \), and is represented on Fig. 16.b. It regularly decreases and smoothly reaches \( U_T \) at \( Bi = Bi_T \).

We can notice the existence of a number \( Bi_S \approx 0.37 \) beyond which the fluid slips everywhere. For \( Bi < Bi_S \), a stick-slip transition point \( y_T \) can be defined. This point is an increasing function of \( Bi \), as it can be seen on Fig. 17. The point \( y_T \) is compared to the position of the dead zone boundary \( y_m \), on Fig. 17. The curve \( (Bi; y_m(Bi)) \) exhibits the non-monotonic behaviour already described for \( \xi_m \) with a minimum at \( Bi \approx 0.22 \) and then full slip at \( Bi = Bi_S \). Both curves \( y_m \) and \( y_T \) meet at \( Bi = Bi_S \), i.e. the dead zones disappear only when the slip is everywhere.

In this section, the analysis of the results can be summarised as follows:

- There exists a value \( Bi_S \approx 0.37 \) above which the material slips on the whole boundary, and below which the slip is partial.
- The stick region decreases with \( Bi \) until the full slip occurs at \( Bi = Bi_S \).
- A central plug grows when \( Bi \) increases.
- The plug reaches the wall at \( Bi = Bi_C \approx 0.5 \).
- The plug fills the whole pipe when \( Bi > Bi_T \approx 0.71 \), then the material translates with the constant velocity \( U_T \approx 0.05 \).
- Small dead zones appear when \( Bi \) increases, and then vanish for \( Bi < Bi_C \).

### 4.3. Identification of the flow regimes

In the Newtonian case [18], we have shown the existence of two numbers \( S_A \) and \( S_G \) characterising the velocity profile at the boundary of the cross-section:

- for \( 0 \leq S \leq S_G \), the fluid slips on all the wall,
- for \( S_A \leq S \), the fluid sticks on all the wall,
- for \( S_G < S < S_A \), the fluid sticks in the corners while it slips on the remainder of the wall.

The study of the role of \( Bi \) for \( S \neq 0 \) in the sections 4.2.1 and 4.2.2 has shown that \( S_A \) and \( S_G \) still exist for \( Bi \neq 0 \), leading to a block translation, possibly with a zero velocity. The synthesis Fig. 18 completes this analysis, by displaying \( S_A \) and \( S_G \) as functions of \( Bi \), and \( Bi_T \) as a function of \( S \). The curves delimit five flow regimes:

1. full adhesion (A),
2. full slip (G),
3. adhesion in the corners, slip elsewhere (A+G),
4. cessation of flow (B),
5. block translation (T).

The curves \( (Bi; S_A(Bi)) \) and \( (Bi; S_G(Bi)) \) have opposite variation and join at \( X = (Bi_T(S_T), S_T) \approx (0.71, 0.53) \). Then, they remain identical for \( Bi \geq Bi_T(S_T) \). The number \( Bi_T(S) \) only varies in \( S \in [S_T; 0.53] \) from \( Bi_T(S_T) = Bi_T(0) \approx 0.71 \) to \( Bi_T(0.53) = Bi_T(\infty) = \frac{2}{2+\sqrt{2}} \). Thus, for any fixed \( S \), when \( Bi \) increases, the flow tends to:

- either a full adhesion and then a cessation of flow (for \( S > S_T \)), then the stop value \( Bi_T(\infty) \) does not depend on \( S \) if \( S - S_T \) is high enough,
- or a full slip and then a block translation (for \( S < S_T \)), the value \( Bi_T = Bi_T(0) \) does not depend on \( S \).

Table 1 summarises the main critical values of the dimensionless numbers.
Moreover, the curve \((S; Bi_T(S))\) only varies when it is identical to \((Bi; S_A(Bi))\), for \(S_T \leq S \leq S_A(Bi_T(\infty))\). Notice that we found \(S_A(Bi_T(\infty)) = Bi_T(\infty)\), this means: for a given \(S\) between \(S_T\) and \(Bi_T(\infty)\), when \(Bi\) increases, the slipping exists somewhere on the wall until the stopping value \(Bi = Bi_T(S)\) is reached (with \(Bi_T(S)\) between \(Bi_T(\infty)\) and \(Bi_T(0)\)).

In the sections 4.2.1 and 4.2.2, two particular values of \(S\) have evidenced that the qualitative evolution of the flow with \(Bi\) depends on the sign of \(S - S_T\). In the following, the investigation of the flow structures (rigid-fluid boundary, stick-slip transition) is completed with some intermediate values of \(S\) between 0.45 and 0.6 (displayed on Fig. 18).

Fig. 19.b represents the transition \(y_T\) as a function of \(Bi\), for some \(S\). When \(S \geq S_T\), all the curves tend to 0 with a final slope close to the vertical. For intermediate values between \(S = S_T = 0.5\) and \(S = 0.53\), each curve increases to a maximum and then decreases to 0.

The boundaries of the rigid zones along the diagonal of the cross-section, as function of \(Bi\), are compared on Fig. 19.a, for the values of \(S\) shown with dashed lines on Fig. 18. For a given value of \(Bi\), the greater \(S\) the larger the rigid zones (plug and dead zones). Moreover, the phenomenon of vanishing dead zones seems to be specific to the case where \(S \leq S_T\), in this case the plug grows until it fills the entire pipe at \(Bi = Bi_T\). When at the contrary \(S > S_T\), the dead zones grow until they meet the plug at \(Bi = Bi_T\) and the flow stops.

These last observations on stick-slip transition and rigid zones evolution lead us to define three sub-regimes in the regime \(A + G\):

- \(AG1\) : It is defined by the couples \((S, Bi)\) from \(A + G\) such that \(S > S_A(Bi_T(+\infty)) \approx 0.53\). When \(Bi\) increases, full adhesion is reached (regime \(A\)).
- \(AG2\) : defined by the couples \((S, Bi)\) from \(A + G\) such that \(1/2 = S_T \leq S \leq S_A(Bi_T(+\infty)) \approx 0.53\). When \(Bi\) increases, full adhesion and cessation of flow arise simultaneously (regime \(B\)).
- \(AG3\) : defined by the couples \((S, Bi)\) from \(A + G\) such that \(S \leq S_T = 1/2\). When \(Bi\) increases, a full slip is reached (regime \(G\)).

All the flow configurations are summarized on Fig. 20 and Fig. 21.

5. Conclusion

This paper presents a combination of the two previous non-linear yield stress phenomena: the Poiseuille flow of a Bingham fluid with slip yield boundary condition at the wall. This problem is of practical interest, for instance for pipeline flows of yield stress fluids such as concrete and cements, and was not addressed to the best of our knowledge from a computational point of view.

An anisotropic auto-adaptive mixed finite element method for a general pipe cross-section has been developed and applied here to the case of a square cross-section. This generalizes the works previously achieved for two particular cases: a viscoplastic fluid with no-slip at the wall, and a Newtonian fluid with the yield-force slip law. The case of a pipe with a square cross-section has been investigated in detail. The computations cover the full range of the two main dimensionless numbers and exhibit complex flow patterns.

Considering the two main parameters \(S\) and \(Bi\) of the material, the main result is the identification of five flow regimes and three sub-regimes. More precisely:

- the limiting values of \(Bi\) and \(S\) separating the regimes have been obtained:
the evolution of the rigid zones and stick-slip transition points has been established, with respect to $Bi$ and $S$ in each of the eight regimes.

In particular, we have shown the existence of a regime where slipping occurs everywhere on the wall. The results concerning this regime has important consequences on the manner yield-stress fluids in pipes are considered:

- a yield-stress fluid may not be blocked in a pipe with a plug touching the wall, even with a zero shear rate in the whole pipe,
- rigid zones in corners may not exist for $Bi \neq 0$,

Another uncommon result is that dead zones in corners may reduce their area when the $Bi$ number increases (for $S \leq S_T$).

For $Bi$ large enough, the material is a unique rigid zone. Using variational analysis for a possibly non-square cross-section, we found that the velocity of the translating block of material is: $U_T = \max(0, S_T - S)$, where $S_T = \text{area}(\Omega)/\text{length}(\partial \Omega)$. For $S > S_T$, we recover the well-known case where the fluid is blocked.

Finally, the simulations results have evidenced complex flow pattern, which have been caught thanks to the use of an auto-adaptive mesh process. The completeness of the results demonstrates the efficiency of the numerical method.

Appendix A. Some theoretical results

It is possible to explain why $Bi_T$ remains equal to $Bi_T(\infty)$ when $S > S_A$, using a result proved in [30] and [5]. In the present case, if $S$ and $Bi$ are so that $u_{\partial \Omega} = 0$, there exists a value $Bi_T$ defined by:

$$Bi_T = \sup \left\{ \frac{\int_{\Omega} v \, dx}{\int_{\Omega} |\nabla v| \, dx} : v \in H_0^1(\Omega) \text{ and } \int_{\Omega} |\nabla v| \, dx \neq 0 \right\},$$  \hspace{1cm} (A.1)

such that $u = 0$ if $Bi \geq Bi_T$, and $u > 0$ otherwise. Hence, $Bi_T$ does not depend on $S$ and this remains true as far as $u_{\partial \Omega} = 0$ on both side of the curve $(S; Bi_T(S))$. Moreover, the present results concerning the limit of the cessation of flow regime have a good agreement with the mathematical work of Ionescu and Sofonea [31]. The results of these authors are:

(Ionescu-Sofonea [31], theorem 4.1., page 294)

(i) The set $B$ is convex and (topologically) closed,
(ii) If $(Bi, S) \in B$, then $[Bi, +\infty[\times[0; +\infty[ \subset B$,
(iii) There exists numbers $L_1$ and $L_2$ such that $B \subset [L_1, +\infty[ \times [L_2, +\infty[$.

Following the same authors, let us moreover introduce the function:

$$F_1(Bi, S) = \inf \left\{ Bi \int_\Omega |\nabla v| \, dx + S \int_{\partial \Omega} |\gamma v| \, ds - \int_\Omega v \, dx : v \in H^1(\Omega) \text{ and } \int_\Omega |\nabla v|^2 \, dx + \int_{\partial \Omega} |\gamma v|^2 \, ds = 1 \right\}$$ \hspace{1cm} (A.2)

The function $F_1$ is concave upper semi-continuous, for fixed $Bi$ and $S$, $F_1(., S)$ and $F_1(Bi, .)$ are increasing and the numbers $L_1$ and $L_2$ are therefore determined as follows (see [31], Lemma 2.1, page 294):

$$L_1 = \lim_{S \rightarrow +\infty} \inf \{ Bi \geq 0 ; F_1(Bi, S) \geq 0 \}$$  \hspace{1cm} (A.3)

$$L_2 = \lim_{Bi \rightarrow +\infty} \inf \{ S \geq 0 ; F_1(Bi, S) \leq 0 \}$$

for all $S \geq S_T$, the following properties are satisfied:

(i) $G_1$ is a convex decreasing function,
(ii) $Bi \geq G_1(S)$ if, and only if, $(Bi, S) \in B$,

Another result characterises the blocking values of $Bi$ as functions of $S$:

(Ionescu-Sofonea [31], theorem 5., page 295)

Let us define $G_1 : 0; +\infty[ \rightarrow ]0; +\infty[$ by :

$$G_1(S) = \sup \left\{ \frac{\int_\Omega v \, dx - S \int_{\partial \Omega} |\gamma v| \, ds}{\int_{\Omega} |\nabla v| \, dx} : v \in H^1(\Omega) \text{ and } \int_{\Omega} |\nabla v| \, dx \neq 0 \right\}$$ \hspace{1cm} (A.4)

for all $S \geq S_T$, the following properties are satisfied:

(i) $G_1$ is a convex decreasing function,
(ii) $Bi \geq G_1(S)$ if, and only if, $(Bi, S) \in B$.

For $S \in ]S_T; +\infty[$, the number $G_1(S)$ is the critical value of $Bi$ denoted $Bi_T(S)$ in this article.

It is possible to explicitly give the velocity along the curve $(S; Bi_T(S))$, the formula is identical to the case of a circular cross-section:
\[ U_T(S) = \begin{cases} 
\frac{1}{2} - S & \text{if } S < S_T = \frac{1}{2} \\
0 & \text{otherwise.} 
\end{cases} \] (A.5)

This leads to the following questions: does \( S_T \) depend on the geometry? in the translation regime \((T)\), is the velocity constant (w.r.t. \( Bi \)) when \( Bi \) increases? For the answer, let us consider a couple \((S, Bi)\) in the regime \( T \). The velocity is constant in \( \Omega \) and positive\(^3\). The variational slip law:

\[
\int_{\partial \Omega} \gamma u (\zeta - \gamma u)\,ds + S \left\{ \int_{\partial \Omega} |\zeta|\,ds - \int_{\partial \Omega} |\gamma u|\,ds \right\} \geq \int_{\partial \Omega} \lambda (\zeta - \gamma u)\,ds \quad \forall \zeta \in L^2(\partial \Omega) \quad (A.6)
\]

can then be simplified by replacing \( \zeta \) by \( u + \epsilon \zeta \), where \( \epsilon > 0 \) is a real number, and then by dividing by \( \epsilon \) and finally letting \( \epsilon \) tend to 0:

\[
\int_{\partial \Omega} \gamma u \zeta\,ds + S \int_{\partial \Omega} \frac{\gamma u}{|\gamma u|} \zeta\,ds \geq \int_{\partial \Omega} \lambda \zeta\,ds \quad \forall \zeta \in L^2(\partial \Omega). \quad (A.7)
\]

In other words, \( u \) is a positive constant and:

\[
u \int_{\partial \Omega} \zeta\,ds + S \int_{\partial \Omega} \zeta\,ds \geq \int_{\partial \Omega} \lambda \zeta\,ds \quad \forall \zeta \in L^2(\partial \Omega). \quad (A.8)
\]

Now the equilibrium equation writes:

\[
\int_\Omega \sigma : \nabla v\,dx + \int_{\partial \Omega} \lambda \gamma v\,ds = \int_\Omega v\,dx \quad \forall v \in H^1(\Omega),
\]

therefore, using (A.8) in which we choose \( \zeta = v_{\partial \Omega} \), we obtain:

\[
\int_\Omega \sigma : \nabla v\,dx + (u + S) \int_{\partial \Omega} \gamma v\,ds = \int_\Omega v\,dx \quad \forall v \in H^1(\Omega),
\]

in particular, for \( v = u \):

\[
\int_\Omega \sigma : \nabla u\,dx + (u + S) u \text{ length}(\partial \Omega) = u \text{ area}(\Omega),
\]

now, using the hypothesis \( \nabla u = 0 \), the velocity is obtained:

\[
u = U_T(\Omega, S) = \frac{\text{area}(\Omega)}{\text{length}(\partial \Omega)} - S,
\]

it leads to the value of \( S_T \) by considering \( u = 0 \) and assuming the monotonicity of \( u \) along \((S; Bi_T(S))\):

\[
S_T = \frac{\text{area}(\Omega)}{\text{length}(\partial \Omega)}.
\]

\(^3\) the positivity seems obvious and can be shown by a method given in [5], where the author demonstrate that \( u \geq 0 \) in the case of adhesion at the wall.
