The numerical solution of the three-dimensional time-harmonic Maxwell equations using high order methods such as discontinuous Galerkin formulations require efficient solvers. A domain decomposition strategy is introduced for this purpose. This strategy is based on optimized Schwarz methods applied to the first order form of the Maxwell system and leads to the best possible convergence of these algorithms. The principles are explained for a 2D model problem and numerical simulations confirm the predicted theoretical behavior. The efficiency is further demonstrated on more realistic 3D geometries including a bioelectromagnetism application.

Index Terms—Discontinuous Galerkin methods, domain decomposition methods, optimized interface conditions.

I. INTRODUCTION

DISCONTINUOUS Galerkin (DG) methods are emerging for the solution of time-harmonic Maxwell’s equations \cite{1} because of the enhanced flexibility compared to the conforming edge element method \cite{2}. For instance, by using a DG method, dealing with non-conforming meshes is straightforward. The formulation of such methods in the case of the first order elliptic Maxwell system has been fully analyzed in \cite{3} and an extension to the time-harmonic first order system is introduced in \cite{4} where a numerical comparison of different schemes is proposed.

Nonetheless, before taking advantage of the flexibility of the DG methods, the design of efficient algorithms for the resulting sparse linear system has to be addressed. Here we propose a domain decomposition (DD) strategy based on optimized Schwarz methods \cite{5}–\cite{7}. First, the DD strategy is introduced in the two-domain case for a 2D transverse electric model problem. Then the discretization of the problem by a DG method is presented. Finally, numerical results for a 2D problem confirm the expected theoretical behavior of the DD method and 3D numerical experiments on simplified problems pave the way for more realistic applications.

II. THE DOMAIN DECOMPOSITION STRATEGY

For the sake of simplicity we consider the following non-dimensionalized transverse electric model problem in a domain \( \Omega \subset \mathbb{R}^2 \):

\[
\begin{align*}
\text{Find the non-dimensional field } (\mathbf{E}, \mathbf{H}) \text{ satisfying: } \\
\omega \varepsilon \mathbf{E} - \text{curl} \mathbf{H} &= 0, \text{ in } \Omega \\
\omega \mu \mathbf{H} + \text{curl} \mathbf{E} &= 0, \text{ in } \Omega \\
\mathbf{n} \times (\mathbf{E} - \mathbf{E}^{inc}) + (\mathbf{H} - \mathbf{H}^{inc}) &= 0, \text{ on } \partial \Omega
\end{align*}
\]

(1)

\( \omega \) the angular frequency, \( \mathbf{n} \) the unitary outgoing normal and \((\mathbf{E}^{inc}, \mathbf{H}^{inc})\) the components of an incident electromagnetic wave.

For solving (1), the domain \( \Omega \) is decomposed in two non-overlapping subdomains \( \Omega_1 \) and \( \Omega_2 \). The common interface to \( \Omega_1 \) and \( \Omega_2 \) is denoted by \( \Gamma \). The DD strategy is then a variant of the classical Schwarz method.

- We start with an initial electromagnetic field \((\mathbf{E}_0^l, \mathbf{H}_0^l)\) on each subdomain \( \Omega_l, l = 1, 2 \).
- The \((p+1)\)th iterate \((\mathbf{E}_{p+1}^l, \mathbf{H}_{p+1}^l)\) is the solution of (1) restricted to the subdomain \( \Omega_l \) with an interface transmission condition on \( \Gamma \) of the form

\[
\begin{align*}
\mathbf{n} \times (\mathbf{E}_{p+1}^l - \mathbf{E}_0^l) + S_l (\mathbf{H}_{p+1}^l - \mathbf{H}_0^l) &= 0
\end{align*}
\]

(2)

where \( S_l \) denotes the second-order derivative along the interface. The operator \( S_l \) ensures the transmission of the field \((\mathbf{E}_0^l, \mathbf{H}_0^l)\) computed at the previous iteration in the neighboring subdomain \( m \) with parameters \( \alpha_l, \beta_l \) properly chosen to control the convergence of the algorithm.

- The limit of the sequence \((\mathbf{E}_p^l, \mathbf{H}_p^l)\) is the restriction to \( \Omega_l \) of \((\mathbf{E}, \mathbf{H})\) the solution of (1). Thus, we can use a stopping criterion

\[
\sum_{l=1}^{2} \frac{\| (\mathbf{E}^{l+1}_p, \mathbf{H}^{l+1}_p) - (\mathbf{E}^l_p, \mathbf{H}^l_p) \|}{\| (\mathbf{E}_l^1, \mathbf{H}_l^1) - (\mathbf{E}_0^l, \mathbf{H}_0^l) \|} < \text{tol}
\]

(3)

where tol is the prescribed accuracy and \( \| \cdot \| \) a norm.

\textsuperscript{50} Desprès in \cite{8} was the first to use this strategy for time-harmonic equations with the choice \( S_l = 1 \), for \( l = 1, 2 \) which coincides with a first order absorbing boundary condition. However, the convergence rate of the iterative process with this boundary condition is strongly dependent on the mesh size used for the discretization and the convergence to the solution can be slow. We refer to this condition as the classical condition in the following.

Nonetheless, it is possible to greatly improve the convergence rate by optimizing it with respect to \( \alpha_l, \beta_l \). This theoretical study is done in [7] directly on (1) and in [9] for the second order \( \text{curl curl} \) formulation.
such that
\[
\frac{\sqrt{2}C_{2\alpha}}{c_{\alpha}h^{\frac{3}{2}}} + \frac{\sqrt{2}C_{2\beta}}{c_{\beta}h^{\frac{3}{2}}}
\]
for Case 2.

The matrix \( N_h^4 \) denotes \((-n_x, n_y, n_z)\), for a vector \( n \) of \( \mathbb{R}^3 \), \( \{G\} \) and \( \{F\}_7 \) denotes respectively the mean of \( G \) and the jump of the tangential component of \( F \) over a face \( F \) of the set of interior faces \( \Gamma^0 \). Note that in order to keep the consistency with the continuous problem, a numerical flux is defined on the interface of each element enforcing weakly the tangential continuity constraint for the electric and magnetic field. The proper choice of different kind of fluxes has been discussed from the numerical point of view in [4]. For instance, the choice \( \alpha = 0 \) corresponds to the case of the centered flux, and \( \alpha = 1/2 \) to the choice of a simplified upwind flux. The former has the advantage to be easy to implement and requires a lower memory storage. The latter has better convergence properties.

### IV. Two-Dimensional Numerical Results

The agreement between the theoretical and numerical convergence rates is demonstrated on a problem with \( \Omega = [0, 1]^2 \), \( \{E^{\text{ex}}, H^{\text{ex}}\} = \exp(-i\omega r)(0, 1, 1) \) and \( \omega = 2\pi \) discretized by discontinuous Galerkin methods. Firstly, we study the influence of the choice of the numerical flux and of the polynomial order on the theoretical convergence rate. Secondly, we study the multidomain case.

#### A. Influence of the Element Order and of the Numerical Flux

The first DG discretization is based on a triangular uniform mesh with \( P_1(K) \) as the local space in each element \( K \). On Fig. 1, the number of iterations for achieving a prescribed accuracy against the mesh size is shown for both boundary conditions (Case 1 and Case 2). The curves fit nicely the dependence in \( h \) predicted by the theory i.e., they behave like \( h^{-0.15} \) for Case 1 and like \( h^{-0.25} \) for Case 2.

In order to demonstrate that the theoretical results are independent of the choice of the DG discretization, we also approximate numerically this asymptotic convergence rate using three polynomial orders for the element interpolation (here quadrilateral elements are considered to simplify the management of the multi-domain case for this academic problem) and two different fluxes; these experiments are reported in Table II. A behavior close to \( h^{-0.15} \) and \( h^{-0.25} \) for the number of iterations is obtained by the numerical experiments, independently of the choice of the numerical flux and of the numerical order.

Fig. 3. Number of iterations against the number of subdomains. The number of degrees of freedom is constant. Results for the upwind flux.

B. Influence of the Number of Subdomains

As in practice more than two domains are used, the performances of the optimized conditions are evaluated for more subdomains. The same problem as in Section IV-A is solved. The numerical experiments are still performed on a structured grid and then the partition into several subdomains is made in a regular way: a decomposition in $N \times N$ rectangular subdomains of the unit square. The results for the centered case are shown on Fig. 2 and the results for the upwind case on Fig. 3; a $Q_1$ polynomial approximation is used for these figures. Note that for obtaining these results, a Krylov subspace method is coupled to the Schwarz algorithm. Indeed, as it is explained in [5], the DD method can be formulated as a linear system whose unknowns are auxiliary interface variables. This interface system is usually solved by a Krylov method which gives more robustness to the DD strategy. Here we make use of GMRES for solving the interface system. We observe that, independently of the flux chosen, the number of iterations grows roughly as $N_d^{0.3}$ where $N_d$ is the number of subdomains. Thus, the convergence deteriorates with the number of subdomains and it advocates for the use of a coarse grid in order to obtain an optimal solver. Nevertheless, the hierarchy of the transmission conditions is maintained and the optimized versions enable us to accelerate the convergence compared to the classical condition [8].

V. THREE-DIMENSIONAL PROBLEM

A. Scattering by a Sphere

The implementation of optimized interface conditions for three-dimensional time-harmonic Maxwell’s equations is a work in progress. Here, we give preliminary results for the DD strategy based on first order absorbing boundary conditions as transmission conditions.

The problem under consideration is the scattering of a plane wave by a perfectly conducting unit sphere. The incident wave is given by $\mathbf{E}^{inc} = (\exp(-i \omega r), 0, 0)^T$ and $\mathbf{H}^{inc} = (0, \exp(-i \omega r), 0)^T$, with $\omega = 4\pi$. The absorbing boundary is set to one wavelength from the surface of the perfectly conducting sphere. The mesh is composed of 1,382,400 tetrahedra and a $P_1$ ($\mathcal{K}$) local space is used for the DG method. The total number of unknowns is $8,294,400$.

Numerical experiments are conducted on a cluster of 64 AMD Opteron/2 GHz processors with a Gigabit Ethernet interconnection. One subdomain is associated to each processor and a sparse matrix direct method is used to solve the subdomain problem. Note that we use a BiCGstab($l$) method [10] either for solving the interface system or as a global solver without preconditionner.

Performance results are given in Table III where ‘DDM’ refers to the DD solution strategy. The per processor time for performing the factorization is $18.0$ sec (min)/$102.0$ sec (max) while the associated memory usage is $405$ MB (min)/$1001$ MB (max). In addition to the gain in computing time, a clear advantage of the DD strategy is its parallel efficiency that can be evaluated here as the ratio of ‘CPU (max)’ over ‘Elapsed’
TABLE III

<table>
<thead>
<tr>
<th>Solver</th>
<th># iterations</th>
<th>CPU (min)</th>
<th>CPU (max)</th>
<th>Elapsed</th>
</tr>
</thead>
<tbody>
<tr>
<td>Global</td>
<td>2031</td>
<td>1940.0 sec</td>
<td>2142.0 sec</td>
<td>2919.0 sec</td>
</tr>
<tr>
<td>DDM</td>
<td>14</td>
<td>259.0 sec</td>
<td>413.0 sec</td>
<td>449.0 sec</td>
</tr>
</tbody>
</table>

Performance results are given in Table V. The parallel efficiency, evaluated using the maximum CPU to REAL ratio, ranges from 65% to 75%.

VI. Conclusion

In this paper, classical and optimized Schwarz algorithms have been applied to time-harmonic Maxwell’s equations discretized by DG methods. Concerning Schwarz algorithms based on optimized interface conditions, two-dimensional numerical results show a good agreement with the theory in the case of the simplest optimized conditions and the behavior is independent of the choice of the flux and the polynomial order for the finite element space. Preliminary results in the three-dimensional case are very promising for classical interface conditions, opening the way to improvements by using optimized interface conditions on realistic applications.
