(Dated: February 27, 2007)

We report accurate measurements of the equation of state (EOS) of cubic boron nitride by x-ray diffraction up to 160 GPa at 295 K and 80 GPa in the range 500-900 K. Experiments were performed on single-crystals embedded in a quasi-hydrostatic pressure medium (helium or neon). Comparison between the present EOS data at 295 K and literature allows us to critically review the recent calibrations of the ruby standard. The full P-V-T3 data set can be represented by a Mie-Grüneisen model, which enables us to extract all relevant thermodynamic parameters: bulk modulus and its first pressure-derivative, thermal expansion coefficient, thermal Grüneisen parameter and its volume dependence. This equation of state is used to determine the isothermal Grüneisen mode parameter of the Raman TO band. A new formulation of the pressure scale based on this Raman mode, using physically-constrained parameters, is deduced.

PACS numbers: 62.50.+p,61.10.Nz,65.40.De

I. INTRODUCTION

Cubic boron nitride (c-BN) is a material with remarkable properties: extreme hardness, chemical inertness, large band gap and high mechanical and thermal stabilities. This makes it very attractive for a number of applications including abrasive or protective-coating material and microelectronic devices. Knowing the properties of c-BN under conditions of high pressure (P) and temperature (T) is important for some of these applications. It has also been recognized that c-BN could be a useful pressure sensor in high pressure (HP)- high temperature (HT) experiments in diamond anvil cells, based on its intense Raman TO band. This article is organized as follows: in section II, we present the experimental procedure; section III is devoted to the presentation of the room-temperature equation of state; the thermal expansion at room pressure follows in section IV; the presentation and analysis of P–V–T data at simultaneous HP-HT are given in section V; in section VI, the thermal dependence of the isothermal Grüneisen parameter of the Raman TO band is investigated and a new formulation of the Raman pressure scale is then presented. Section VII finally gives concluding remarks.

II. EXPERIMENTAL PROCEDURE

The present experiments were conducted with single crystals of c-BN of size ranging from 3 to 15 µm. These crystals were selected from a powder batch using their Raman signal as a criterium for good crystallinity: crystals which presented intense Raman first-order TO and LO bands along with lorentzian shapes and small bandwidths (5 cm−1) were selected. A few crystals were then loaded into the experimental volume of a diamond anvil cell, along with ruby and SrB4O7:Sn2+ as pressure sensors. Care was
taken in order to position the samples and the pressure sensors within a few micron distance to each other and at the center of the diamond culet. We used diamond anvils with flat culets of 0.1 to 0.4 mm and rhenium gaskets. Helium was chosen as pressure transmitting medium for the room temperature experiments above 50 GPa and neon was used otherwise. In the $P - T$ range of the present experiments, these two pressure transmitting media are known to provide the best approximation to hydrostatic conditions.

Membrane diamond anvil cells (MDAC) designed for high-temperature operation were used. The cells could be fitted as a whole inside a ring-shaped resistive heater. To achieve temperatures above 800 K, a smaller, additional heater made of a resistive wire coiled around a ceramic tube, is positioned around the anvil-gasket assembly. The temperature of the heaters are regulated within 1 K using commercial devices. An isolated, K-type thermocouple is fixed by ceramic cement with its head in contact with the diamond anvil, close to the gasket. The ensemble is heated in air or in a Ar-H$_2$(2%) reducing atmosphere. Numerous previous experiments have shown that the temperature measured by the thermocouple is within 5 K of the sample temperature.

Pressure was determined using the pressure shift of the luminescence lines of ruby (at 295 K) or SrB$_4$O$_7$: Sm$^{2+}$. The pressures reported here are based on Holzapfel’s 2005 ruby scale, hereafter denoted H2005. We also compared the results obtained with other ruby calibrations and, as discussed below, H2005 was found to provide excellent consistency between present and literature data. The calibration of the SrB$_4$O$_7$: Sm$^{2+}$ sensor, initially based on the ruby scale from Ref. 21, was also modified to match the H2005 scale. For the measurements above 100 GPa at 295 K, the ruby signal was too weak, thus the pressure was determined from the equation of state of $^4$He (Ref. 24 with proper correction for the H2005 ruby scale). The volume of $^4$He was calculated using the reflections present on the same diffraction patterns as the c-BN sample and excellent agreement between this pressure determination and that from ruby was observed below 100 GPa.

Angular-dispersive x-ray diffraction experiments were performed on beamline ID27 of the European Synchrotron Radiation Facility (ESRF, Grenoble, France). The monochromatic beam ($\lambda = 0.3738$ Å) was focused to a $\approx 7 \times 10$ $\mu$m$^2$ spot. Dispersed x-rays were collected by a MAR345 image plate while the MDAC was continuously rotated about the $\phi$-axis by $\pm 20^\circ$. The images were integrated using the fit2D program. Between 6 and 9 single-crystal reflections could be observed depending on the sample, with a resolution up to $\approx 0.83$ Å. All of them could be indexed in the zinc-blende structure (space group $F\bar{4}m$) reported for this material. The lattice parameter $a$ was refined with the program UnitCell using the measured $d$-spacings of all observed reflections. The uncertainty on $a$ was on average $5 \times 10^{-4}$ Å.

![FIG. 1: (Color online) Volume per atom of c-BN as a function of pressure at 295 K. The open and solid circles are present measurements on samples in a neon and helium pressure medium respectively. The estimated error bars are within the symbol sizes. Triangles: Ref. 1 (in methanol/ethanol); dashed line: Ref. 11 (in helium); squares: Ref. 13 (in nitrogen). The solid line is the fit to the present data using the Vinet equation $V_0 = 5.9062(6)$ Å$^3$/at, $B_0 = 395(2)$ GPa, $B'_0 = 3.62(5)$](image)

TABLE I: Comparison between values for the zero-pressure isothermal bulk modulus $B_0$ and its first-pressure derivative $B'_0$ obtained by fitting the present data at ambient temperature to different EOS models: Vinet, second-order Birch-Murnaghan (BM), and Holzapfel’s AP2 form. The zero-pressure volume $V_0$(295 K) was fixed to 5.9062 Å$^3$/at.

III. THE ROOM-TEMPERATURE EQUATION OF STATE

The volume per atom $V$ of c-BN at 295 K ($V = a^3/8$) was measured up to 57.8 GPa in a neon pressure medium and up to 162 GPa in a helium pressure medium. Excellent agreement is observed between the two data sets. The results are gathered in Fig. 1 and Table I. As expected, no phase transition was observed in this pressure range.

To extract the values of the zero-pressure isothermal bulk modulus $B_0$ and its first-pressure derivative $B'_0$ from the present data, we considered three different phenomenological models of equation of state: the Vinet form, the Birch-Murnaghan second-order form, and Holzapfel’s AP2 equation. These relations were least-
squares fitted to the data. The results are listed in Table and the fit using the Vinet equation is plotted in Fig. In the compression range probed here (0.77 ≤ V/V₀ ≤ 1) the three models fit equally well the data and give very similar values for B₀ (395(2) ± 397(2) GPa) and its first pressure-derivative B′₀ (3.50(5) ± 3.62(5)). Here as in all the text, the number in parenthesis indicate the standard deviation for the last digit of the fitting parameter; it does not reflect its absolute uncertainty, which primarily depends here on the one of the ruby standard. The volume and pressure difference between experimental data and the Vinet fit is shown in Fig. 2. The volume V₀ at P = 0 and 295 K was taken as the measured value at 1 atm of 5.9062 Å³ (hereafter denoted as MXB1986). The latter value is identical, within uncertainties, to previous reports.

Figs. 2 and also show experimental data obtained in previous studies. For comparison with the present work, the original pressure values have been rescaled onto the H2005 scale. Aleksandrov et al. reported their measurements up to 34 GPa in He in the form of a quadratic fit of the compression factor Δρ/ρ₀—where ρ is the density, vs. the relative shift of the ruby R₁ line. Their absolute volume values differ from ours by less than 2 × 10⁻³ Å³/at, corresponding to a maximum pressure difference of 2 GPa. By contrast, systematic deviations are observed between our measurements and those of Solozhenko et al. and Knittle et al. above about 40 GPa, where their measured volume at a given pressure is systematically higher than ours. This is likely due, at least in part, to the larger nonhydrostatic stresses produced by the N₂ or methanol-ethanol pressure medium used in Solozhenko et al. and Knittle et al. experiments respectively.

As mentioned above, the values of B₀ and B′₀ obtained by fitting the EOS of highly incompressible solids like c-BN and diamond are very sensitive to the chosen pressure calibration for the ruby standard. As a matter of fact, the first hint that the commonly used Mao et al.’s 1986 calibration (hereafter denoted as MXB1986) becomes increasingly wrong with pressure was given by the measurements of the diamond EOS by Abdurrokhmanov et al. to 40 GPa in 1989. More recently, the very accurate measurements of the diamond EOS up to megabar pressures by Occelli et al. evidenced more firmly the discrepancy between the value found for B′₀ using ultrasonic techniques (4.0 ± 0.7), on one hand, and that obtained from the EOS (3.0) when pressure is calculated with the MXB1986 scale, on the other hand. Consequently, a revision of the latter scale has been proposed by several authors based on the diamond data and/or those recently obtained for the EOS of several metals that showed the same trend.

In Table we compare the B₀ and B′₀ parameters obtained by fitting the Vinet EOS to the present c-BN data using the various ruby calibrations proposed in the literature. For comparison and consistency check, we also show the results obtained with the diamond data of Occelli et al. To decide which ruby scale(s) seem(s) more reasonable, we list in Table the values of B₀ and B′₀ determined by other means, whether experimental (ultrasonic or Brillouin scattering measurements) or theoretical. Unfortunately, there exists only one determination of B′₀ for diamond using ultrasonic experiments under pressure, which has a limited accuracy, and none has been reported yet for c-BN. The largest source of comparison comes thus from the numerous theoretical studies based on first-principles (ab initio) techniques. Whereas the bulk modulus and zero-pressure volume show large

Variations among the various theoretical studies, the values for $B'_0$ appear much less dependent on the theoretical approaches and approximations used in each of them, especially if we consider the most recent works. Indeed, the two latest studies of diamond give values of $B'_0$ between 3.65 and 3.8(1), whether the density functional theory (DFT), within LDA or GGA approximations, or the quantum Monte-Carlo approach is used. Similarly, all DFT-LDA calculations on c-BN give $B'_0 = 3.6 \pm 0.05$, irrespective of the considered pseudopotential. In the case of c-BN also, there is a nice agreement between the latest studies on the values of $B'_0$ which vary from 395 to 398 GPa, i.e. in very good agreement with the Brillouin scattering experiments (400 ± 20 GPa). We see from Table III that the ruby scales H2003, H2005 and DO2007 are those giving the best consistency with available literature data, while providing the best fits based on the least-squares $\chi^2$ criterium. The DLM2004 and CNSS2005 calibrations give close results but a larger $\chi^2$, which could be ascribed to the used functional form. This also confirms that the MXB1986 scale becomes increasingly wrong with pressure, underestimating it by about 8.5% at 160 GPa. We note that H2003, H2005, DLM2004, CNSS2005 and DO2007 scales agree within 3% at 160 GPa, which may be considered as the present uncertainty of the ruby scale at this pressure. It is now clear that independent experimental determination of $B'_0$ such as given by sound-propagating experiments, for both c-BN and diamond could help to better establish the ruby scale in the megabar range.

IV. THERMAL EXPANSION AT AMBIENT PRESSURE

We performed volume measurements at room pressure as a function of temperature between 295 and 948 K. The results are plotted in Fig. 3 and reproduced in Table IV. They are compared to those of Slack and Bertram between 77 and 1289 K. The two data sets agree within error bars in the overlapping range, although we systematically find larger volume values at a given temperature above 300 K. The calculations of Albe are also shown as the dotted line in Fig. 3. They are based on the density functional theory (DFT) within the local density approximation (LDA) for the static part, and a Debye-Grüneisen model for the thermal part. The calculated volume follows very well the experimental data below 500 K but increasingly overestimate them above this temperature. Present and Slack and Bertram data were fitted to-

![FIG. 3: (Color online) Volume and thermal expansion coefficient as a function of temperature. The solid circles are present data and triangles show measurements of Ref. 30. The fit to both data sets using Eq. (1) is shown as the red line. The blue dotted line represents the calculations of Albe. In the inset, the volume thermal coefficient $\alpha_0$ is represented.](image-url)

Together using the second-order approximation to the zero-pressure Grüneisen equation of state (see Ref. [2] and references therein). In this approximation, the temperature dependence of the volume is given by:

$$V_0(T) = V_{0,0} \left[ 1 + \frac{U_{th}(T)}{Q - bU_{th}(T)} \right]$$  \hspace{1cm} (1)

where $U_{th}(T)$ is the internal energy due to lattice vibrations, $b = \frac{1}{2}(B'_{0,0} - 1)$ and $Q = (V_{0,0} B_{0,0})/\gamma$. $V_{0,0}$, $B_{0,0}$ and $B'_{0,0}$ are respectively the volume, bulk modulus and its first derivative at zero pressure and temperature. $\gamma$ is the thermobaric Grüneisen parameter defined by:

$$\gamma = -\frac{\langle V/U_{th}\rangle(\partial F_{th}/\partial V)_T}{(V/U_{th})P_{th}}$$  \hspace{1cm} (2)

where $F_{th}(V,T)$ is the thermal part of the Helmholtz free energy and $P_{th} = -\langle\partial F_{th}/\partial V\rangle_T$. If $\gamma$ is independent of $T$, we assume here, then $\gamma = \gamma_{th}$ where $\gamma_{th}$ is the thermodynamic Grüneisen parameter ($\gamma_{th} = (V/C_v)(\partial P/\partial T)_V$ with $C_v$ the specific heat at constant volume) and $U_{th}(T)$ was evaluated within the Debye model:

$$U_{th}(T) = \frac{RT}{\Theta_\gamma} \left( \frac{\Theta_\gamma}{T} \right)^3 \int_0^{\Theta_\gamma/T} \frac{x^3}{\exp(x) - 1} \, dx$$  \hspace{1cm} (3)

where $R$ is the ideal gas constant and $\Theta_\gamma$ the Debye temperature at $P = 0$. For the latter, we used the value of 1700 K estimated from the infrared spectrum by Gielisse et al, which is also in agreement with data on specific heat $C_p$. $B_{0,0}$ was fixed at 397 GPa, which is obtained by adding to the value of $B_{0,0}(295 \text{ K})$ found above (Vinet fit), the small correction (2 GPa) calculated by Abella between 0 and 300 K (Table III). $B'_{0,0}$ was fixed equal to $B'_0$ (295 K) = 3.62.

The fit of the $V_0(T)$ data with Eq. (1) then gives $V_{0,0} = 5.9026(4) \text{ Å}^3$/at and $\gamma_{th} = 1.04(1)$ ($\gamma_{th} = \gamma_{th}(P = 0)$). It is shown as the solid red line in Fig. 5. The temperature dependence of the thermal expansion coefficient $\alpha_\gamma$, calculated by differentiating Eq. (1), is plotted in the inset of the same figure. It is seen that Eq. (1) gives a good reproduction of $V_0(T)$ in the considered temperature range. We also note that the present value for $\gamma_{th}$ is close to the one obtained by Brillouin-zone integration of the phonon dispersion curve ($\gamma_{th} > 0.95$) determined by Kern et al using density functional theory.

V. HIGH PRESSURE AND TEMPERATURE EQUATION OF STATE

High pressure and temperature measurements were performed up to 80 GPa at 500, 600, 750 and 900 K, with the results listed in Table V. These are to our knowledge the first reported data at simultaneous HP-HT conditions. The $P-V-T$ data set is represented in Fig. 6a.

This data set was least-squares fitted using a Mie-Grüneisen model. In this model, the pressure is expressed as the sum of a "cold" ($P_0$) and thermal ($P_{th}$) part, i.e.:

$$P(V,T) = P_0(V) + P_{th}(V,T)$$  \hspace{1cm} (4)

with $P_0(V,T) = 0$ at 0 K. To represent $P_0(V)$, a Vinet equation [3] was used, whereas the thermal part is written
thus be regarded as the best one for the Mie-Grüneisen
model. The parameter set given in Table V can

\[ \gamma \] and \[ q \] values are identical to the starting ones within their stan-

determined as described above. The obtained value for \[ q \] is 0.8 with a rms deviation of 0.6 GPa. If we allow \[ B_{0,0} \]

\[ \Theta \] and \[ \gamma_{th} \] to vary in the fitting procedure, the resulting values are identical to the starting ones within their stan-

dard deviations. The parameter set given in Table V can

in the Debye-Grüneisen (quasi-harmonic) approximation, using Eqs. (24). In this approximation, we have the identity \( \gamma_{th} = \gamma = \gamma_D \), where \( \gamma_D = -\frac{\partial \ln(\Theta)}{\partial \ln(V)} \) is the Debye-Grüneisen parameter. The variation of the Debye temperature \( \Theta \) with volume is thus given by that of \( \gamma_{th} \). Here \( \gamma_{th} \) was allowed to vary with the compression ratio according to the empirical relation

\[ \gamma_{th} = \gamma_{th0}(V/V_{0,0})^q \], where \( q \) was taken as constant.

In the fit, the only varying parameter is \( q \). All the others

\( V_{0,0}, B_{0,0}, B'_{0,0}, \gamma_{th0} \) and \( \Theta_0 \) were fixed to the values determined as described above. The obtained value for \( q \) is 4 ± 1.5 and the whole parameter set is given in Table V.

Fig. 4(b) shows the difference between the experimental pressures and the one predicted by the present model. This difference is for most data points smaller than 1 GPa and the rms deviation is 0.6 GPa. If we allow \( B_{0,0} \)

\[ \Theta \] and \[ \gamma_{th0} \] to vary in the fitting procedure, the resulting values are identical to the starting ones within their stan-
dard deviations. The parameter set given in Table V can

\[ \gamma_{th0} \) and \( \gamma_{th} \) may be obtained by the Brillouin-

zone integration of the phonon mode Grüneisen param-

eters. A large reduction of \( \rho \) may thus indicate that the Grüneisen parameters for the acoustic modes, which give the dominant contribution, rapidly decrease with pressure. As a matter of fact, the calculated \( \gamma \) for the trans-
verse acoustic branches at \( P = 0 \) are very low (~0.25) along some directions of the Brillouin zone, especially near the zone boundaries. In diamond, which presents similar phonon dispersion curves, calculations show a decrease of these parameters with pressure, eventually leading to negative values of \( \gamma \) and \( \rho \) at ultra-high pressures (\( P > 700 \) GPa). We also note that a similar phe-

nomenon is responsible for the negative thermal expansion in Si at ambient pressure and low temperatures. To illustrate the decrease of \( \rho \) with pressure, we plot in

FIG. 5: Variation of the thermal expansion coefficient with temperature along several iso-

bars, as deduced from the Mie-Grüneisen EOS.

The value found for \( q \) is large compared to the typical range for this parameter (0.8 < \( q < 2.2 \)) [63]. This is to be related to the rapid decrease of the thermal expansion coefficient with pressure that is observed from present data. Indeed, \( \gamma_{th} \) and \( \rho \) are related by the thermody-
namic relation \( \rho = (1/\beta)\gamma_{th}C_V \). In the quasi-harmonic approximation, \( \gamma_{th} \) may be obtained by the Brillouin-

zone integration of the phonon mode Grüneisen param-

eters. A large reduction of \( \rho \) may thus indicate that the Grüneisen parameters for the acoustic modes, which give the dominant contribution, rapidly decrease with pressure. As a matter of fact, the calculated \( \gamma \) for the trans-
verse acoustic branches at \( P = 0 \) are very low (~0.25) along some directions of the Brillouin zone, especially near the zone boundaries. In diamond, which presents similar phonon dispersion curves, calculations show a decrease of these parameters with pressure, eventually leading to negative values of \( \gamma \) and \( \rho \) at ultra-high pressures (\( P > 700 \) GPa). Mie-Grüneisen EOS.
VI. THE CONSTRAINED RAMAN PRESSURE SCALE

A. Temperature dependence of the TO mode Gr"uneisen parameter

The present construction of a $P-V-T$ EOS enables us to reanalyze our previous measurements of the Raman TO mode at HP-HT. In particular, we are now able to precisely determine the isothermal mode Gr"uneisen parameter $\gamma^{TO}(T)$ based on the measurements of the TO mode frequency $\nu^{TO}(T)$, where $\nu^{TO}$ is the frequency of the TO mode. To do so, the sample volume was calculated for each $P-T$ conditions at which $\nu^{TO}$ was measured (see Ref. 3) by inverting Eq. (4).

The results are reported in Fig. 6 where we plot the experimental values of $\ln(\nu^{TO})$ as a function of $\ln[V/V_0(T)]$. In the scanned pressure range ($P < 21$ GPa), and for each of the five studied isotherms ($300 < T < 723$ K), these two quantities appear to be linearly related. This tells us that $\gamma^{TO}(T)$ is constant along each isotherm and may then be directly determined by a linear regression of the data, using the expression:

$$\ln \nu^{TO}(V, T) = -\gamma^{TO}(T) \ln \frac{V(P, T)}{V_0(T)} + \ln \nu_0^{TO}(T) \quad (5)$$

where $\nu_0^{TO}(T) = \nu^{TO}(P = 0, T)$. The fits to the latter equation are shown as dotted lines in Fig. 6. The values of $\gamma^{TO}(T)$ and $\nu_0^{TO}(T)$ so obtained are listed in Table VI. It can be seen that, within error bars, $\gamma^{TO}(T)$ is constant in this $P-T$ range, with an average value of $1.257(5)$. This value is slightly larger than that given by Aleksandrov et al. [1.188] and in good agreement with the theoretical determination of Kern et al. [1, 2].

It can also be observed that $\nu_0^{TO}(T)$ follows $V_0(T)$ in a linear way in the probed $T$ range. Extrapolating this line to 0 K gives a value of $\nu_0^{TO}$ at zero temperature of $1055.1(1)$ or $1054.6(2)$ cm$^{-1}$, depending on whether the fitted or experimental $\nu_0^{TO}(T)$ is used.

B. The high-temperature pressure scale

In Ref. 3 we recalled the various reasons that make c-BN a good candidate for pressure measurement in a DAC at high temperature. A pressure scale was given based on the measurements of the TO mode frequency ($\nu^{TO}$) at high $P-T$. The form of this pressure scale derives from the first-order Murnaghan EOS, and is obtained by inverting the following equation for the $P-T$ dependence of $\nu^{TO}$:

$$\nu^{TO}(P, T) = \nu_0^{TO}(T) \left(1 + \frac{B_0}{B_0(T)} P\right) \gamma^{TO}/B_0' \quad (6)$$

In Ref. 3, $B_0(T)$ and $B_0'$ were considered as fit parameters, taking for $\gamma^{TO}$ the value reported by Ref. 3. We assumed then that $\gamma^{TO}$ was independent of temperature, which is confirmed by the present work. Our EOS allows us to better constrain Eq. (6) by imposing physical constraints on the various parameters. Since this pressure scale is to be used for high temperatures, we only consider variations above 300 K. The variation of $B_0$ with temperature was deduced from our Mie-Gr"uneisen EOS by fitting isotherms at 100 K intervals by a Vinet equation. A quadratic form is found suitable to represent the behavior of $B_0$ between 300 and 2000 K, with the following expression:

$$B_0(T > 300 K) = 396.5(5) - 0.0288(14) (T - 300) - 6.84(77) 10^{-6} (T - 300)^2 \quad (7)$$

![FIG. 6: (Color online) Frequencies of the TO Raman mode as a function of $V/V_0(T)$ on a logarithmic scale. The crosses show experimental data, and the dashed lines are linear fits.](image-url)
A revised pressure scale, reading as a quadratic form, where the coefficients are allowed to vary above was used. As in Ref. 3, we kept it as constant. The value of \( \nu \) in the 0-100 GPa and 300-1000 K range. Ramifications up to 1750 K and 40 GPa in argon pressure dependence to \( B_0 \) as in Eq. (7) as the expression for \( B \) does not improve the fit, so we would be desirable to extend the calibration. Adding a temperature parameter gives us confidence that it can be safely used and reaches \( \sim 10\% \) at 50 GPa and 1000 K. The fact that \( \nu_0 \) was expressed as a quadratic form, where the coefficients are allowed to vary within the boundaries given by Ref. 45. We thus obtain a revised pressure scale, reading as:

\[
P = \left( B_0(T)/3.62 \right) \left\{ \left[ \frac{\nu^{TO}(P,T)}{\nu_0^{TO}(T)} \right]^{2.876} - 1 \right\}
\]

with \( B_0(T) \) as in Eq. (6) and \( \nu_0^{TO}(T) = 1058.4(5) - 0.0091(23)T - 1.54(22) \times 10^{-5}T^2 \)

Recently, Goncharov et al. reported Raman measurements up to 1750 K and 40 GPa in argon pressure medium and proposed a pressure scale in a form similar to Eq. (5). The two scales are compared in Fig. 7 in the pressure range 0-50 GPa at 300, 1000 and 1500 K. The difference increases with pressure and temperature and reaches \( \sim 10\% \) at 50 GPa and 1000 K. The fact that the present scale is constrained by measured physical parameters gives us confidence that it can be safely used in the 0-100 GPa and 300-1000 K range. \( P-V-T \) as well as Raman data to higher \( T \) would be desirable to extend the calibration.

VII. CONCLUSIONS

We have reported experimental \( P-V-T \) data on c-BN from x-ray diffraction experiments in a resistively-heated diamond anvil cell. Volume measurements extend to 160 GPa at 295 K and 80 GPa at 500-900 K. To our knowledge, these are the first reported EOS data at simultaneous HP-HT conditions. By fitting the room-temperature EOS to various EOS models, we extracted the values of the bulk modulus [395(2) GPa] and its first-pressure derivative [3.62(5)]. We have also examined the variation of these parameters with respect to the chosen calibration of the ruby standard and showed that the one recently proposed by Holzapfel (H2005) provides very good consistency between static compression data and \emph{ab initio} predictions. Coupling the present information with independent measurements of \( B_0 \), such as obtained by sound-propagating experiments, would be of great interest to better constrain the ruby standard calibration in the megabar range. A good description of our full data set was obtained using a Mie-Grüneisen model, where the thermal pressure originating from lattice vibrational energy is calculated in the Debye approximation. We observe a rapid decrease of the thermal expansion coefficient with pressure, which itself reflects on the strong variation of the thermal Grüneisen parameter. The Mie-Grüneisen EOS was then used to determine the mode Grüneisen parameter of the Raman TO mode, which was found to be temperature independent in the range 300-723 K. A new formulation of the Raman pressure scale was then deduced from the present results, which should hold in the \( P-T \) range 0-100 GPa and 300-1000 K. Extension of this work to higher temperatures would be valuable to better constrain the thermal effects, and extend the calibration of the Raman scale.

Acknowledgments

We thank V. L. Solozhenko for providing us with c-BN samples, B. Canny (IMPMC) for his help in preparing the experiments, and M. Mezouar (ESRF ID27) for his help during the x-ray diffraction runs. The authors acknowledge the European Synchrotron Radiation Facility for provision of synchrotron radiation facility during beamtime allocated to proposal HS-2514.
