Abstract. We study the one-way number-on-the-forehead (NOF) communication complexity of the $k$-layer pointer jumping problem with $n$ vertices per layer. This classic problem, which has connections to many aspects of complexity theory, has seen a recent burst of research activity, seemingly preparing the ground for an $\Omega(n)$ lower bound, for constant $k$. Our first result is a surprising sublinear — i.e., $o(n)$ — upper bound for the problem that holds for $k \geq 3$, dashing hopes for such a lower bound.

A closer look at the protocol achieving the upper bound shows that all but one of the players involved are collapsing, i.e., their messages depend only on the composition of the layers ahead of them. We consider protocols for the pointer jumping problem where all players are collapsing. Our second result shows that a strong $n - O(\log n)$ lower bound does hold in this case. Our third result is another upper bound showing that nontrivial protocols for (a non-Boolean version of) pointer jumping are possible even when all players are collapsing.

Our lower bound result uses a novel proof technique, different from those of earlier lower bounds that had an information-theoretic flavor. We hope this is useful in further study of the problem.

1. Introduction

Multi-party communication complexity in general, and the pointer jumping problem (also known as the pointer chasing problem) in particular, has been the subject of plenty of recent research. This is because the model, and sometimes the specific problem, bears on several aspects of computational complexity: among them, circuit complexity [Yao90, HG91, BT94], proof size lower bounds [BPS05] and space lower bounds for streaming algorithms [AMS99, GM07, CJP08]. The most impressive known consequence of a strong

1998 ACM Subject Classification: F.1.3, F.2.2.
Key words and phrases: Communication complexity, pointer jumping, number on the forehead.

multi-party communication lower bound would be to exhibit non-membership in the complexity class $\mathsf{ACC}^0$; details can be found in Beigel and Tarui [BT94] or in the textbook by Arora and Barak [AB09]. Vexingly, it is not even known whether or not $\mathsf{ACC}^0 = \mathsf{NEXP}$.

The setting of multi-party communication is as follows. There are $k$ players (for some $k \geq 2$), whom we shall call $\mathsf{PLR}_1, \mathsf{PLR}_2, \ldots, \mathsf{PLR}_k$, who share an input $k$-tuple $(x_1, x_2, \ldots, x_k)$. The goal of the players is to compute some function $f(x_1, x_2, \ldots, x_k)$. There are two well-studied sharing models: the number-in-hand model, where $\mathsf{PLR}_i$ sees $x_i$, and the number-on-the-forehead (NOF) model, where $\mathsf{PLR}_i$ sees all $x_j$s such that $j \neq i$. Our focus in this paper will be on the latter model, which was first introduced by Chandra, Furst and Lipton [CFL83]. It is in this model that communication lower bounds imply lower bounds against $\mathsf{ACC}^0$. We shall use $C(f)$ to denote the deterministic communication complexity of $f$ in this model. Also of interest are randomized protocols that only compute $f(x)$ correctly with high probability: we let $R_\varepsilon(f)$ denote the $\varepsilon$-error randomized communication complexity of $f$. Our work here will stick to deterministic protocols, which is a strength for our upper bounds. Moreover, it is not a serious weakness for our lower bound, because the $\mathsf{ACC}^0$ connection only calls for a deterministic lower bound.

Notice that the NOF model has a feature not seen elsewhere in communication complexity: the players share plenty of information. In fact, for large $k$, each individual player already has “almost” all of the input. This intuitively makes lower bounds especially hard to prove and indeed, to this day, no nontrivial lower bound is known in the NOF model for any explicit function with $k = \omega(\log n)$ players, where $n$ is the total input size. The pointer jumping problem is widely considered to be a good candidate for such a lower bound. As noted by Damm, Jukna and Sgall [DJS98], it has many natural special cases, such as shifting, addressing, multiplication and convolution. This motivates our study.

1.1. The Pointer Jumping Problem and Previous Results

There are a number of variants of the pointer jumping problem. Here we study two variants: a Boolean problem, $\mathsf{MPJ}_k^n$, and a non-Boolean problem, $\overline{\mathsf{MPJ}}_k^n$ (henceforth, we shall drop the superscript $n$). In both variants, the input is a subgraph of a fixed layered graph that has $k + 1$ layers of vertices, with layer 0 consisting of a single vertex, $v_0$, and layers 1 through $k − 1$ consisting of $n$ vertices each (we assume $k \geq 2$). Layer $k$ consists of 2 vertices in the case of $\mathsf{MPJ}_k$ and $n$ vertices in the case of $\overline{\mathsf{MPJ}}_k$. The input graph is a subgraph of the fixed layered graph in which every vertex (except those in layer $k$) has outdegree 1. The desired output is the name of the unique vertex in layer $k$ reachable from $v_0$, i.e., the final result of “following the pointers” starting at $v_0$. The output is therefore a single bit in the case of $\mathsf{MPJ}_k$ or a $\lceil \log n \rceil$-bit string in the case of $\overline{\mathsf{MPJ}}_k$.

The functions $\mathsf{MPJ}_k$ and $\overline{\mathsf{MPJ}}_k$ are made into NOF communication problems as follows: for each $i \in [k]$, a description of the $i$th layer of edges (i.e., the edges pointing into the $i$th layer of vertices) is written on $\mathsf{PLR}_i$’s forehead. In other words, $\mathsf{PLR}_i$ sees every layer of edges except the $i$th. The players are allowed to write one message each on a public blackboard and must do so in the fixed order $\mathsf{PLR}_1, \mathsf{PLR}_2, \ldots, \mathsf{PLR}_k$. The final player’s message must be the desired output. Notice that the specific order of speaking — $\mathsf{PLR}_1, \mathsf{PLR}_2, \ldots, \mathsf{PLR}_k$ — is important to make the problem nontrivial. Any other order of speaking allows an easy deterministic protocol with only $O(\log n)$ communication.

---

1Throughout this paper we use “log” to denote logarithm to the base 2.
Consider the case $k = 2$. The problem $\text{mpj}_2$ is equivalent to the two-party communication problem $\text{index}$, where Alice holds a bit-vector $x \in \{0, 1\}^n$, Bob holds an index $i \in [n]$, and Alice must send Bob a message that enables him to output $x_i$. It is easy to show that $C(\text{mpj}_2) = n$. In fact, Ablayev [Abl96] shows the tight tradeoff $R_\varepsilon(\text{mpj}_2) = (1 - H(\varepsilon))n$, where $H$ is the binary entropy function. It is tempting to conjecture that this lower bound generalizes as follows.

**Conjecture 1.1.** There is a nondecreasing function $\xi : \mathbb{Z}^+ \rightarrow \mathbb{R}^+$ such that, $\forall k : C(\text{mpj}_k) = \Omega(n/\xi(k))$.

Note that, by the results of Beigel and Tarui [BT94], in order to show that $\text{mpj}_k / \in \text{ACC}^0$ it would suffice, for instance, to prove the following (possibly weaker) conjecture.

**Conjecture 1.2.** There exist constants $\alpha, \beta > 0$ such that, for $k = n^\alpha$, $C(\text{mpj}_k) = \Omega(n^{\beta})$.

Conjecture 1.2 is consistent with (and to an extent motivated by) research prior to this work. In weaker models of information sharing than the NOF model, an equivalent statement is known to be true, even for randomized protocols. For instance, Damm, Jukna and Sgall [DJS98] show an $\Omega(n/k^2)$ communication lower bound in the so-called conservative model, where $\text{plr}_i$ has only a limited view of the layers of the graph behind her: she only sees the result of following the first $i - 1$ pointers. Chakrabarti [Cha07] extends this bound to randomized protocols and also shows an $\Omega(n/k)$ lower bound in the so-called myopic model, where $\text{plr}_i$ has only a limited view of the layers ahead of her: she cannot see layers $i + 2, \ldots, k$.

For the full NOF model, Wigderson, building on the work of Nisan and Wigderson [NW93], showed that $C(\text{mpj}_3) = \Omega(\sqrt{n})$. This result is unpublished, but an exposition can be found in Babai, Hayes and Kimmel [BHK01]. Very recently, Viola and Wigderson [VW07] generalized this result and extended it to randomized protocols, showing that $R_{1/3}(\text{mpj}_k) = \Omega(n^{1/(k-1)} k^{O(k)})$. Of course, this bound falls far short of that in Conjecture 1.1 and does nothing for Conjecture 1.2. However, it is worth noting that the Viola-Wigderson bound in fact applies to the much smaller subproblem of tree pointer jumping (denoted $\text{tpj}_k$), where the underlying layered graph is a height-$k$ tree, with every vertex in layers 0 through $k - 2$ having $n^{1/(k-1)}$ children and every vertex in layer $k - 1$ having two children. It is easy to see that $C(\text{tpj}_k) = O(n^{1/(k-1)})$. Thus, one might hope that the more general problem $\text{mpj}_k$ has a much stronger lower bound, as in Conjecture 1.1.

On the upper bound side, Damm et al. [DJS98] show that $C(\widetilde{\text{mpj}}_k) = O(n \log^{(k-1)} n)$, where $\log^{(i)} n$ is the $i$th iterated logarithm of $n$. This improves on the trivial upper bound of $O(n \log n)$. Their technique does not yield anything nontrivial for the Boolean problem $\text{mpj}_k$, though. However, Pudlak, Rödl and Sgall [PRS97] obtain a sublinear upper bound of $O(n \log \log n / \log n)$ for a special case of $\text{mpj}_3$. Their protocol works only when every vertex in layer 2 has indegree 1, or equivalently, when the middle layer of edges in the input describes a permutation of $[n]$.

### 1.2. Our Results

The protocol of Pudlak et al. [PRS97] did not rule out Conjecture 1.1, but it did suggest caution. Our first result is the following upper bound — in fact the first nontrivial upper bound on $C(\text{mpj}_k)$ — that falsifies the conjecture.
Theorem 1.3. For \( k \geq 3 \), we have

\[
C(\text{MPJ}_k) = O\left(n \left(\frac{k \log \log n}{\log n}\right)^{(k-2)/(k-1)}\right).
\]

In particular, \( C(\text{MPJ}_3) = O(n^{\sqrt{\log \log n}/\log n}) \).

A closer look at the protocol that achieves the upper bound above reveals that all players except for \( \text{PLR}_1 \) behave in the following way: the message sent by \( \text{PLR}_i \) depends only on layers 1 through \( i-1 \) and the composition of layers \( i+1 \) through \( k \). We say that \( \text{PLR}_k \) is collapsing. This notion is akin to that of the aforementioned conservative protocols considered by Damm et al. Whereas a conservative player composes the layers behind hers, a collapsing player does so for layers ahead of hers.

We consider what happens if we require all players in the protocol to be collapsing. We prove a strong linear lower bound, showing that even a single non-collapsing player makes an asymptotic difference in the communication complexity.

Theorem 1.4. In a protocol for \( \text{MPJ}_k \) where every player is collapsing, some player must communicate at least \( n - \frac{1}{2} \log n - 2 = n - O(\log n) \) bits.

Finally, one might wonder whether the collapsing requirement is so strong that nothing nontrivial is possible anyway. The same question can be raised for the conservative and myopic models where \( \Omega(n/k^2) \) and \( \Omega(n/k) \) lower bounds were proven in past work. It turns out that the upper bound on \( C(\text{MPJ}_k) \) due to Damm et al. \[\text{DJS98}\] (see Section 1.1) is achievable by a protocol that is both conservative and myopic. We can show a similar upper bound via a different protocol where every player is collapsing.

Theorem 1.5. For \( k \geq 3 \), there is an \( O(n \log^{(k-1)} n) \)-communication protocol for \( \text{MPJ}^{\text{perm}}_k \) in which every player is collapsing. Here \( \text{MPJ}^{\text{perm}}_k \) denotes the subproblem of \( \text{MPJ}_k \) in which layers 2 through \( k \) of the input graph are permutations of \([n]\).

The requirement that layers be permutations is a natural one and is not new. The protocol of Pudlak et al. also had this requirement; i.e., it gave an upper bound on \( C(\text{MPJ}^{\text{perm}}_3) \). Theorem 1.5 can in fact be strengthened slightly by allowing one of the layers from 2 through \( k \) to be arbitrary; we formulate and prove this stronger version in Section 4.

1.3. Organization

The rest of the paper is organized as follows. Theorems 1.3, 1.4 and 1.5 are proven in Sections 2, 3 and 4 respectively. Section 2.1 introduces some notation that is used in subsequent sections.

2. A Sublinear Upper Bound

2.1. Preliminaries, Notation and Overall Plan

For the rest of the paper, “protocols” will be assumed to be deterministic one-way NOF protocols unless otherwise qualified. We shall use \( \text{cost}(P) \) to denote the total number of bits communicated in \( P \), for a worst case input.
Let us formally define the problems $\text{MPJ}_k$ and $\widehat{\text{MPJ}}_k$. We shall typically write the input $k$-tuple for $\text{MPJ}_k$ as $(i, f_2, \ldots, f_{k-1}, x)$ and that for $\widehat{\text{MPJ}}_k$ as $(i, f_2, \ldots, f_k)$, where $i \in [n]$, each $f_j \in [n]^n$ and $x \in \{0, 1\}^n$. We then define $\text{MPJ}_k : [n] \times ([n]^n)^{k-2} \times \{0, 1\}^n \rightarrow \{0, 1\}$ and $\widehat{\text{MPJ}}_k : [n] \times ([n]^n)^{k-1} \rightarrow [n]$ as follows.

$\text{MPJ}_2(i, x) := x_i$; \quad $\text{MPJ}_k(i, f_2, f_3, \ldots, f_{k-1}, x) := \text{MPJ}_{k-1}(f_2(i), f_3, \ldots, f_{k-1}, x)$, for $k \geq 3$

$\widehat{\text{MPJ}}_2(i, f) := f(i)$; \quad $\widehat{\text{MPJ}}_k(i, f_2, f_3, \ldots, f_k) := \widehat{\text{MPJ}}_{k-1}(f_2(i), f_3, \ldots, f_k)$, for $k \geq 3$.

Here, $x_i$ denotes the $i$th bit of the string $x$. It will be helpful, at times, to view strings in $\{0, 1\}^n$ as functions from $[n]$ to $\{0, 1\}$ and use functional notation accordingly. It is often useful to discuss the composition of certain subsets of the inputs. Let $i_2 := i$, and for $3 \leq j \leq k$, let $i_j := f_{j-1} \circ \cdots \circ f_2(i)$. Similarly, let $\hat{x}_k := x$, and for $1 \leq j \leq k-2$, let $\hat{x}_j := \hat{x}_{j+1} \circ \cdots \circ f_{j+1}$. Unrolling the recursion in the definitions, we see that, for $k \geq 2$,

$$\text{MPJ}_k(i, f_2, \ldots, f_{k-1}, x) = x \circ f_{k-1} \circ \cdots \circ f_2(i) = \hat{x}_1(i) = x_{i_k}; \quad (2.1)$$

$$\widehat{\text{MPJ}}_k(i, f_2, \ldots, f_k) = f_k \circ \cdots \circ f_2(i) = f_k(\hat{x}_k). \quad (2.2)$$

We also consider the subproblems $\text{MPJ}_k^{\text{perm}}$ and $\widehat{\text{MPJ}}_k^{\text{perm}}$ where each $f_j$ above is a bijection from $[n]$ to $[n]$ (equivalently, a permutation of $[n]$). We let $S_n$ denote the set of all permutations of $[n]$.

Here is a rough plan of the proof of our sublinear upper bound. We leverage the fact that a protocol $P$ for $\text{MPJ}_k^{\text{perm}}$ with sublinear communication is known. To be precise:

**Fact 2.1** (Pudlak, Rödl and Sgall [PRS97, Corollary 4.8]). $C(\text{MPJ}_3^{\text{perm}}) = O(n \log \log n / \log n)$.

The exact structure of $P$ will not matter; we shall only use $P$ as a black box. To get a sense for why $P$ might be useful for, say, $\text{MPJ}_k$, note that the players could replace $f_2$ with a permutation $\pi$ and just simulate $P$, and this would work if $\pi(i) = f(i)$. Of course, there is no way for PLR$_1$ and PLR$_3$ to agree on a suitable $\pi$ without communication. However, as we shall see below, it is possible for them to agree on a small enough set of permutations such that either some permutation in the set is suitable, or else only a small amount of side information conveys the desired output bit to PLR$_3$.

This idea eventually gives us a sublinear protocol for $\text{MPJ}_3$. Clearly, whatever upper bound we obtain for $\text{MPJ}_3$ applies to $\text{MPJ}_k$ for all $k \geq 3$. However, we can decrease the upper bound as $k$ increases, by embedding several instances of $\text{MPJ}_3$ into $\text{MPJ}_k$. For clarity, we first give a complete proof of Theorem 1.3 for the case $k = 3$.

### 2.2. A 3-Player Protocol

Following the plan outlined above, we prove Theorem 1.3 for the case $k = 3$ by plugging Fact 2.1 into the following lemma, whose proof is the topic of this section.

**Lemma 2.2.** Suppose $\phi : \mathbb{Z}^+ \rightarrow (0, 1]$ is a function such that $C(\text{MPJ}_3^{\text{perm}}) = O(n \phi(n))$. Then $C(\text{MPJ}_3) = O(n \sqrt{\phi(n)})$.

**Definition 2.3.** A set $\mathcal{A} \subseteq S_n$ of permutations is said to $d$-cover a function $f : [n] \rightarrow [n]$ if, for each $r \in [n]$, at least one of the following conditions holds:

(i) $\exists \pi \in \mathcal{A}$ such that $\pi(r) = f(r)$,

(ii) $|f^{-1}(f(r))| > d$.  

Therefore, for each claim that \( \pi \) condition (ii) holds. Otherwise, from Eq. (2.3), we conclude that \( \pi \) satisfies at least one of the two conditions in Definition 2.3. Pick any \( f \) \( \alpha \) where, for convenience, we require "all \( i \) \( n \) define bijections between the corresponding parts. To be precise, suppose \( \text{Range}(f) = \{s_1, s_2, \ldots, s_t\} \). Let \( A_i = f^{-1}(s_i) \) be the corresponding fibers of \( f \). Clearly, \( \{A_i\}_{i=1}^t \) is a partition of \( [n] \). It is also clear that there exists a partition \( \{B_i\}_{i=1}^t \) of \( [n] \) such that, for all \( i \in [t] \), \( B_i \cap \text{Range}(f) = \{s_i\} \) and \( |B_i| = |A_i| \). We shall now define certain bijections \( \pi_{i,\ell} : A_i \rightarrow B_i \) for each \( i \in [t] \) and \( \ell \in [d] \).

Let \( a_{i,1} < a_{i,2} < \cdots < a_{i,|A_i|} \) be the elements of \( A_i \) arranged in ascending order. Similarly, let \( b_{i,1} < \cdots < b_{i,|B_i|} \) be those of \( B_i \). We define

\[
\pi_{i,\ell}(a_{i,j}) := b_{i,(j-\ell) \mod |B_i|}, \quad \text{for } i \in [t], \ell \in [d],
\]

where, for convenience, we require "\( \alpha \mod \beta \)" to return values in \([\beta]\), rather than \(\{0, 1, \ldots, \beta-1\}\). It is routine to verify that \( \pi_{i,\ell} \) is a bijection. Notice that this construction ensures that for all \( i \in [t] \) and \( j \in [|A_i|] \) we have

\[
|\{\pi_{i,\ell}(a_{i,j}) : \ell \in [d]\}| = \min\{d, |B_i|\}. \tag{2.3}
\]

Let \( \pi : [n] \rightarrow [n] \) be the bijection given by taking the "disjoint union" of \( \pi_{1,\ell}, \ldots, \pi_{t,\ell} \). We claim that \( \mathcal{A}_d(f) = \{\pi_1, \ldots, \pi_d\} \) satisfies the conditions of the lemma.

It suffices to verify that this choice of \( \mathcal{A}_d(f) \) \( d \)-covers \( f \), i.e., to verify that every \( r \in [n] \) satisfies at least one of the two conditions in Definition 2.3. Pick any \( r \in [n] \). Suppose \( r \in A_i \), so that \( f(r) \in B_i \) and \( \pi_{i}(r) = \pi_{i,\ell}(r) \). If \( |B_i| > d \), then \( |f^{-1}(f(r))| = |A_i| = |B_i| > d \), so condition (ii) holds. Otherwise, from Eq. (2.3), we conclude that \( \{\pi_{i,\ell}(r) : \ell \in [d]\} = B_i \). Therefore, for each \( s \in B_i \) — in particular, for \( s = f(r) \) — there exists an \( \ell \in [d] \) such that \( \pi_{i,\ell}(r) = s \), so condition (i) holds.

**Proof of Lemma 2.4.** Let \((i, \pi, x) \in [n] \times S_n \times \{0,1\}^n \) denote an input for the problem \( \text{MPJ}_3^{\text{perm}} \). Then the desired output is \( x_{\pi(i)} \). The existence of a protocol \( P \) for \( \text{MPJ}_3^{\text{perm}} \) with \( \text{cost}(P) = O(n\phi(n)) \) means that there exist functions

\[
\alpha : S_n \times \{0,1\}^n \rightarrow \{0,1\}^m, \quad \beta : [n] \times \{0,1\}^n \times \{0,1\}^m \rightarrow \{0,1\}^m,
\]

and

\[
\gamma : [n] \times S_n \times \{0,1\}^n \times \{0,1\}^m \rightarrow \{0,1\},
\]

where \( m = O(n\phi(n)) \), such that \( \gamma(i, \pi, \alpha(\pi, x), \beta(i, x, \alpha(\pi, x))) = x_{\pi(i)} \). The functions \( \alpha, \beta \) and \( \gamma \) yield the messages in \( P \) of \( \text{PLR}_1, \text{PLR}_2 \) and \( \text{PLR}_3 \) respectively.

To design a protocol for \( \text{MPJ}_3 \), we first let \( \text{PLR}_1 \) and \( \text{PLR}_3 \) agree on a parameter \( d \), to be fixed below, and a choice of \( \mathcal{A}_d(f) \) for each \( f : [n] \rightarrow [n] \), as guaranteed by Lemma 2.3. Now, let \((i, f, x) \in [n] \times [n]^{[n]} \times \{0,1\}^n \) be an input for \( \text{MPJ}_3 \). Our protocol works as follows.

- **PLR1** sends a two-part message. The first part consists of the strings \( \{\alpha(\pi, x)\}_{\pi} \) for all \( \pi \in \mathcal{A}_d(f) \). The second part consists of the bits \( x_s \) for \( s \in [n] \) such that \( |f^{-1}(s)| > d \).
- **PLR2** sends the strings \( \{\beta(i, x, \alpha)\}_{\alpha} \) for all strings \( \alpha \) in the first part of \( \text{PLR}_1 \)'s message.
- **PLR3** can now output \( x_{f(i)} \) as follows. If \(|f^{-1}(f(i))| > d \), then she reads \( x_{f(i)} \) off from the second part of \( \text{PLR}_1 \)'s message. Otherwise, since \( \mathcal{A}_d(f) \) \( d \)-covers \( f \), there exists a \( \pi_0 \in \mathcal{A}_d(f) \) such that \( f(i) = \pi_0(i) \). She uses the string \( \alpha_0 := \alpha(\pi_0, x) \) from the second part of \( \text{PLR}_1 \)'s message.
the first part of \(\text{PLR}_1\)’s message and the string \(\beta_0 := \beta(i, x, \alpha_0)\) from \(\text{PLR}_2\)’s message to output \(\gamma(i, \pi_0, \alpha_0, \beta_0)\).

To verify correctness, we only need to check that \(\text{PLR}_3\)’s output in the “otherwise” case indeed equals \(x_{f(i)}\). By the correctness of \(P\), the output equals \(x_{\pi_0(i)}\) and we are done, since \(f(i) = \pi_0(i)\).

We now turn to the communication cost of the protocol. By the guarantees in Lemma 2.4, \(|A_d(f)| \leq d\), so the first part of \(\text{PLR}_1\)’s message is at most \(dm\) bits long, as is \(\text{PLR}_2\)’s message. Since there can be at most \(n/d\) values \(s \in [n]\) such that \(|f^{-1}(s)| > d\), the second part of \(\text{PLR}_2\)’s message is at most \(n/d\) bits long. Therefore the communication cost is at most \(2dm + n/d = O(dn\phi(n) + n/d)\). Setting \(d = \lceil 1/\sqrt{\phi(n)} \rceil\) gives us a bound of \(O(n\sqrt{\phi(n)})\), as desired.

2.3. A k-Player Protocol

We now show how to prove Theorem 1.3 by generalizing the protocol from Lemma 2.2 into a protocol for \(k\) players. It will help to view an instance of \(\text{MPJ}_k\) as incorporating several "embedded" instances of \(\text{MPJ}_3\). The following lemma makes this precise.

**Lemma 2.5.** Let \((i, f_2, \ldots, f_{k-1}, x)\) be input for \(\text{MPJ}_k\). Then, for all \(1 < j < k\),

\[
\text{MPJ}_k(i, f_2, \ldots, x) = \text{MPJ}_3(f_{j-1} \circ \cdots \circ f_2(i), f_j, x \circ f_{k-1} \circ \cdots \circ f_{j+1}).
\]

In our protocol for \(\text{MPJ}_k\), for \(2 \leq j \leq k - 1\), the players \(\text{PLR}_1, \text{PLR}_j,\) and \(\text{PLR}_k\) will use a modified version of the protocol from Lemma 2.2 for \(\text{MPJ}_3\) on input \((f_{j-1} \circ \cdots \circ f_2(i), f_j, x \circ \cdots \circ f_{j+1})\). Before we get to the protocol, we need to generalize the technical definition and lemma from the previous subsection.

**Definition 2.6.** Let \(S \subseteq [n]\) and let \(d\) be a positive integer. A set \(A \subseteq S_n\) of permutations is said to \((S, d)-cover\) a function \(f : [n] \to [n]\) if, for each \(r \in S\), at least one of the following conditions holds:

(i) \(\exists \pi \in A\) such that \(\pi(r) = f(r)\), or

(ii) \(|S \cap f^{-1}(f(r))| > d\).

**Lemma 2.7.** Let \(f : [n] \to [n]\) be a function, \(S \subseteq [n]\), and \(d\) be a positive integer. There exists a set \(A_{S,d}(f) \subseteq S_n\), with \(|A_{S,d}(f)| \leq d\), that \((S, d)-covers\ f\).

**Proof.** This proof closely follows that of Lemma 2.4. As before, we give an explicit algorithm to construct \(A_{S,d}(f)\). Suppose \(\text{Range}(f) = \{s_1, s_2, \ldots, s_l\}\), and let \(\{A_i\}\) and \(\{B_i\}\) be defined as in Lemma 2.4. Let \(a_{i,1} < \cdots < a_{i,z}\) be the elements of \(A_i \cap S\) arranged in ascending order, and let \(a_{i,z+1} < \cdots < a_{i,|A_i|}\) be the elements of \(A_i \setminus S\) arranged in ascending order. Similarly, let \(b_{i,1} < \cdots < b_{i,|B_i|}\) be the elements of \(B_i \setminus \{s_i\}\) arranged in ascending order, and let \(b_{i,|B_i|} = s_i\). For \(i \in [l], \ell \in [d]\), we define \(\pi_{i,\ell}(a_{i,j}) := b_{i,\ell - j \mod |B_i|}\). As before, it is routine to verify that \(\pi_{i,\ell}\) is a bijection. Let \(\pi_{\ell} : [n] \to [n]\) be the bijection given by taking the "disjoint union" of \(\pi_{1,\ell}, \ldots, \pi_{l,\ell}\). We claim that \(A_{S,d}(f) = \{\pi_1, \ldots, \pi_d\}\) satisfies the conditions of the lemma.

It suffices to verify that this choice of \(A_{S,d}(f)\) \((S, d)-covers\ f\), i.e., to verify that every \(r \in S\) satisfies at least one of the two conditions in Definition 2.4. Pick any \(r \in S\). Suppose \(r \in A_i\), and fix \(j\) such that \(r = a_{i,j}\). If \(|S \cap f^{-1}(f(r))| > d\), then condition (ii) holds. Otherwise, setting \(\ell = j - |S \cap f^{-1}(f(r))| \leq d\), we conclude that \(\pi_{\ell}(r) = \pi_{i,\ell}(r) = \pi_{i,\ell}(a_{i,j}) = b_{i,\ell \mod |B_i|} = s_i = f(r)\), so condition (i) holds.

\[\blacksquare\]
Proof of Theorem 4.3. To design a protocol for $MP_j$, we first let $PLR_1$ and $PLR_k$ agree on a parameter $d$, to be fixed later. They also agree on a choice of $A_{S,d}(f)$ for all $S \subseteq [n]$ and $f : [n] \rightarrow [n]$. Let $(i, f_2, \ldots, f_k, x)$ denote an input for $MP_j$. Also, let $S_j = [n]$, and for all $2 \leq j \leq k - 1$, let $S_j = \{ s \in [n] : |S_{j-1} \cap f_j^{-1}(s)| > d \}$. Our protocol works as follows:

- $PLR_1$ sends a $(k-1)$-part message. For $1 \leq j \leq k-2$, the $j$th part of $PLR_1$’s message consists of the strings $\{ \alpha(\pi, \hat{x}_{j+1}) \}_\pi$ for each $\pi \in A_{S_{j-1},d}(f_{j+1})$. The remaining part consists of the bits $x_s$ for $s \in S_{k-1}$.

- For $2 \leq j \leq k - 1$, $PLR_j$ sends the strings $\{ \beta(\hat{t}_j, \hat{x}_j, \alpha) \}_\alpha$ for all strings $\alpha$ in the $(j-1)$th part of $PLR_j$’s message.

$PLR_k$ can now output $x_{\hat{t}_k}$ as follows. If $|S_1 \cap f_2^{-1}(f_2(i))| \leq d$, then, because $A_{S_1,d}(f_2) (S_1, d)$-covers $f_2$, there exists $\pi_0 \in A_{S_1,d}(f_2)$ such that $f_2(i) = \pi_0(i)$. She uses the string $\alpha_0 = \alpha(\pi_0, \hat{x}_2)$ from the first part of $PLR_1$’s message and the string $\beta_0 = \beta(i, \hat{x}_2, \alpha_0)$ from $PLR_2$’s message to output $\gamma_0 = \gamma(i, \pi_0, \alpha_0, \beta_0)$. Similarly, if there is a $j$ such that $2 \leq j \leq k - 2$ and $|S_j \cap f_{j+1}^{-1}(f_{j+1}(i_{j+1}))| \leq d$, then since $A_{S_j,d}(f_{j+1}) (S_j, d)$-covers $f_{j+1}$, there exists $\pi_0 \in A_{S_j,d}(f_{j+1})$ such that $f_{j+1}(\hat{i}_{j+1}) = \pi_0(\hat{i}_{j+1})$. She uses the string $\alpha_0 = \alpha(\pi_0, \hat{x}_j, \alpha_0)$ from the $j$th part of $PLR_j$’s message and the string $\beta_0 = \beta(\hat{i}_{j+1}, \hat{x}_j, \alpha_0)$ from $PLR_{j+1}$’s message to output $\gamma_0 = \gamma(\hat{i}_{j+1}, \pi_0, \alpha_0, \beta_0)$. Otherwise, $|S_{k-2} \cap f_{k-1}^{-1}(f_{k-1}(\hat{i}_{k-1}))| > d$, hence $\hat{t}_k \in S_{k-1}$, and she reads $x_{\hat{t}_k}$ off from the last part of $PLR_k$’s message.

To verify correctness, we need to ensure that $PLR_k$ always outputs $x \circ f_{k-1} \circ \cdots \circ f_2(i)$. In the following argument, we repeatedly use Lemma 2.3. We proceed inductively. If $|S_1 \cap f_2^{-1}(f_2(i))| \leq d$ then there exists $\pi_0 \in A_{S_1,d}(f_2)$ such that $f_2(i) = \pi_0(i)$, $\alpha_0 = \alpha(\pi_0, \hat{x}_2)$, and $\beta_0 = \beta(i, \hat{x}_2, \alpha_0)$, and $PLR_k$ outputs $\gamma_0 = \gamma(i, \pi_0, \alpha_0, \beta_0) = \hat{x}_2(\pi_0) = x \circ f_{k-1} \circ \cdots \circ f_2(i)$. Otherwise, $|S_1 \cap f_2^{-1}(f_2(i))| > d$, hence $f_2(i) \in S_2$. Inductively, if $\hat{i}_j \in S_{j-1}$, then either $|S_{j-1} \cap f_{j+1}^{-1}(f_{j+1}(\hat{i}_{j}))| \leq d$, or $|S_{j-1} \cap f_{j+1}^{-1}(f_{j+1}(\hat{i}_j))| > d$. In the former case, there is $\pi_0 \in A_{S_{j-1},d}(f_{j+1})$ such that $f_{j+1}(\hat{i}_j) = \pi_0(\hat{i}_j)$; $\alpha_0(\pi_0, \hat{x}_j, \beta_0) = \hat{x}_j(\pi_0) = x \circ f_{k-1} \circ \cdots \circ f_2(i)$. In the latter case, $f_{j+1}(\hat{i}_j) \in S_j$. By induction, we have that either $PLR_k$ outputs $x \circ f_{k-1} \circ \cdots \circ f_2(i)$, or $\hat{t}_k \in S_{k-1}$. But in this case, $PLR_k$ outputs $x(\hat{t}_k) = x \circ f_{k-1} \circ \cdots \circ f_2(i)$ directly from the last part of $PLR_j$’s message. Therefore, $PLR_k$ always outputs $x \circ f_{k-1} \circ \cdots \circ f_2(i)$ correctly.

We now turn to the communication cost of the protocol. By Lemma 2.3, $|A_{S_j,d}(f_j)| \leq d$ for each $2 \leq j \leq k - 1$, hence the first $k - 2$ parts of $PLR_j$’s message each are at most $dn$ bits long, as is $PLR_k$’s message for all $2 \leq j \leq k - 1$. Also, since for all $2 \leq j \leq k - 1$, there are at most $|S_{j-1}|/d$ elements $s \in S_j$ such that $|S_{j-1} \cap f_j^{-1}(s)| > d$, we must have that $|S_2| \leq |S_1|/d = n/d, |S_3| \leq |S_2|/d \leq n/d^2$, etc., and $|S_{k-1}| \leq n/d^{k-2}$. Therefore, the final part of $PLR_j$’s message is at most $n/d^{k-2}$ bits long, and the total communication cost is at most $2(k-2)dn + n/d^{k-2} = O((k-2)dn\phi(n) + n/d^{k-2})$. Setting $d = \lfloor 1/(\phi(n)^{1/(k-1)}) \rfloor$ gives us a bound of $O(n(k\phi(n))^{(k-2)/(k-1)})$ as desired.

Note that, in the above protocol, except for the first and last players, the remaining players access very limited information about their input. Specifically, for all $2 \leq j \leq k - 1$, $PLR_j$ needs to see only $i_j$ and $\hat{x}_j$, i.e., $PLR_j$ is both conservative and collapsing. Despite this severe restriction, we have a sublinear protocol for $MP_k$. As we shall see in the next section, further restricting the input such that $PLR_1$ is also collapsing yields very strong lower bounds.
3. Collapsing Protocols: A Lower Bound

Let $F : \mathcal{A}_1 \times \mathcal{A}_2 \times \cdots \times \mathcal{A}_k \rightarrow B$ be a $k$-player NOF communication problem and $P$ be a protocol for $F$. We say that $\text{PLR}_j$ is collapsing in $P$ if her message depends only on $x_1, \ldots, x_{j-1}$ and the function $g_{x,j} : \mathcal{A}_1 \times \mathcal{A}_2 \times \cdots \times \mathcal{A}_j \rightarrow B$ given by $g(x_j, z_1, \ldots, z_j) = F(z_1, \ldots, z_j, x_{j+1}, \ldots, x_k)$. For pointer jumping, this amounts to saying that $\text{PLR}_j$ sees all layers $1, \ldots, j - 1$ of edges (i.e., the layers preceding the one on her forehead), but not layers $j + 1, \ldots, k$; however, she does see the result of following the pointers from each vertex in layer $j$. Still more precisely, if the input to MPJ$_k$ (or MPJ$_k$) is $(i, f_2, \ldots, f_k)$, then the only information $\text{PLR}_j$ gets is $i, f_2, \ldots, f_{j-1}$ and the composition $f_k \circ f_{k-1} \circ \cdots \circ f_{j+1}$.

We say that a protocol is collapsing if every player involved is collapsing. We shall prove Theorem 1.4 by contradiction. Assume that there is a collapsing protocol $P$ for MPJ$_k$ in which every player sends less than $n - \frac{1}{2} \log n - 2$ bits. We shall construct a pair of inputs that differ only in the last layer (i.e., the Boolean string on $\text{PLR}_k$’s forehead) and that cause players $1$ through $k - 1$ to send the exact same sequence of messages. This will cause $\text{PLR}_k$ to give the same output for both these inputs. But our construction will ensure that the desired outputs are unequal, a contradiction. To aid our construction, we need some definitions and preliminary lemmas.

Definition 3.1. A string $x \in \{0, 1\}^n$ is said to be consistent with $(f_1, \ldots, f_j, \alpha_1, \ldots, \alpha_j)$ if, in protocol $P$, for all $h \leq j$, $\text{PLR}_h$ sends the message $\alpha_h$ on seeing input $(i = f_1, \ldots, f_{h-1}, x \circ f_j \circ f_{j-1} \circ \cdots \circ f_{h+1})$ and previous messages $\alpha_1, \ldots, \alpha_{h-1}$. A subset $T \subseteq \{0, 1\}^n$ is said to be consistent with $(f_1, \ldots, f_j, \alpha_1, \ldots, \alpha_j)$ if $x$ is consistent with $(f_1, \ldots, f_j, \alpha_1, \ldots, \alpha_j)$ for all $x \in T$.

Definition 3.2. For strings $x, x' \in \{0, 1\}^n$ and $a, b \in \{0, 1\}$, define the sets

$$I_{ab}(x, x') := \{j \in [n] : (x_j, x'_j) = (a, b)\}.$$ 

A pair of strings $(x, x')$ is said to be a crossing pair if for all $a, b \in \{0, 1\}$, $I_{ab}(x, x') \neq \emptyset$. A set $T \subseteq \{0, 1\}^n$ is said to be crossed if it contains a crossing pair and uncrossed otherwise. The weight of a string $x \in \{0, 1\}^n$ is defined to be the number of $1$s in $x$, and denoted $|x|$.

For the rest of this section, we assume (without loss of generality) that $n$ is large enough and even.

Lemma 3.3. If $T \subseteq \{0, 1\}^n$ is uncrossed, then $|\{x \in T : |x| = n/2\}| \leq 2$.

Proof. Let $x$ and $x'$ be distinct elements of $T$ with $|x| = |x'| = n/2$. For $a, b \in \{0, 1\}$, define $t_{ab} = |I_{ab}(x, x')|$. Since $x \neq x'$, we must have $t_{01} + t_{10} > 0$. An easy counting argument shows that $t_{01} = t_{10}$ and $t_{00} = t_{11}$. Since $T$ is uncrossed, $(x, x')$ is not a crossing pair, so at least one of the numbers $t_{ab}$ must be zero. It follows that $t_{00} = t_{11} = 0$, so $x$ and $x'$ are bitwise complements of each other. Since this holds for any two strings in $\{x \in T : |x| = n/2\}$, that set can have size at most 2.

Lemma 3.4. Suppose $t \leq n - \frac{1}{2} \log n - 2$. If $\{0, 1\}^n$ is partitioned into $2^t$ disjoint sets, then one of those sets must be crossed.

\footnote{It is worth noting that, in Definition 3.1, $x$ is not to be thought of as an input on $\text{PLR}_k$’s forehead. Instead, in general, it is the composition of the rightmost $k - j$ layers of the input graph.}
Proof. Let \( \{0,1\}^n = T_1 \sqcup T_2 \sqcup \cdots \sqcup T_m \) be a partition of \( \{0,1\}^n \) into \( m \) uncrossed sets. Define \( X := \{x \in \{0,1\}^n : |x| = n/2\} \). Then \( X = \bigcup_{i=1}^m (T_i \cap X) \). By Lemma 3.3

\[
|X| \leq \sum_{i=1}^m |T_i \cap X| \leq 2m.
\]

Using Stirling’s approximation, we can bound \(|X| > 2^n/(2\sqrt{n})\). Therefore, \( m > 2^{n-\frac{1}{2}\log n - 2} \).

Proof of Theorem 3.4. Set \( t = n - \frac{1}{2} \log n - 2 \). Recall that we have assumed that there is a collapsing protocol \( \overline{P} \) for \( \text{MPJ}_k \) in which every player sends at most \( t \) bits. We shall prove the following statement by induction on \( j \), for \( j \in [k-1] \).

\((*)\) There exists a partial input \((i = f_1, f_2, \ldots, f_j) \in [n] \times ([n]^{[n]})^{j-1}\), a sequence of messages \((\alpha_1, \ldots, \alpha_j)\) and a crossing pair of strings \((x, x') \in \{(0,1)^n\}^2\) such that both \( x \) and \( x' \) are consistent with \((f_1, \ldots, f_j, \alpha_1, \ldots, \alpha_j)\), whereas \( x \circ f_j \circ \cdots \circ f_2(i) = 0 \) and \( x' \circ f_j \circ \cdots \circ f_2(i) = 1 \).

Considering \((*)\) for \( j = k - 1 \), we see that \( \text{PLR}_k \) must send identically on the two inputs \((i, f_2, \ldots, f_{k-1}, x) \) and \((i, f_2, \ldots, f_{k-1}, x') \). Therefore she must err on one of these two inputs. This will give us the desired contradiction.

To prove \((*)\) for \( j = 1 \), note that \( \text{PLR}_1 \)'s message, being at most \( t \) bits long, partitions \( \{0,1\}^n \) into at most \( 2^t \) disjoint sets. By Lemma 3.4, one of these sets, say \( T \), must be crossed. Let \((x, x')\) be a crossing pair in \( T \) and let \( \alpha_1 \) be the message that \( \text{PLR}_1 \) sends on seeing a string in \( T \). Fix \( i = f_1 \) such that \( i \in I_{01}(x, x') \). These choices are easily seen to satisfy the conditions in \((*)\). Now, suppose \((*)\) holds for a particular \( j \geq 1 \). Fix the partial input \((f_1, \ldots, f_j)\) and the message sequence \((\alpha_1, \ldots, \alpha_j)\) as given by \((*)\). We shall come up with appropriate choices for \( f_{j+1}, \alpha_{j+1} \) and a new crossing pair \((y, y')\) to replace \((x, x')\), so that \((*)\) is satisfied for \( j + 1 \). Since \( \text{PLR}_{j+1} \) sends at most \( t \) bits, she partitions \( \{0,1\}^n \) into at most \( 2^t \) subsets (the partition might depend on the choice of \((f_1, \ldots, f_j, \alpha_1, \ldots, \alpha_j)\)).

As above, by Lemma 3.4, she sends a message \( \alpha_{j+1} \) on some crossing pair \((y, y')\). Choose \( f_{j+1} \) so that it maps \( I_{ab}(x, x') \) to \( I_{ab}(y, y') \) for all \( a, b \in \{0,1\} \); this is possible because \( I_{ab}(y, y') \neq 0 \). Then, for all \( i \in [n], x_i = yf_{j+1}(i) \) and \( x'_i = y'f_{j+1}(i) \). Hence, \( x = y \circ f_{j+1} \) and \( x' = y' \circ f_{j+1} \). Applying the inductive hypothesis and the definition of consistency, it is straightforward to verify the conditions of \((*)\) with these choices for \( f_{j+1}, \alpha_{j+1}, y \) and \( y' \).

This completes the proof. ■

We now turn to proving Theorem 3.5 by constructing an appropriate collapsing protocol for \( \text{MPJ}^\text{perm}_k \). Our protocol uses what we call bucketing schemes, which have the flavor of the conservative protocol of Damm et al. [DJS98]. For any function \( f \in [n]^{[n]} \) and any \( S \subseteq [n] \), let \( 1_S \) denote the indicator function for \( S \); that is, \( 1_S(i) = 1 \iff i \in S \). Also, let \( f|_S \) denote the function \( f \) restricted to \( S \); this can be seen as a list of numbers \( \{i_s\} \), one for each \( s \in S \). Players will often need to send \( 1_S \) and \( f|_S \) together in a single message. This is because later players might not know \( S \), and will therefore be unable to interpret \( f|_S \) without \( 1_S \). Let \( \langle m_1, \ldots, m_t \rangle \) denote the concatenation of messages \( m_1, \ldots, m_t \).

Definition 4.1. A bucketing scheme on a set \( X \) is an ordered partition \( \mathcal{B} = (B_1, \ldots, B_t) \) of \( X \) into buckets. For \( x \in X \), we write \( \mathcal{B}[x] \) to denote the unique integer \( j \) such that \( B_j \ni x \).
We actually prove our upper bound for problems slightly more general than $\widetilde{\MP}^\perm_k$. To be precise, for an instance $(i, f_2, \ldots, f_k)$ of $\MP^k$, we allow any one of $f_2, \ldots, f_k$ to be an arbitrary function in $[n]^n$. The rest of the $f_j$s are required to be permutations, i.e., in $S_n$.

**Theorem 4.2** (Slight generalization of Theorem 1.3). There is an $O(n \log^{(k-1)} n)$ collapsing protocol for instance $(i, f_2, \ldots, f_k)$ of $\MP^k$ when all but one of $f_2, \ldots, f_k$ are permutations. In particular, there is such a protocol for $\MP^k$.

**Proof.** We prove this for $\MP^\perm_k$ only. For $1 \leq t \leq \lfloor \log n \rfloor$, define the bucketing scheme $B_t = (B_1, \ldots, B_{2^t})$ on $[n]$ by $B_j := \{r \in [n] : 2^j r/n = j\}$. Note that each $|B_j| \leq \lfloor n/2^t \rfloor$ and that a bucket can be described using $t$ bits. For $1 \leq j \leq k$, let $b_j = \lfloor \log^{(k-j)} n \rfloor$. In the protocol, most players will use two bucketing schemes, $B$ and $B'$. On input $(i, f_2, \ldots, f_k)$:

- PLR$_1$ sees $\hat{f}_1$, computes $B' := B_{b_1}$, and sends $\langle B'[\hat{f}_1(1)], \ldots, B'[\hat{f}_1(n)] \rangle$.
- PLR$_2$ sees $\hat{i}_2, \hat{f}_2$, and PLR$_1$'s message. PLR$_2$ computes $B := B_{b_1}$ and $B' := B_{b_2}$. She recovers $b := B[\hat{f}_2(\hat{i}_2)]$ and hence $B_b$. Let $S_2 := \{s \in [n] : \hat{f}_2(s) \in B_b\}$. Note that $\hat{f}_2(\hat{i}_2) \in S_2$. PLR$_2$ sends $\langle 1_{S_2}, \{B'[\hat{f}_2(s)] : s \in S_2\} \rangle$.

- PLR$_j$ sees $\hat{i}_j, \hat{f}_j$, and PLR$_{j-1}$'s message. PLR$_j$ computes $B := B_{b_{j-1}}$ and $B' := B_{b_j}$. She recovers $b := B[\hat{f}_j(\hat{i}_j)]$ and hence $B_b$. Let $S_j := \{s \in [n] : \hat{f}_j(s) \in B_b\}$. Note that the definitions guarantee that $\hat{f}_j(\hat{i}_j) \in S_j$. PLR$_j$ sends $\langle 1_{S_j}, \{B'[\hat{f}_j(s)] : s \in S_j\} \rangle$.

- PLR$_k$ sees $\hat{i}_k$ and PLR$_{k-1}$’s message and outputs $f_k(\hat{i}_k)$.

We claim that this protocol costs $O(n \log^{(k-1)} n)$ and correctly outputs $\MP^k(i, f_2, \ldots, f_k)$. For each $2 \leq j \leq k - 1$, PLR$_j$ uses bucketing scheme $B_{b_{j-1}}$ to recover the bucket $B_b$ containing $\hat{f}_j(\hat{i}_j)$. She then encodes each element in $B_b$ in the bucketing scheme $B_{b_j}$. Each bucket in $B_{b_j}$ has size at most $\lfloor n/b_{j+1} \rfloor$. In particular, each bucket in scheme $B_{b_{k-1}}$ has size at most $\lfloor n/b_k \rfloor = 1$, and the unique element in the bucket (if present) is precisely $f_k(\hat{i}_k)$. Turning to the communication cost, PLR$_1$ sends $b_1 = \lfloor \log^{(k-1)} n \rfloor$ bits to identify the bucket for each $i \in [n]$, giving a total of $n \lfloor \log^{(k-1)} n \rfloor$ bits. For $1 < j < k$, PLR$_j$ uses $n + b_j(n/b_j) = O(n)$ bits. Thus, the total cost is $O(n \log^{(k-1)} n + kn)$ bits.

For $k \leq \log^* n$ players, we are done. For larger $k$, we can get an $O(n)$ protocol by doubling the size of each $b_j$ and stopping the protocol when the buckets have size $\leq 1$.

### 5. Concluding Remarks

We have presented the first nontrivial upper bound on the NOF communication complexity of $\MP^k$, showing that $C(\MP^k) = o(n)$. A lower bound of $\Omega(n)$ had seemed a priori reasonable, but we show that this is not the case. One plausible line of attack on lower bounds for $\MP^k$ is to treat it as a direct sum problem: at each player’s turn, it seems that $n$ different paths need to be followed in the input graph, so it seems that an information theoretic approach (as in Bar-Yossef et al. [BJS02] or Chakrabarti [Cha07]) could lower bound $C(\MP^k)$ by $n$ times the complexity of some simpler problem. However, it appears that such an approach would naturally yield a lower bound of the form $\Omega(n/\xi(k))$, as in Conjecture 1.4, which we have explicitly falsified.
The most outstanding open problem regarding MPJ$^k$ is to resolve Conjecture 1.2. A less ambitious, but seemingly difficult, goal is to get tight bounds on $C(\text{MPJ}^3)$, closing the gap between our $O(n^{\sqrt{\log \log n}/\log n})$ upper bound and Wigderson’s $\Omega(\sqrt{n})$ lower bound. A still less ambitious question is to prove that MPJ$^3$ is harder than its very special subproblem TPJ$^3$ (defined in Section 1.1). Our $n – O(\log n)$ lower bound for collapsing protocols is a step in the direction of improving the known lower bounds. We hope our technique provides some insight about the more general problem.
