Abstract

This study investigated the contribution of the reflected appraisal process to the ontogeny of children’s self-perceptions of physical competence. Emanating from symbolic interactionist thought, reflected appraisals refer to individuals’ perceptions of others’ evaluations of their abilities. The influence of parents’ appraisals of their child’s competence on the child’s self-appraisals was hypothesized to be mediated by parents’ reflected appraisals. Data were collected from a sample of 147 sixth graders and their parents in three waves over one school year. Structural equation modeling revealed that (1) parents’ appraisals at Wave 1 influenced children’s reflected appraisals of parents at Wave 2; (2) reflected appraisals at Wave 2 influenced children’s self-appraisals at Wave 3, controlling for both the child’s actual level in sport (as assessed by the child’s grade in physical education) and the child’s self-appraisals at Wave 1; and (3) the influence of parents’ appraisals on their child’s self-appraisals was nonsignificant when reflected appraisals were controlled for. This study supported the mediational role of the reflected appraisal process. The findings from this study provide a unique contribution to the sport socialization knowledge base by highlighting the role of the reflected appraisal process in the formation of children’s self-appraisals of ability.

Key words: reflected appraisal, parental influence, perceived competence, physical activity, mediation, motivation.
Parents’ appraisals, reflected appraisals, and children’s self-appraisals of sport competence: A yearlong study.

Numerous theoretical models in contemporary psychology have highlighted the role of perceived competence, or ability, as a central antecedent of achievement motivation and behavior (e.g., Deci & Ryan, 2000; Eccles, Wigfield & Schiefele, 1998; Elliot & Church, 1997; Harter, 1981). Although these frameworks differ from each other in numerous ways, each proposes that individuals who have high perceptions of their ability in a particular achievement domain will demonstrate greater motivation, as demonstrated through their decision to become involved, as well as by their levels of effort, perseverance, and affective characteristics in a given context. In the sport and physical activity setting, considerable support has been found for the role of perceived competence in contributing to motivation (for reviews, see Weiss & Ebbeck, 1996; Weiss & Ferrer-Caja, 2002).

Given the influence of competence perceptions on motivation, an important area of study involves understanding the processes individuals use to evaluate or judge their personal competence or ability in achievement contexts. Although much of this research has been conducted in academic contexts (e.g., Stipek & Mac Iver, 1989), a handful of studies have also examined these issues in the physical activity domain (see for reviews, Horn & Amorose, 1998; Horn & Harris, 1996; Weiss, Ebbeck & Horn, 1997). Several theoretical frameworks have highlighted the importance of significant others in shaping one’s self-perceptions. Contemporary developmental and social psychologists (e.g., Harter, 1998; Eccles et al., 1998) have continued in the line of symbolic interactionists such as Cooley (1902) and Mead (1934) in asserting that our self-perceptions develop and change in relation to other people in the social environment. Specifically, our self-perceptions tend to reflect the appraisals of others. This process, whereby perceptions of others’ evaluations
function as a mirror in which one sees oneself, has been referred to as the reflected appraisal process (see Felson, 1993; Kinch, 1963; Shrauger & Schoeneman, 1979; Tice & Wallace, 2003).

In essence, the reflected appraisal process consists of three elements (Felson, 1993; Kinch, 1963; Shrauger & Schoeneman, 1979), including the individual's self-appraisals or self-perceptions, the actual appraisals of significant others, and the person's perceptions of those appraisals, called reflected appraisals. Moreover, theory suggests three basic postulates (Felson, 1993). The first postulate asserts that people are generally accurate to some extent in perceiving what others think of them (Cooley, 1902; Mead, 1934). In sport, for example, a child may believe that his/her father perceives him/her as having high, moderate, or low ability through the use of varied indices such as the father's enthusiasm level, the amount of attention provided, the feedback and encouragement that the father displays, and the participatory opportunities that he offers to the child. The second postulate is that reflected appraisals are generally internalized by the child, whether they are positive or negative, accurate or not. In this regard, if the child believes that his or her parent has a positive appraisal of his or her sport competence he or she is likely to develop a similarly positive perception of sport competence. In contrast, if the child believes that the parent has a less favorable view of their competence, he or she is likely to perceive himself or herself as less competent in sport. In the ontogeny of self-appraisals, the symbolic interactionist perspective gives critical importance to the internalization of the reflected appraisal. The third postulate is that the actual appraisals of others influence self-appraisals indirectly, as mediated by reflected appraisals. That is, actual appraisals of others have no effect on self-appraisals when reflected appraisals have been taken into account.
Few researchers have investigated the issue raised by the first postulate (see for reviews, Felson, 1993; Shrauger & Schoeneman, 1979). Generally, the studies that have been conducted have found weak correlations between reflected appraisals and the actual appraisals of others. In other words, respondents are not very accurate in guessing what significant others think of them, probably because others often conceal their actual opinions, particularly when these opinions are negative (Felson, 1989, 1993; Tice & Wallace, 2003). That is why Shrauger and Schoeneman (1979) have changed the original metaphor somewhat by suggesting that people see “through the looking glass darkly.”

Nevertheless, studies (e.g., Malloy, Albright, Kenny, Agatstein, & Winquist, 1997) have found that the degree of accuracy depends on the significant other with whom one is interacting. In this research, people were most accurately aware of the perceptions of family members rather than other people such as friends or coworkers.

Many investigations have provided support for the second postulate, namely the relationship between individuals’ self-appraisals and the reflected appraisals of various significant others (see for reviews, Harter, 1998; Schrauger & Schoeneman, 1979). In the sport and physical activity domain, some studies have revealed a correspondence between the reflected appraisals of parents and the physical self-appraisals of children and adolescents (e.g., Babkes & Weiss, 1999; Brustad, 1993, 1996; Kimiecik, Horn, & Shurin, 1996). Two recent studies by Amorose (2002, 2003) found that athletes’ self-appraisals of competence could be predicted by the reflected appraisals of mothers, fathers, coaches, and teammates.

Very few studies have attempted to test the third postulate of the theory, namely that reflected appraisals mediate the influence of another person’s actual appraisal on the individual’s self-appraisal. Support for the two first postulates is, by itself, not sufficient to prove the mediation effect of the reflected appraisal process (Shrauger & Schoeneman,
It is also necessary to demonstrate the existence of a relationship between the actual appraisals of others and individuals' own self-appraisals as well as a diminishment or a disappearance of the strength of this relationship when reflected appraisals are controlled for (see Baron & Kenny, 1986).

A number of studies have examined the relationship between the actual appraisals of others and individuals' self-appraisals (see for a review, Eccles et al., 1998; Shrauger & Schoeneman, 1979). The majority of these studies have found significant relationships between the two, although the magnitude of the relationship tends to be moderate. Studies have found that children's self-appraisals are linked to their parents' appraisals of the child's capacity in both academic (e.g., Frome & Eccles, 1998; Parsons et al., 1982; Phillips, 1987) and sport (e.g., Bois, Sarrazin, Brustad, Trouilloud, & Cury, in press, 2002; Dempsey, Kimiecik, & Horn, 1993; Felson & Reed, 1986; Jacobs & Eccles, 1992) domains. For example, using structural equation modeling on a sample of third through fifth grade children, Bois et al. (2002) demonstrated that mothers' appraisals of her child's sport competence predicted the child's self-appraisal of sport competence one year later controlling for both the child's initial self-appraisal and their actual physical performance.

Nevertheless, none of these studies mentioned has directly tested whether such influences occur through a process of internalization of reflected appraisals.

Few studies have specifically tested if actual appraisals have an effect on self-appraisals when reflected appraisals are controlled for. Three studies carried out with adults have supported the mediating role of the reflected appraisal on several self-attributes (Ichiyama, 1993; Jussim, Soffin, Brown, Ley, & Kohlhepp, 1992; Swann, Milton, & Polzer, 2000). Only one study to our knowledge has been conducted with children (Felson, 1989) and this study did not support the mediation hypothesis. More precisely, using a sample of fourth through seventh grade children and longitudinal data, Felson
Reflected appraisal process

investigated the role of reflected appraisals in mediating the influence of parents’
appraisals on children’s self-appraisals in relation to children’s self-evaluations in the
academic and athletic domains as well as to their self-evaluations of appearance and
popularity over a one-year period. Findings revealed that the reflected appraisals of
mothers and fathers were very similar, and could be combined into a single variable
representing the reflected appraisals of “parents.” The main findings were consistent
across the four domains and indicated that parents’ actual appraisals affected both reflected
appraisals and children’s self-appraisals and that reflected appraisals had substantial effects
on self-appraisals, after controlling for the self-perceptions of children one year earlier.
However, the magnitude of the effect of parents’ appraisals on children’s self-appraisals
was not significantly reduced after controlling for the reflected appraisals. This finding,
which casts doubt on a basic component of the reflected appraisal process, deserves further
examination.

The present study

The purpose of this study was to examine the reflected appraisal process as it
applies to the influence of parents on sixth graders’ self-appraisals of sport competence.
For a number of reasons it is generally assumed that parents have a substantial influence on
their children’s self-appraisals in school (e.g., Eccles et al., 1998; Jacobs & Eccles, 1992)
and sport (e.g., Brustad et al., 2001; Greendorfer, 1992). First, parents are typically
responsible for providing children with their initial opportunities to play sport and parents
are integrally involved in the youth sport experience (Brustad et al, 2001; Greendorfer,
1992). Second, parental feedback is highly salient to youngsters during childhood and the
early adolescent years. Research indicates that youngsters are likely to use adult sources of
feedback in assessing their competence in various achievement domains throughout
childhood and into early adolescence (Frieze & Bar-Tal, 1980; Horn & Weiss, 1991). As
Reflected appraisal process

children enter adolescence, they also tend to become increasingly reliant on peer sources of feedback about their competence (e.g., Horn & Weiss, 1991). However, parental appraisals still have influence through adolescence, particularly in the sport domain, because parents are likely to be extensively involved in their children’s sport experiences at this age in terms of transporting children, attending games and practices, coaching teams, etc. In contrast to other achievement domains, such as academics, parents have extensive opportunities to convey competence information in the sport and physical activity domain and thus should remain an important significant other. Socialization research to date has focused upon how parents may influence children’s self-appraisals but minimal attention has been devoted to understanding the role of reflected appraisals in contributing to children’s self-appraisals in the physical domain.

To date, only one study has completely tested the reflected appraisal process by assessing the three elements of the model simultaneously (Felson, 1989) and the findings from this study did not support the mediation hypothesis. The present study was designed to examine these relationships more thoroughly and special attention was devoted to methodological concerns because previous studies suffer from limitations identified by Felson (1989, 1993). A major problem with most previous work is that investigations have relied on data collected at a single point in time, making directional interpretation problematic. For example, the correlation between actual appraisal of a significant other and the reflected appraisal or self-appraisal can be the result of an influence of the first on the second (i.e., the first postulate of the reflected appraisal process) as much as it could be through the reverse influence. In this regard, a child who has a high self-appraisal of their sport ability can carry out superior sport performance likely to convince other people that he/she is good at sport.
Similarly, if the correlation between reflected appraisals and self-appraisals is in accordance with the reflected appraisal postulates, one could not rule out the alternative interpretation that self-appraisals “cause” reflected appraisals. Individuals may project their own self-perceptions onto others, especially if there is insufficient information to know how others view them. This alternative explanation has been named a “false consensus effect” (e.g., Felson, 1993; Ross, Greene, & Hoise, 1977), or “projection effect” (e.g., Jussim et al., 1992). To overcome these alternative explanations, longitudinal designs including auto-regressive influence are particularly useful (Felson, 1993; MacCallum & Austin, 2000).

In addition, an omitted variable, such as the individual’s performance level, could produce spurious relationships between self-appraisals, reflected appraisals, and the appraisals of significant others. It may be that successful people evaluate themselves more favorably, believe that others evaluate them more favorably, and are actually evaluated by others more favorably. For example, more highly skilled young athletes may believe that they are athletically able and that others think they are good, and others may logically think they are gifted. Thus, if one variable predicts the other ones (for example, if the others’ actual appraisals predict others’ reflected appraisal and/or individual’s self-appraisal) it is perhaps for reasons of a shared standard. For this reason, as recommended by Felson (1993), it is necessary to control for objective measures of ability (like grades or standardized test scores) when one is examining the reflected appraisal process with correlational data.

The main hypothesis of this study was that parents’ appraisals of their child’s sport competence would predict the child’s self-appraisals indirectly, as mediated by the reflected appraisal. To test for this mediation hypothesis, three models were compared (see Figure 1) in order to thoroughly examine the three requirements for mediation defined by
Baron and Kenny (1986). The first model reflected by Figure 1 represents a fully mediated (FM) model in which it is hypothesized that parents’ appraisals affect reflected appraisals (i.e., Path A) that, in turn, influence children’s self-appraisals (i.e., Path B) after controlling for children initial self-appraisals and actual level of ability (as assessed by child’s grades in sport and physical education). The second model represents a partially mediated (PM) model in which an additional path was added to the FM model between the parents’ appraisals of their child’s competence and the child’s physical self-appraisals (i.e., Path C).

Finally, Model 3 represents an unmediated (NM) model in which parents’ appraisals directly predict children’s self-appraisal when paths A and B have been deleted. The PM and NM models allow for examination of the third requirement for the mediation effect, namely “when Paths A and B are controlled, a previously significant relation between the independent and dependent variables is no longer significant” (Baron & Kenny, 1986, p. 1176). The NM model allows us to see if Path C is significant, and the PM model allows us to see if this path is reduced, or is near zero, when Paths A and B have been controlled.

We tested these models using a three wave longitudinal design over one school year, in order to allow for a more sensitive test of our specific directional hypotheses. We also used more sophisticated data analytic techniques, specifically structural equation modeling (SEM), than those which have typically been used in previous studies. SEM allows for the examination of hypothesized relations among all of the constructs involved in a model, using a latent representation of those constructs that is less vulnerable to measurement errors such as those that can be encountered in research with child populations (see MacCallum & Austin, 2000). It might be that the lack of support for the mediation hypothesis found in Felson’s study (1989) was attributable to measurement limitations, to the extent that each variable was only assessed with a single item.
A related focus of this study addresses possible gender differences in the functioning of the reflected appraisal process. Some researchers (e.g., Eccles, Wigfield, Harold, & Blumenfeld, 1993) have found that mothers have a stronger impact than fathers on children's behavior, beliefs, and attitudes. Other authors (e.g., Bussey & Bandura, 1999) have suggested that a parent's influence may be stronger for a child of the same gender in that sons might be more sensitive to what their fathers think of them and daughters might be more sensitive to what their mothers think of them. Therefore, it is possible that the RA process is different for sons compared to daughters. Thus, a related objective of this study was to test the invariance of the reflected appraisal process across gender.

Method

Participants

A sample of 147 sixth graders (73 boys and 74 girls) enrolled in two different French schools, their mothers ($M_{age} = 40.34 \pm 4.61$ years) and fathers ($M_{age} = 42.99 \pm 6.12$ years) were the participants in this study. The child participants ranged in age from 10 to 13 years old ($M_{age} = 11.73 \pm 0.58$ years). The schools were located in a medium size city (100,000 inhabitants) in the southeast of France. The participant sample was comprised primarily of middle to upper class families.

Procedure

Parents and children completed a consent form prior to participating in the study. Data were obtained from questionnaires in three waves during one school year. The first wave (in September 2001) was collected from parents and children. In the second (February 2002) and third (in June 2002) waves, we only collected data from children. Data were collected during the PE class by a Master's degree student familiar with the precautions needed for data collection. Children completed questionnaires in groups of
Reflected appraisal process

about 10 individuals in the classroom. After completion of the first-wave questionnaire, children whose parents agreed to participate were given a questionnaire to complete and were asked to return them a week later. Conditions (i.e. groups and location) for completing the questionnaire in Wave 1, 2 and 3 were the same for the children.

Measures

Child's perceived physical competence. Child’s self-appraisals of competence in physical activity were assessed in Wave 1 and Wave 3 with a 3-item questionnaire, similar to the one developed by Nicholls and colleagues (e.g., Duda & Nicholls, 1992). Participants were asked to answer questions such as “when you are playing sport and physical activity, you consider yourself…” on 7-point scales anchored by “very bad” (1) and “very good” (7). This scale has demonstrated good construct validity, internal consistency and predictive validity in previous studies (e.g., Sarrazin, Roberts, Cury, Biddle, & Famose, 2002; Trouilloud, Sarrazin, Martinek, & Guillet, 2002).

Parents’ appraisals of their child’s physical competence. During Wave 1, mothers and fathers completed a French version of the Jacobs and Eccles’ (1992) questionnaire on parents’ appraisals of their child’s competence. The back-translation method (see Brislin, 1986) was used to translate the original scale into French. This 3-item scale is comprised of questions such as “In general how good is your child in sports?” Each item was rated on a scale from 1 = “not at all good” through 7 = “very good.” In previous research, this scale has been found to be valid and reliable (e.g., Bois et al., 2002).

Reflected appraisal of parents. Children’s reflected appraisal of parents was assessed distinctly for mothers and fathers at Wave 2, with a six-item questionnaire similar to the one developed by Amorose (e.g., 2002). Specifically, three items for each parent tapped the extent to which children thought that their mother and their father considered them physically competent. The items were designed to match the ones used in assessing
parents’ appraisals of their child’s competence (e.g., “How good does your mother/father think you are at sports”). The child responded according to a 7-point scale with higher scores reflecting more positive reflected appraisals.

Child’s physical education grade. In France, all students from the sixth through the twelfth grades take mandatory sport and physical education classes. Each student is graded at the end of each term on a scale ranging from 0 to 20. We collected the teacher’s evaluation of the participating students for the first term (i.e., from September to December, before the assessment of Wave 2 variables).

Data Analysis

Preliminary data analyses and descriptive statistics were performed before testing the hypotheses. First, a confirmatory factor analysis (CFA) was conducted to examine the construct validity of the variables in the study. Then, SEM was used to test relations among the variables as hypothesized in the three models of Figure 1. To investigate the issue of mediation, the requirements advocated by Baron and Kenny (1986) were carefully examined. A chi-square difference test between the PM and FM models was carried out to see whether the global fit is improved by including the path C. If this were the case, the chi-square difference between the two models should be significant and would mean that the mediation of the reflected appraisal is not complete. Subsequently, multi-sample analysis was used to assess the invariance of the model across gender of the child.

Results

Descriptive Statistics and Preliminary Analyses

Results from descriptive statistics of all indices under study revealed that the data were normally distributed with values for skewness and kurtosis within an acceptable range of –1.0 to +1.0. Seven participants (less than 5% of the sample) did not provide
complete responses to questionnaires and their responses were not included in the data analysis.

Table 1 presents the Cronbach alphas reflecting internal reliability of the scales as well as the means and standard deviations of the variables included in the study. A MANOVA was conducted to investigate possible gender differences on variables of interest. Results revealed a marginally significant main effect, Wilks' lambda = .92, $R(6, 140) = 2.06, p = .062$. Follow-up univariate ANOVAS indicated only two gender differences in that boys had higher scores than girls on self-appraisal at Time 1 ($F(1, 145) = 9.21, p < .01, \eta^2 = .06$) and at Time 3 ($F(1, 145) = 5.31, p < .05; \eta^2 = .04$, see group means in Table 1). To test whether parents' appraisals of their child's competence varied as a function of their own or their child's gender, a $2 \times 2$ analysis of variance was conducted, with repeated measures on the last variable. Neither main effects nor significant interactions were present in this analysis.

Measurement Model

To examine the construct validity of the measures included in the study, a confirmatory factor analysis was conducted. On the first step of this analysis a model based on six latent constructs (i.e., child perceived competence at Wave 1 and Wave 3, mothers' appraisals, fathers' appraisals, reflected appraisals of mother and father) and 18 observed variables (individual items from each questionnaire) was tested. The analysis was conducted with LISREL 8.3 (Jöreskog & Sörbom, 1996) using a covariance matrix and maximum likelihood method of estimation. In view of the current controversy regarding measures of overall goodness of fit, it is generally considered appropriate to report multiple indices of fit (Bollen, 1989). Thus, the chi-square statistic, the non-normed fit index (NNFI), the comparative fit index (CFI) and the standardized root mean square residual (SRMR) all were used to evaluate the adequacy of the fit of the model to the data. For the
NNFI and CFI, values above .90 are considered satisfactory. For SRMR, values below .10 indicate a good fit of the model to the data.

This first model presented a poor fit to the data: $\chi^2(120, N = 147) = 364.34, p < .001$, NNFI = .72, CFI = .78, SRMR = .08. Analysis of the output revealed large residuals between the three indicators of mothers’ and fathers’ reflected appraisals. As the questions for reflected appraisals of mothers and fathers were the same (only the word “mother” or “father” differed) some children may have answered the same way for mothers and fathers on this variable. Hence we decided to add three covariance errors between the three indicators of mothers’ reflected appraisals and the three indicators of fathers’ reflected appraisal. This modification resulted in a significant improvement of the fit of the model: $\chi^2(117, N = 147) = 185.08, p < .001$, NNFI = .94, CFI = .96, SRMR = .05. The correlations between all the variables were low to moderate except for the correlation between mothers’ and fathers’ appraisals of their child’s competence ($r = .79$) on one hand and between reflected appraisals of mothers and fathers ($r = .99$) on the other hand. Therefore, we decided to test the discriminant validity of these constructs. We examined whether each of those two pairs of latent factors could be treated as a single construct by setting each correlation to 1.0 and comparing the constrained model to the original one in which the correlation was free to be estimated (see Anderson & Gerbing, 1988). This test was performed separately for each pair of latent construct. Chi-square difference tests indicated that the models with the correlation set to 1.0 were not different from the model freely estimated ($p < .10$). Therefore mothers’ and fathers’ appraisals of their child’s ability on one hand, and the child’s reflected appraisals of mothers and fathers on the other hand were combined to form two factors (in place of four) based on six observed variables each. The first term was labeled “parents’ appraisals of their child’s perceived competence” and the second was labeled “reflected appraisals of parents.” The new four-
factor model presented an adequate fit to the data: $\chi^2(126, N = 147) = 222.7, p < .001$, NNFI = .93, CFI = .94, SRMR = .05 and was used in the subsequent analyses. The construct reliability of the four factors were $\rho = .82, .87, .84, .82$, respectively for children's self-appraisals at Wave 1, parents' perceptions of their child competence, parents' reflected appraisal and children's self-appraisals at Wave 3.

Comparison of Structural Models

Since the validity of the factor structure was confirmed, the hypothesized relationships between the four latent variables and the child's grade (considered as a manifest variable) were estimated and the three proposed models (see Figure 1) were tested.

The FM model presented an adequate fit to the data: $\chi^2(141, N = 147) = 229.25, p < .001$, NNFI = .93, CFI = .95, SRMR = .05. The structural and measurement coefficients of this model are presented in Figure 2. Parents' appraisals significantly predicted reflected appraisals ($\gamma = .52, p < .001$) independent of the effects of children's initial self-appraisals ($\gamma = .17, p > .05$) and grades ($\gamma = .05, p > .05$). In turn, reflected appraisals affected children self-appraisals at Time 3 ($\beta = .44, p < .001$), independent of children initial self-appraisals ($\gamma = .39, p < .001$) and grades ($\gamma = .12, p > .05$). This model accounted for 59 percent of the variance of the child's self-appraisals at Time 3.

PM model presented an adequate fit to the data: $\chi^2(140, N = 147) = 229.24, p < .001$, NNFI = .93, CFI = .94, SRMR = .05. Nevertheless, the effect of parents' appraisals on child's self-appraisals at Time 3 (i.e., Path C) was nonsignificant ($\gamma = .01, p > .05$). This model account for 59 percent of the variance of the child's self-appraisals at Time 3. The comparison between the PM and FM models suggested that the addition of the Path C did not significantly improve the fit [$\Delta \chi^2(1) = .01, p > .05$], hence the simplest model (i.e., the FM model) should be preferred.
The NM model presented a poorer, albeit adequate, fit to the data: $\chi^2(141, N = 147) = 244.06, p < .001$, NNFI = .92, CFI = .94, SRMR = .064. Parents’ appraisals significantly predicted their child’s self-appraisals at Time 3 ($\gamma = .26, p < .05$) independent of the effects of children’s initial self-appraisals ($\gamma = .47, p < .001$) and grades ($\gamma = .12, p > .05$).

This model accounted for 50 percent of the variance of the child’s self-appraisals at Time 3.

Inspection of the relevant parameters indicated that the three criteria for mediation listed by Baron and Kenny (1986) were fully achieved: (1) parents’ appraisals significantly influenced reflected appraisals (i.e., Path A; $\gamma = .52, p < .001$); (2) reflected appraisals of parents significantly predicted the child’s final self-appraisals (i.e., Path B; $\gamma = .44, p < .001$); and (3) the direct path from parents’ appraisals to child’s self-appraisals (i.e., Path C) was nonsignificant when Paths A and B were controlled for ($\gamma = .01, p > .05$, in the PM model), whereas this path was significant ($\gamma = .26, p < .05$) when the Paths A and B were removed (in the NM model).

**Multigroup analyses**

A multi-group analysis was conducted to test invariance of the FM model across gender. This involved testing to determine if setting the parameters to be equal across gender produced a significant change in chi-square compared to the free-constraint model. The free-constraint model represents a model in which parameters of the boys’ and girls’ models are evaluated without any between-group constraints. The results demonstrated that constraining the parameters did not significantly decrease the fit of the model [$A\chi^2(6) = 8.73, p > .05$], which suggests that the processes involved in the model appear to be similar across gender.

**Discussion**
Reflected appraisal process

The goal of this study was to examine the role of the reflected appraisal process between parents and sixth graders in the ontogeny of children's self-appraisals of physical competence. Reflected appraisals may constitute an important dimension of the sport and physical activity socialization process and a primary purpose of this study was to extend the current knowledge base on sport socialization influence by systematically evaluating the role of reflected appraisals on children's self-appraisal of sport competence.

Preliminary findings and issues dealing with the validity of our model will be discussed before addressing the question of the reflected appraisal process per se.

Preliminary Findings

Preliminary analyses revealed marginally significant gender differences, with boys having greater perceived competence than girls, both at Wave 1 and at Wave 3. Those findings are consistent with numerous previous studies (e.g., Bois et al., in press, 2002; Dempsey et al., 1993; Eccles & Harold, 1991), which have found that boys tend to be more confident in their physical abilities than are girls. On the other hand, parents' appraisals of their child's competence did not vary in relation to the child's gender. This finding is consistent with some recent studies (e.g., Bois et al., in press, 2002; Kimiecik & Horn, 1998) but not with some others (e.g., Eccles, Jacobs, & Harold, 1990; Jacobs & Eccles, 1992) which have found a differentiation in parents' expectancies in relation to the child's gender.

A confirmatory factor analysis indicated that mothers' and fathers' appraisals of their child's competence were strongly related. Although some authors (e.g., Brustad et al., 2001) have argued that the two parents might not share similar appraisals of their child's ability, we are not aware of studies that have found substantial parental differences in ability appraisals. It was also found through the CFA that the reflected appraisals of parents were not appreciably different between mothers and fathers. This finding suggests
that children of this age do not distinguish between their mother's and their father's
appraisals of them. This finding is in accordance with other studies (Amorose, 2003;
Felson, 1989) that have found that children were more influenced by a generalized other
(e.g., parents or sport others) than by a distinctly perceived significant other. However this
finding was not surprising given that mothers' and fathers' ability perceptions were not
highly differentiated. Hence, children in this sample may not distinguish between mothers'
and fathers' evaluations of their competence because those appraisals are not actually
different. These findings considered together seem to be consistent with the hypothesis
from symbolic interactionist theory (Felson, 1993; Mead, 1934) that individuals have a
better idea of how they are viewed by collective others than how they are viewed by
individual others alone.

Reflected Appraisal Process

The main hypothesis of this study was that reflected appraisals mediate the effect of
parents' appraisals on children's self-appraisals of physical competence. According to
Baron and Kenny (1986), providing support for this mediation effect required: (1) a link
between parents' appraisals and reflected appraisals; (2) a link between reflected appraisals
and children's self-appraisals; (3) a significant decrease in the path between parents'
appraisals and children self-appraisals after the first two links had been controlled.

In relation to the first point it was hypothesized that parents' appraisals would have
positive effects on the child's reflected appraisals of parents, controlling for actual level of
ability in sport as well as prior level of self-appraisals. The effect of initial level of self-
appraisals on later reflected appraisals is called the projection effect (e.g., Jussim et al.,
1992) or "false consensus effect" (e.g., Felson, 1993; Ross et al., 1977) and refers to the
processes whereby individuals can base their reflected appraisals from others on their own
self-views rather than on what others think of them (e.g., Jussim et al., 1992; Tice &
Reflecting appraisal process

Walla, 2003). In other words, people's inferences on how they are appraised by others may be based on their self-views rather than on an accurate understanding of how others actually see them especially if there is insufficient information to know how others view them.

Our results (see Figure 2) lend support to an effect of parents' appraisals on children's reflected appraisal ($\gamma = .52, p < .001$) and don't provide evidence for the projection effect ($\gamma = .17, p > .05$). The significant influence of parents' appraisals on children's reflected appraisals indicates that children are rather accurate in perceiving their parents' appraisals. This finding is controversial to the extent that it does not support most of the recent work in this line of research that has found that people are not very accurate in identifying what significant others think of them (Felson, 1993; Shrauger & Schoeneman, 1979; Ice & Wallace, 2003). But how can one explain that the youngsters in this study were more accurate than participants in previous studies in identifying significant others' appraisals of their abilities? Two explanations can be provided. First, we investigated the accuracy of the appraisal between children and parents. Some investigators (Malloy et al., 1997) have found that people are more accurate in guessing how they are viewed by family members than by other people (i.e. friends or coworkers). Moreover, as children in our sample are relatively young they are likely to be more attuned to their parents' judgments than to other significant others, such as peers. Hence the close relationship between parents and children at this age may explain those results.

However, it can also be emphasized that the methodology used in this study with data collected at three points in time combined with structural equation modeling may contribute to the explanation of these results. In particular, the fact that measurement error is partly controlled for by SEM may have provided a more thorough test of the hypotheses in this study than in previous studies. This sort of methodology (i.e. combining SEM and
longitudinal data) had not been used in the previously cited studies. Hence the difference in
the pattern of results might arise from this analytical strategy. In comparison to previous
studies, our results demonstrated a relatively high accuracy of reflected appraisals, in
contrast to what has been found in the past (Felson, 1993; Tice & Wallace, 2003) but has
casts doubt on the presence of the projection effect. Further longitudinal studies are
needed to disentangle the relationships among those variables.

The second point hypothesized that the reflected appraisals of parents would have
positive effects on children’s self-appraisals, independent of the child’s initial self-
appraisals and the child’s actual level of ability in sport. The results support this
hypothesis. The fact that reflected appraisals and self-appraisals are significantly related is
acknowledged in the literature (e.g. Babkes & Weiss, 1999; Felson, 1993). However our
results show only a moderate relationship between reflected appraisals and self-appraisals.
Hence, even though children are rather accurate in perceiving what their parents think of
them, they don’t completely base their self-views on these perceptions. It is likely that
numerous significant others, such as peers, coaches or teammates are involved in this
process as has been hypothesized by Amorose (2003). Further studies that extend the
number of significant others investigated are needed to get a better understanding of the
role of social influences in the development of children’s self-appraisals.

It was also proposed that the magnitude of the influence of parents’ appraisals on
children’s self-appraisals would be reduced when reflected appraisals had been controlled
for. The results supported this expectation. In the NM model, the path from parents’
appraisals to children’s self-appraisals was significant ($\gamma = .26, p < .05$) although it was
nonsignificant in the PM model ($\gamma = .01, p > .05$) where the influence of reflected
appraisals on self-appraisals was controlled for and significant ($\beta = .43, p < .01$). Subsequent analyses led us to prefer the FM model (see Figure 2) which was more
parsimonious and powerful in terms of variance explained in the dependent variable. To our knowledge, this study is the first conducted in a natural setting that fully demonstrates the three hypothesized steps in the reflected appraisal process. Previous studies either only partially tested this process (e.g., Amorose, 2002, 2003), or failed to demonstrate the mediation effect (e.g., Felson, 1989). The fact that our results are not consistent with Felson’s study is intriguing. However, two methodological points might explain those discrepancies. First, all of the constructs involved in Felson’s study (1989) were assessed using only a single item. This could have caused some measurement difficulties. Second, the sample used in the Felson study (1989) covered a broader age range (fourth through seventh grade children) than our sample of sixth grade children. We are aware that as children get older they become increasingly able to use others’ appraisals to estimate their physical competence (e.g., Horn & Amorose, 1998). Therefore, the mediational process identified in our study might have been masked in Felson’s study because younger and older children were included in the same sample.

We also investigated the invariance of the reflected appraisal process across gender. The goal of this analysis was to test whether parental influence through the reflected appraisal process could vary as a function of the child’s gender. The multigroup analysis revealed no significant differences in the model between boys and girls. This seems to indicate that the process does not differ between boys and girls. However, other individual difference factors such as age or level of involvement in sport may influence the reflected appraisal process and could constitute a new area of investigation.

Special attention was dedicated to the methodology used in this study; however some limitations have to be acknowledged. First, although we used a longitudinal design to enhance directional inferences that can be drawn from our data, the findings remain correlational in nature and therefore must be interpreted cautiously. Due to the use of a
longitudinal design we can be sure that the variables assessed at the start of the year were
not caused by the ones assessed ten months later, but it is always possible that an omitted
variable is the origin of a link found between a predictor variable and an outcome variable.
Nevertheless, including the variables of the child’s physical education grade and the
child’s initial level of perceived competence limits the likelihood that this occurred.
Secondly, the use of grades as an indication of the child’s actual physical ability may
constitute another limitation of the study. As emphasized by Jussim (1991), marks can be
biased by the teacher’s beliefs or a priori opinion. Furthermore, the fact that grades are
often specific to a limited range of physical activities may reflect that they do not entirely
capture the overall physical competence of the child. These two points can explain why
grades did not predict reflected appraisals and self-appraisals. However using grades as an
objective indicator of ability also enhanced the quality of the study as it enabled us to
control for, to some extent, the actual physical ability of the child. A third limitation of the
study pertains to the independence of mothers’ and fathers’ responses. As no specific
mechanism was used to ensure that each parent completed his/her questionnaire
independently from the other, it is possible that some of the parents completed the
questionnaires together.
In sum, this study has demonstrated a link between parents’ appraisals and the
reflected appraisals of ability in the sport domain held by their children. Secondly, a link
was found between reflected appraisals and self-appraisals that is consistent with symbolic
interactionist perspectives (Cooley, 1902; Mead, 1934) and certain empirical studies
(Amorose, 2002, 2003; Babkes & Weiss, 1999). This result cannot be explained by a
projection effect, a concurrent hypothesis to the reflected appraisal process that has been
mentioned by some authors (e.g. Felson, 1989, 1993; Tice & Wallace, 2003), since the
projection effect was controlled for. Finally, this study supports the mediation of parents’
appraisal effects on child’s self-appraisals by reflected appraisals although this relation has
not been previously supported (Felson, 1989).

From a pragmatic view, these results emphasize the importance of the interpretation
that children can make about their parents’ beliefs and behaviors and helps to further the
knowledge base on parental socialization effects in the physical domain. Parents should be
aware not only of what they do and say to their children, but also of the way children
understand, perceive and interpret those beliefs and behaviors as it affects their subsequent
motivation. In terms of positive outcomes, parents may promote positive reflected
appraisals and self-appraisals, positive expectancies, and encouragement and thus
contribute to their children’s successful involvement in physical activity and sport.

Footnotes

1. We used alternatively the terms “sport” or “physical activity”, because in France the two
have a very similar meaning and designate all forms of exercise and leisure-time physical
activity.

2. The covariance matrix used for this analysis is available upon request to the second
author.

3. Reliability estimates for the total scales are obtained by (Bollen, 1989): \( \rho = \frac{(\sum \lambda_i)^2}{(\sum \lambda_i)^2 + \sum \delta_{ii}} \) where \( \lambda_i \) are the factor loading and \( \delta_{ii} \) the error variances.

4. Omission of the three error covariance between measurement error of indicators of
reflected appraisal resulted in a poorer fit of the model: \( \chi^2 (129, N = 147) = 425.24, p < .001, \text{NNFI} = .71, \text{CFI} = .76, \text{SRMR} = .09, \Delta \chi^2 (df= 3) = 202.5, p < .001 \). To the extent that
the same person (i.e. the child) answers to questions where only the word “father” or
“mother” change, the error covariance has to be seen as method variance due to the
similarity of the items.

5. Omission of the three insignificant paths did not significantly alter the fit of this model:
\( \chi^2 (144, N = 147) = 231.92, p < .001, \text{NNFI} = .93, \text{CFI} = .94, \text{SRMR} = .06. \)
