Blockwise similarity in \([0,1]\) via triangular norms and Sugeno integrals – Application to cluster validity

Hoël Le Capitaine, Thomas Batard, Carl Frélicot and Michel Berthier

Abstract—In many fields, e.g. decision-making, numerical values in \([0,1]\) are available and one is often interested in detecting which are similar. In this paper, we propose an operator which is able to detect whether some values can be gathered by blocks with respect to their similarity or not. It combines the values and a kernel function using triangular norms and Sugeno integrals. This operator allows to estimate this blockwise similarity at different levels. For illustration purpose, we use it to define an index suitable for the cluster validity problem in pattern recognition.

I. INTRODUCTION

The main topic of this paper is to define a new indicator which measures, for a given \(c\)-tuple of values in \([0,1]\), whether some values can be gathered by blocks with respect to their similarity or not. For this purpose, we propose a new operator based on triangular norms and Sugeno integrals which combines the values and a kernel function. The resolution parameter of the kernel allows to view the induced similarity at different levels.

Such an operator can be used in many fields, in pattern recognition in particular and more specifically in supervised and unsupervised classification. Within this framework, the values to be aggregated generally express to which extent a pattern recognition in particular and more specifically in supervised classification. Within this framework, the values to be aggregated generally express to which extent a pattern can either be associated to a specified class (supervised) or contribute to the definition of a particular cluster (unsupervised). Therefore, given a pattern, such a similarity operator is suitable for detecting, either ambiguities with respect to the classes at hand or a natural grouping tendency.

The remainder of this paper is organized as follows. In section II, we briefly recall previous works that lead us to consider aggregation functions of a new kind. The blockwise similarity operator is proposed in section III. Properties and numerical examples are given. Next, in section IV, we use it to define an new index for cluster validity in the framework of fuzzy clustering. Results on artificial and real data show that the proposed index is performant thanks to the similarity operator.

II. PREVIOUS WORK

Aggregation functions or operators aim at combining (say \(c\)) numerical values. They are used in many fields, e.g. in multicriteria decision making and pattern recognition where values to be aggregated are most often in \([0,1]\). Then, many families of functions have been defined that are formally mappings \(\Phi: [0,1]^c \rightarrow [0,1], u = \{u_1, u_2, \ldots, u_c\} \mapsto \Phi(u),\)

All authors are with the Mathematics, Image and Applications (MIA) – Université de La Rochelle Avenue M. Crépeau, 17042 La Rochelle Cedex 1, FRANCE, email:{firstname.lastname}@univ-lr.fr
e.g. the triangular norms (briefly t-norm) and dual t-conorms, e.g. in subsection IV-B, refer to [10] for complete definitions and examples. Because of applications in pattern recognition, we have in mind, we are interested in functions that qualify the similarity between some of the \(u_i\)'s. For convenience, the \(u_i\)'s are supposed to be sorted in decreasing order but of course operators do not need this assumption.

In [11], the \(\perp_k\) operator has been defined as follows. Let \(P\) be the powerset of \(C = \{1,2,\ldots,c\}\) and \(P_k = \{A \in P : |A| = k\}\) where \(|A|\) denotes the cardinality of subset \(A\), then

\[
\bigwedge_{i=1}^{k} u_i = \bigwedge_{A \in P_{k-1}} \left( \bigvee_{j \in C \setminus A} u_j \right.
\]

where \(\bigwedge\) is a t-norm and \(\bigvee\) is its dual t-conorm.

It must be viewed as some kind of generalization of the notion of "\(k\)th bigger", with \(k\) in \(C\). In particular, with standard triangular norms, \(\bigwedge_k\) is exactly the "\(k\)th bigger". This operator satisfies nice mathematical properties (see [11] for details and applications).

By combining \(\perp\), \(k = 1,2\), the authors built a fuzzy exclusive OR operator that extends the crisp XOR operator to the fuzzy context [6]:

\[
\bigwedge_{i=1}^{k} u_i = \left( \bigwedge_{i=1}^{1} u_i \right) \bigwedge \left( \bigvee_{i=1}^{2} u_i \right) \bigvee \left( \bigwedge_{i=1}^{1} u_i \right)
\]

where \(\bigwedge = \bigwedge\) and \(\bigvee\) is the fuzzy complement of \((\cdot)\). Intuitively, it can be understood as \(u_1\) being significantly high and \(u_2\) significantly low while remaining greater than the other \(u_i\)'s.

This leads us to investigate the question of how to define blockwise similarity and what kind of mathematical properties must be taken into account.

III. BLOCKWISE SIMILARITY

A. Definition

We define a blockwise similarity operator as a family of functions \(\Phi_{j,k}: [0,1]^c \rightarrow [0,1], (j,k) \in \{1,2,\ldots,c\}^2, j < k\), satisfying the following four properties:

(P1) \(\Phi_{j,k}(u) = 0\) whenever \(u_j = 1\) and \(u_k = 0\)

(P2) \(\Phi_{j,k}(1) = \perp_k\)

(P3) \(\forall 0 \leq \varepsilon \leq u_{j-1} - u_j, \Phi_{j,k}(u_1,\ldots,u_j + \varepsilon,\ldots,u_c) \leq \Phi_{j,k}(u_1,\ldots,u_j,\ldots,u_c)\)
The function $\Phi_{j,k}$ measures the similarity of $u_i$'s belonging to the block bounded by $j$ and $k$, and consequently $\Phi_{1,c}$ measures the similarity in the largest block, i.e. the total similarity in $u$. In the particular case when the sum of the $u_i$'s is one, it follows from (P2) that $\Phi_{j,k} = 1$ whenever $u_1 = u_2 = \cdots = u_c$.

A straightforward solution to define blockwise similarity is to define $\Phi_{j,k}$ as the quotient $\frac{k-j}{k}$. However, it can be shown that this quotient does not satisfy the properties listed above.

### B. The new operator

Since fuzzy integrals are able to model some kind of interaction between features, let us study the Sugeno integral. In the context described before the Sugeno integral (refer to [13] for complete definitions and examples) takes the following form:

$$S_\mu(u) = \max_{i=1,\cdots,c}[\min(u_i, \mu\{i, \cdots, c\})]$$

for a fuzzy measure $\mu$ on $\{1, 2, \cdots, c\}$. This definition can be extended to any pair ($\cap$, $\cup$) of t-norm and t-conorm. $S_\mu$ is then the fuzzy integral of $u$ on subsets $\{i, \cdots, c\}$ with respect to the fuzzy measure $\mu$. and thus can be used to measure the ambiguity associated to $u$. Let $A_i = \{j, u_j \geq u_i\}$ and $\mu_k$ be defined by:

$$\mu_k(A_i) = \begin{cases} 0 & \text{if } \text{Card}(A_i) < k \\ 1 & \text{else} \end{cases} \quad (3)$$

we set

$$\frac{k}{j}(u) = \prod_{i=1,\cdots,c} \frac{u_i}{1} \mu_k(A_i) \quad (4)$$

(take care that these operators differ from those in II; we adopt the same notations for simplicity).

It is easy to show that:

$$\frac{k}{j}(u) = \begin{cases} \frac{1}{u_{k-1} > u_k} & \text{if } u_{k-1} > u_k \\ \frac{1}{u_{j-1} > u_j} & \text{otherwise} \end{cases} \quad (5)$$

(with the convention: $u_0 > u_1$).

It can be proved that the operator $\Phi_{j,k} = \frac{k}{j}$ satisfies the four properties of subsection III-A for standard and algebraic t-norms. However, it is not fully convenient for measuring the similarity between $u_j$ and $u_k$ since the result depends on all the $u_i$'s for $l \geq k + 1$ while the $u_i$'s for $l < j$ are not taken into account. To make the values between $u_j$ and $u_k$ meaningful, we introduce symmetrical kernel functions $K_\lambda(i, l)$ centered at $l$ and actually define:

$$\Phi_{j,k}(u) = \begin{cases} \frac{k}{j} & \text{if } k - j \text{ is even} \\ \frac{k}{j} & \text{if } k - j \text{ is odd} \end{cases} \quad (6)$$

Many kernel functions can be used, all being parametrized by a resolution parameter $\lambda$ which controls its area of influence. Let us consider the particular case of a gaussian kernel $K_\lambda(i, l) = N_\lambda(i, l)$ defined by (see Figure 1):

$$N_\lambda(i, l) = \exp\left(-\frac{(i - l)^2}{\lambda}\right) \quad (7)$$

Fig. 1. Kernel $N_{10}(i, l)$ and cardinal measure with $u_5 > u_6$ for $l = 6$.

When $\lambda$ tends to 0, this kernel becomes a dirac $\delta_k$ centered in $k$, the convergence being not uniform by continuity of $K$ and discontinuity of $\delta_k$. If the triangular norms used are continuous, then:

$$\lim_{\lambda \to 0} \Phi_{j,k}(u) = \begin{cases} 1 & \text{if } u_j = 0 \\ \frac{u_k}{u_j} & \text{otherwise} \end{cases} \quad (8)$$

and

$$\lim_{\lambda \to +\infty} \Phi_{j,k}(u) = \begin{cases} \frac{k}{j} & \text{if } k - j \text{ is even} \\ \frac{k}{j} & \text{if } k - j \text{ is odd} \\ 1 & \text{if } u_j = 0 \end{cases} \quad (9)$$

These results show how it is possible to adjust the weights that are given to the values between $u_j$ and $u_k$: the contribution of $u_{j+1}, \ldots, u_{k-1}$ is small if $\lambda$ is close to zero and
increases with $\lambda$. Note however that $\Phi_{i-1,i} = u_{i-1}/u_i$ does not depend on $\lambda$ in $\mathbb{R}^+$. This means that increasing $\lambda$ will not make two consecutive $u_i$’s more similar but may increase the similarity of blocks of larger size. Note also that if $u_i$ is constant for all $i \in \{j, \ldots, k\}$, then $\Phi_{ijk}(u) = 1$ whenever $(j,k)$, as expected in subsection III-A.

**C. Numerical Examples**

Given $u$, computation of $\Phi_{ijk}(u)$ for all $(i,j) \in C \times C$ result in a symmetrical table, see examples in Tables I and II for $u = \{0.9, 0.8, 0.68, 0.51, 0.5, 0.48, 0.32, 0.1\}$ obtained with kernels $\mathcal{N}_1$ and $\mathcal{N}_5$ respectively. Entries $\Phi_{ijk}(u)$ decrease as $k$ increases for a fixed $j (k > j)$. Detection of similarities then simply consists in exploring the upper triangular part of the table and compare the entries to a user-specified threshold $s$ as follows:

- for $j = 1, c$ (row)
- for $k = j + 1, c$ (column)

if $\Phi_{ijk}(u) > s$, then $\{u_j, \ldots, u_k\}$ are similar.

To understand the behaviour of the operator with respect to $\lambda$, let us compare the 4th row of each table, i.e. $\Phi_{4,ik}$ for $k = 4, \ldots, 8$:

- at resolution $\lambda = 1$, $\Phi_{4,4}$, $\Phi_{4,5}$ and $\Phi_{4,6}$ are greater than $s = 0.9$ and the corresponding $u_k$’s $\{0.51, 0.5, 0.48\}$ are detected to be similar. Small value of $\Phi_{4,7}$ and $\Phi_{4,8}$ indicate that both $u_7 = 0.32$ and $u_8 = 0.1$ are not similar to the previous $u_k$’s.

- at resolution $\lambda = 5$, $\Phi_{4,7}$ becomes greater than $s$ and $u_7 = 0.32$ is considered as being similar to $\{0.51, 0.5, 0.48\}$ while $u_8 = 0.1$ still not.

IV. **APPLICATION TO CLUSTER VALIDITY**

A straightforward application of the proposed operator (6) to pattern recognition is supervised classification with ambiguity rejection. Let $x$ be a pattern in a feature space, say $\mathbb{R}^p$, to be classified with respect to a set $\Omega = \{\omega_1, \ldots, \omega_c\}$ of $c$ classes. Given a labelling function: $x \mapsto u(x) \in [0,1]^c$ whose general term $u_i = u_i(x)$ is the posterior probability that $x$ belongs to $\omega_i$ or a membership degree to a fuzzy set associated to $\omega_i$, a decision rule is generally based on the aggregation of labels $u_i (i = 1, c)$. By thresholding the values of $\Phi_{ijk}(u)$ for an incoming pattern $x$, a reject option can easily be included. Table I gives a good example of how it could be done. A threshold $s = 0.9$ would result in rejecting $x$ for ambiguity between the classes whose membership degrees are $\{0.51, 0.5, 0.48\}$. However, such reject option aims at reducing the misclassification risk, so it often focuses on subsets of degrees that include the higher one. Therefore, depending on the application, a particular attention to $\Phi_{1,ik}(u)$ can be paid. This is clearly the case for cluster analysis, another task of major importance in pattern recognition we are interested in.

A. **Cluster validity for fuzzy clustering and indexes**

Clustering is an instance of unsupervised classification which aims at finding a structure of groups in set of $n$ patterns $X = \{x_1, \ldots, x_n\}$. In this framework, the label vectors $u_k = u(x_k)$ are unknown and clustering algorithms can be used to obtain them from $X$. For instance, the fuzzy $c$-means (FCM) algorithm partitions $X$ into $c > 1$ clusters by minimizing the following objective function [2]:

$$J_m(U, V) = \sum_{k=1}^{c} \sum_{i=1}^{n} u_{ik}^m ||x_k - v_i||^2$$  \quad (10)

where $u_{ik}$ is the membership degree of $x_k$ to the $i^{th}$ cluster represented by its centroid $v_i \in \mathbb{R}^p$. Centroids are gathered into a $(c \times p)$ matrix $V = \{v_1, \ldots, v_c\}$. Degrees $u_{ik}$ are subject to $\sum_{i=1}^{c} u_{ik} = 1$ for all $x_k$ in $X$, to $0 < \sum_{k=1}^{n} u_{ik} < n$ $(\forall i = 1, c)$, and are elements of the fuzzy $c$–partition matrix $U (c \times n)$. The so-called fuzzyfier $m > 1$ is a weighting exponent which makes the resulting partition more or less fuzzy [12]. The higher $m$ is, the softer the cluster boundaries are. Minimization of (10) is obtained by iteratively updating $(U, V)$ as follows:

$$u_{ik} = 1 / \left\{ \sum_{j=1}^{c} \left( \frac{||x_k - v_i||}{||x_k - v_j||} \right)^{2/(m-1)} \right\}$$  \quad (11)

$$v_i = \frac{\sum_{k=1}^{n} u_{ik}^m x_k}{\sum_{k=1}^{n} u_{ik}^m}$$  \quad (12)

The usual euclidian norm $||.||$ induces hyperspherical clusters, hence FCM can only detect clusters with the same shape and orientation. In [8], a variant called FCM-GK has been proposed by extended FCM to cluster-dependent norms $||.||_{A_i}$ in order to detect clusters of different geometrical shapes. This results in modifying the objective function (10) as $J_m(U, V, A)$ where $A$ is a $c$–tuple of norm-inducing
matrices $A_i$ taking part in the minimization process, hence to be iteratively updated. To obtain a feasible solution, the determinant of these matrices are constrained allowing to optimize the clusters’ shapes while their volumes remain constant (see [2], [8] for details).

Validating the provided clustering of $X$ consists in assessing whether the resulting partition reflects the data structure or not. Since $c$ is a user-defined parameter of clustering algorithms such as FCM, most of works on cluster validity focus on the number of clusters problem. Many validity indexes have been proposed for fuzzy clustering (refer to [4], [9], [14] for comparative studies). They can be classified into two main categories. The first one is composed of indexes that only use membership degrees ($U$). Let us cite the Partition Coefficient [2], taking values in $[\frac{1}{c}, 1]$:

$$PC(c) = \frac{1}{n} \sum_{k=1}^{n} \sum_{i=1}^{c} u_{ik}^2$$

or the Partition Entropy [1], taking values in $[0, \log(c)]$:

$$PE(c) = -\frac{1}{n} \sum_{k=1}^{n} \sum_{i=1}^{c} u_{ik} \log(u_{ik})$$

Both $PC$ to be maximized and $PE$ to be minimized are monotonic with $c$, as well as their bounds. Normalized versions have been proposed to reduce this tendency, e.g. in [5]. The second category consists of indexes that use membership degrees but also some information about the geometrical structure of the data ($U, V, X$), e.g. the Xie-Beni index [12], [15]:

$$XB(c) = \frac{J_m(U, V)}{\min_{i,j=1,c,j\neq i} ||v_i - v_j||^2}$$

or the Fukuyama-Sugeno index [7]:

$$FS(c) = J_m(U, V) - \sum_{k=1}^{c} \sum_{i=1}^{n} u_{ik} ||v_i - \bar{v}||^2$$

where $\bar{v}$ is the mean of centroids. Both $XB$ and $FS$ combine the FCM objective function (10) which measures how much clusters are compact and an additional term which measures how much they are separated. Combination indexes that both indexes are to be minimized. The more compact and separated the clusters are, the more optimal $c$ is.

B. A new index

Since the blockwise operator $\Phi_{j,k}$ (6) presents a special case ($j = 1, k = c$) which can reflect the overall similarity of $u_{ik}$’s components, it reflects the overall ambiguity of pattern $x_k$ with respect to the $c$ clusters at hand. Therefore, a very simple cluster validity index belonging to the first category can be derived by averaging $\Phi_{1,c}(u_k)$ over the columns of $U$. Given a $c$-partition matrix $U$ resulting from a fuzzy clustering algorithm (FCM, FCM-GK, ...), we define the $BwS$ (BlockWise Similarity) index by:

$$BwS(c) = \frac{1}{n} \sum_{k=1}^{n} \Phi_{1,c}(u_k)$$

The least valid $c$-partition arises when $U$ is totally fuzzy, i.e. $u_{ik} = \frac{1}{c}$ for all $i = 1, c$. Then $\Phi_{1,c}(u_k) = 1$ by (P2) for all $u_k$ in $X$ and so $BwS(c)$ whatever $c$. On the other hand, the most valid $c$-partition arises when $U$ is hard, i.e. $u_{ik} \in \{0, 1\}$. Then $\Phi_{1,c}(u_k) = 0$ by (P1) and $BwS(c) = 0$ whatever $c$. The more separated clusters are, the less $BwS$, and minimizing (17) gives the optimal number of clusters $c^*$. In practice, $BwS(c)$ is computed for $c$ varying from 2 up to $c_{\text{max}}$ and $c^*$ will correspond to a knee.

Recalling that $\Phi_{j,k}(u)$ defines a family of operators because of the many choices for the pair ($\perp$, $\perp$) and the kernel function $K_\lambda$, therefore $BwS(c)$ is a family of validity indexes. In the remaining part of the paper, we present numerical results using the following basic norms:

- Standard: $a \perp_S b = \min(a, b)$ and $a \perp_S b = \max(a, b)$
- Algebraic: $a \perp_A b = a + b - a b$
- Lukasiewicz: $a \perp_L b = \max(a + b - 1, 0)$

and $a \perp_L b = \min(a + b, 1)$

Among the possible kernel functions, we used the gaussian one (7). The resolution parameter $\lambda$ must be set with great care, depending on the application and the magnitude of the $u_i$ to be aggregated. For instance, since $U$ is fuzzy, degrees $u_{ik}$ become as similar as $c$ increases because of the normalization constraint. So, for the fuzzy cluster validity application, we recommend to chose a low $\lambda$ in order to not take into account too many degrees that are similar only because of this constraint. In a further study, we will propose an upper bound for $\lambda$ as a function of $c$ which will probably result in modifying $BwS$.

In next subsections, we will use either the FCM algorithm or the FCM-GK one with the settings: $m = 2$, a threshold $\epsilon = 10^{-5}$ for termination criterion and a maximum of 100 iterations.

C. Artificial data sets

Experiment #1:

A series of 10 data sets was generated, each composed of 800 points drawn from a mixture of $c = 4$ bivariate normal
distributions. The covariance matrix of each component is the same \( \Sigma_i = I \) for \( i = 1, c \) and the mean vectors are:

- \( \mu_1 = (0 \ 0)^T + \alpha (1 \ 1)^T \),
- \( \mu_2 = (0 \ 0)^T + \alpha (1 \ -1)^T \),
- \( \mu_3 = (0 \ 0)^T + \alpha (-1 \ -1)^T \) and
- \( \mu_4 = (0 \ 0)^T + \alpha (-1 \ 1)^T \)

for increasing values of \( \alpha = 1, 2, \ldots, 10 \). This successively moves the clusters in opposite directions, creating less overlap as the clusters become more and more separated. The first and last data sets are shown in Figure 2. Each data set was then clustered using FCM with \( c = 4 \), providing a fuzzy partition matrix \( U_\alpha \). Corresponding values of \( BwS \) for the different basic norms are plotted in Figure 3 as a function of \( \alpha \). As expected, \( BwS \) decreases towards 0 as \( \alpha \) increases whatever the norms.

Experiment #2:

In order to compare the proposed index to the classical ones recalled in subsection IV-A, we generated a data set containing \( n = 200 \) points consisting of 50 points each drawn from a mixture of \( c = 4 \) bivariate normal distributions with various ellipsoidal shapes. FCM-GK was used with \( c_{\text{max}} = 10 \) and an efficient index should find \( c^* = 4 \). Table III reports the results obtained for the tested indexes. Optimal values are boldfaced and acceptable ones italicized. We can see that \( BwS \) always gives the right number of clusters whatever \( \lambda \) while some classical indexes fail. The centroids (12) resulting from clustering with \( c^* = 4 \) are represented by special symbols (●) in Figure 4.

Experiment #3:

The last artificial data set is similar to the previous one except that clusters are spherically shaped and 100 points drawn from a uniform distribution were added, as shown in Figure 5. These additional points act as noise and can make the FCM algorithm partitioning the data set in more than \( c^* = 4 \) clusters. FCM was used with \( c_{\text{max}} = 10 \) and comparative results of the tested validity indexes are given in Table IV. None of the classical indexes was able to detect the right number of clusters while \( BsW \) succeed whatever \( (\top, \bot) \).

Moreover, multiple runs showed us that it gives more stable results, showing its better robustness to noisy data.

**Iris data:**

The iris data set contains \( n = 150 \) observations from three 4-dimensional classes (iris species) of 50 points each. It is one of the most used benchmarks in pattern recognition, especially for cluster validity because two classes have a substantial overlap in the feature space. Therefore, the number of clusters to be found is debatable, e.g. in [4], some authors claiming that the right physical number \( c = 3 \) has to be detected while others say that the geometrical number is \( c = 2 \). So a good index should detect one of these two values as being \( c^* \). Indexes that only use \( U \) are a priori more prone to merge the two overlapping classes into a single cluster because they do not combine compactness and separation measures like the ones that use \( (U, V, X) \). As
the classes are known to have a hyperellipsoidal shape, we used FCM-GK with \( c_{\text{max}} = 10 \). It can be seen in Table V that all indexes exhibit one of the expected optimal numbers of clusters showing their ability in assessing the structure of the data and that the debate is not closed. However, it is worth noting that \( BSW \), despite it only uses \( U \) (like \( PC \) and \( PE \)), overcomes this limitation because small values of \( \Phi_{1,c} \) and therefore the absence of similarity blocs (in average) clearly indicates that the clusters are well separated.

**Glass data:**

This last set contains 214 observations of \( c = 6 \) types of glass that one can find in the scene of the crime (building window, vehicle window, container, headlamp, ...) described by 9 physical and chemical attributes. As shown in Table VI, \( BSW \) is the only index which was able to select the right number of clusters.

### V. Conclusion

In this paper, we have proposed a new operator which estimates, given a \( c \)-tuple of values in \([0,1]\), the similarity of some components. Based on triangular norms and Sugeno integrals, it combines the values and a kernel function. We have demonstrate how the definition of this operator makes it able to detect blockwise similarities at different levels of resolution via the kernel.

Among the applications that can be considered, we have chosen to present a solution to the cluster validity problem in pattern recognition. For this purpose, we have proposed a new index based on the blockwise similarity operator. Given results show its performance when compared to classical indexes. Further works will concern the different choices the practitioner must make (t-norms, kernel functions and their resolution parameter) to use the blockwise similarity operator as well as its application to selective ambiguity rejection in pattern classification.
