HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Regularization of $\Gamma_1$-structures in dimension 3

FRANÇOIS LAUDENBACH AND GAËL MEIGNIEZ

Abstract. For $\Gamma_1$-structures on 3-manifolds, we give a very simple proof of Thurston’s regularization theorem, first proved in [13], without using Mather’s homology equivalence. Moreover, in the co-orientable case, the resulting foliation can be chosen of a precise kind, namely an “open book foliation modified by suspension”. There is also a model in the non co-orientable case.

1. Introduction

A $\Gamma_1$-structure $\xi$, in the sense of A. Haefliger, on a manifold $M$ is given by a line bundle $\nu = (E \to M)$, called the normal bundle to $\xi$, and a germ of codimension-one foliation $\mathcal{F}$ along the zero section, which is required to be transverse to the fibers (see [8]). To fix ideas, consider the co-orientable case, that is, the normal bundle is trivial: $E \cong M \times \mathbb{R}$; for the general case see section 6. The $\Gamma_1$-structure $\xi$ is said to be regular when the foliation $\mathcal{F}$ is transverse to the zero section, in which case the pullback of $\mathcal{F}$ to $M$ is a genuine foliation on $M$. A homotopy of $\xi$ is defined as a $\Gamma_1$-structure on $M \times [0,1]$ inducing $\xi$ on $M \times \{0\}$. A regularization theorem should claim that any $\Gamma_1$-structure is homotopic to a regular one. It is not true in general. An obvious necessary condition is that $\nu$ must embed into the tangent bundle $\tau M$. When $\nu$ is trivial and $\dim M = 3$ this condition is fulfilled.

The $C^\infty$ category is understood in the sequel, unless otherwise specified. In particular $M$ is $C^\infty$. One calls $\xi$ a $\Gamma_r$-structure ($r \geq 1$) if it is tangentially $C^\infty$ and transversely $C^r$, that is, the foliation charts are $C^r$ in the direction transverse to the leaves. We will prove the following theorem.

Theorem 1.1. If $M$ is a closed 3-manifold and $\xi$ a $\Gamma_r$-structure, $r \geq 1$, whose normal bundle is trivial, then $\xi$ is homotopic to a regular $\Gamma_1$-structure.

Moreover, the resulting foliation of $M$ may have its tangent plane field in a prescribed homotopy class (see proposition 6.1).

This theorem is a particular case of a general regularization theorem due to W. Thurston (see [13]). Thurston’s proof was based on the deep result due to J. Mather [9], [10]: the homology equivalence between the classifying space of the group $\text{Diff}^c(\mathbb{R})$ endowed with the discrete topology and the loop space $\Omega B(\Gamma_1)_+$. We present a proof of this regularization theorem which does not need this result. A regularization theorem in all dimensions, still avoiding any difficult result, is provided in [14]. But there are reasons for considering the dimension 3 separately.

FL supported by ANR Floer Power.
Our proof provides models realizing each homotopy class of $\Gamma_1$-structure. The models are based on the notion of open book decomposition. Recall that such a structure on $M$ consists of a link $B$ in $M$, called the binding, and a fibration $p : M \setminus B \to S^1$ such that, for every $\theta \in S^1$, $p^{-1}(\theta)$ is the interior of an embedded surface, called the page $P_\theta$, whose boundary is the binding. The existence of open book decomposition could be proved by J. Alexander when $M$ is orientable, as a consequence of [1] (every orientable closed 3-manifold is a branched cover of the 3-sphere) and [2] (every link can be braided); but he was ignoring this concept which was introduced by H. Winkelnkemper in 1973 [16]. Henceforth, we refer to the more flexible construction by E. Giroux, which includes the non-orientable case (see section 3). An open book gives rise to a foliation $O$ constructed as follows. The pages endow $B$ with a normal framing. So a tubular neighborhood $T$ of $B$ is trivialized: $T \cong B \times D^2$. Out of $T$ the leaves are the pages modified by spiraling around $T$; the boundary of $T$ is a union of compact leaves; and the interior of $T$ is foliated by a Reeb component, or a generalized Reeb component in the sense of Wood [17]. For technical reasons in the homotopy argument of section 4, the Reeb components of $O$, instead of being usual Reeb components, will be thick Reeb components in which a neighborhood of the boundary is foliated by toric compact leaves. We call such a foliation an open book foliation.

The latter can be modified by inserting a so called suspension foliation. Precisely, let $\Sigma$ be a compact sub-surface of some leaf of $O$ out of $T$ and $\Sigma \times [-1, +1]$ be a foliated neighborhood of it (each $\Sigma \times \{t\}$ being contained in a leaf of $O$). Let $\varphi : \pi_1(\Sigma) \to \text{Diff}_c([-1, +1])$ be some representation into the group of compactly supported diffeomorphisms; $\varphi$ is assumed to be trivial on the peripheral elements. It allows us to construct a suspension foliation $F_\varphi$ on $\Sigma \times [-1, +1]$, whose leaves are transverse to the vertical segments $\{x\} \times [-1, +1]$ and whose holonomy is $\varphi$. The modification consists of removing $O$ from the interior of $\Sigma \times [-1, +1]$ and replacing it by $F_\varphi$. The new foliation, denoted $O_\varphi$, is an open book foliation modified by suspension. Theorem 1.1 can now be made more precise:

**Theorem 1.2.** Every co-orientable $\Gamma_r^1$-structure, $r \geq 1$, is homotopic to an open book foliation modified by suspension.

The proof of this theorem is given in sections 2 - 4 when $r \geq 2$. In section 5, we explain how to get the less regular case $1 \leq r < 2$. We have chosen to treat the case $r = 1 + bv$ (the holonomy local diffeomorphisms are $C^1$ and their first derivatives have a bounded variation). Indeed, Mather observed in [11] that $\text{Diff}^{1+bv}_c(\mathbb{R})$ is not a perfect group and it is often believed that the perfectness of $\text{Diff}^r_c(\mathbb{R})$ plays a role in the regularization theorem.

In section 6 the homotopy class of the tangent plane field will be discussed. Finally the case of non co-orientable $\Gamma_r^1$-structure will be sketched in section 7 where the corresponding models, based on twisted open book, will be presented.

We are very grateful to Vincent Colin, Étienne Ghys and Emmanuel Giroux for their comments, suggestions and explanations.

2. Tsuboi’s construction

A $\Gamma_1$-structure $\xi$ on $M$ is said to be trivial on a codimension 0 submanifold $W$ when, for every $|t|$ small enough, $W \times \{t\}$ lies in a leaf of the associated foliation.
Every closed 3-manifold \( M \) has a so-called *Heegaard decomposition* \( M = H_- \cup H_+ \), where \( H_\pm \) is a possibly non-orientable handlebody (a ball with handles of index 1 attached) and \( \Sigma \) is their common boundary. A *thick Heegaard decomposition* is a similar decomposition where the surface is thickened:

\[
M = H'_- \cup_{\Sigma \times \{1\}} \Sigma \times [-1,1] \cup_{\Sigma \times \{+1\}} H'_+
\]

The following statement is due to T. Tsuboi in \cite{14} where it is left to the reader as an exercise.

**Proposition 2.1.** Given a \( \Gamma_1 \)-structure \( \xi \) of class \( C^r \), \( r \geq 2 \), on a closed 3-manifold \( M \), there exists a thick Heegaard decomposition and a homotopy \((\xi_t)_{t \in [0,1]}\) from \( \xi \) such that:

1) \( \xi_1 \) is trivial on \( H'_\pm \);
2) \( \xi_1 \) is regular on \( \Sigma \times [-1, +1] \) and the induced foliation is a suspension.

**Proof.** With \( \xi \) and its foliation \( \mathcal{F} \) defined on an open neighborhood of the zero section \( M \times 0 \) in \( M \times \mathbb{R} \), there comes a covering of the zero section by boxes, open in \( M \times \mathbb{R} \), bi-foliated with respect to \( \mathcal{F} \) and the fibers. We choose a \( C^1 \)-triangulation \( Tr \) of \( M \) so fine that each simplex lies entirely in a box. With \( Tr \) comes a vector field \( X \) defined as follows.

First, on the standard \( k \)-simplex there is a smooth vector field \( X_{\Delta^k} \), tangent to each face, which is the (descending) gradient of a Morse function having one critical point of index \( k \) at the barycenter and one critical point of index \( i \) at the barycenter of each \( i \)-face. When \( \Delta^i \subset \Delta^k \) is an \( i \)-face, \( X_{\Delta^i} \) is the restriction of \( X_{\Delta^k} \) to \( \Delta^i \). Now, if \( \sigma \) is a \( k \)-simplex of \( Tr \), thought of as a \( C^1 \)-embedding \( \sigma : \Delta^k \to M \), we define \( X_\sigma := \sigma_*(X_{\Delta^k}) \). The union of the \( X_\sigma \)'s is a \( C^0 \) vector field \( X \) which is uniquely integrable. After a reparametrization of each simplex we may assume that the stable manifold \( W^s(b(\sigma)) \) of the barycenter \( b(\sigma) \) is \( C^1 \).

The \( \Gamma_1 \)-structure \( \xi \) (co-oriented by the \( \mathbb{R} \) factor of \( M \times \mathbb{R} \)) is said to be in *Morse position* with respect to \( Tr \) if:

(i) it has a smooth Morse type singularity of index \( k \) at the barycenter of each \( k \)-simplex and it is regular elsewhere;
(ii) \( X \) is (negatively) transverse to \( \xi \) out of the singularities.

**Lemma 2.2.** Let \( \mathcal{F} \) be the foliation associated to \( \xi \). There exists a smooth section \( s \) such that \( s^* \mathcal{F} \) is in Morse position with respect to \( Tr \).

Note that, as \( s \) is homotopic to the zero section, the \( \Gamma_1 \)-structure \( s^* \mathcal{F} \) on \( M \) is homotopic to \( \xi \).

**Proof.** Assume that \( s \) is already built near the \((k-1)\)-skeleton. Let \( \sigma \) be a \( k \)-simplex. We explain how to extend \( s \) on a neighborhood of \( \sigma \). After a fibered isotopy of \( M \times \mathbb{R} \) over the identity of \( M \), we may assume that \( \mathcal{F} \) is trivial near \( \{b(\sigma)\} \times \mathbb{R} \). Now, near \( b(\sigma) \), we ask \( s \) to coincide with the graph of some local positive Morse function \( f_\sigma \) whose Hessian is negative definite on \( T_{b(\sigma)}\sigma \) and positive definite on \( T_{b(\sigma)}W^s(b(\sigma)) \). This function is now fixed up to a positive constant factor. We will extend \( s \) as the graph of some function \( h \) in the \( \mathcal{F} \)-foliated chart over a neighborhood of \( \sigma \). This function is already given on a neighborhood \( N(\partial \sigma) \) of \( \partial \sigma \) where it is \( C^\gamma \), the regularity of \( \xi \), and satisfies \( X_\sigma h < 0 \) except at the barycenter of each face.

On the one hand, choose an arbitrary extension \( h_0 \) of \( h \) to a neighborhood of \( \sigma \) vanishing near \( b(\sigma) \). On the other hand, choose a nonnegative function \( g_\sigma \) such that:
- \( g_\sigma = 0 \) near \( \partial \sigma \);
- \( g_\sigma = f_\sigma \) near \( b(\sigma) \);
- \( X.g_\sigma < 0 \) when \( g_\sigma > 0 \) except at \( b(\sigma) \).

Then, if \( c > 0 \) is a large enough constant, \( h := h_0 + cg_\sigma \) has the required properties, except smoothness. Returning to \( M \times \mathbb{R} \), the section \( s \) we have built is \( C^r \), smooth near the singularities, and \( X \) is transverse to \( s^*\xi \) except at the singularities. Therefore, there exists a smooth \( C^r \)-approximation of \( s \), relative to a neighborhood of the barycenters which meets all the required properties.

Thus, by a deformation of the zero section which induces a homotopy of \( \xi \), we have put \( \xi \) in \emph{Morse position} with respect to \( Tr \). In the same way, applying lemma 2.2 to the trivial \( \Gamma_1 \)-structure \( \xi_0 \), we also have a Morse function \( f \) such that \( X.f < 0 \) except at the barycenters.

Let \( G_- \) (resp. \( G_+ \)) denote the closure of the union of the unstable (resp. stable) manifolds of the singularities of \( X \) of index 1 (resp. 2). The following properties are clear:

(a) In \( M \), the subset \( G_- \) (resp. \( G_+ \)) is a \( C^1 \)-complex of dimension 1.
(b) It admits arbitrarily small handlebody neighborhoods \( H_- \) (resp. \( H_+ \)) whose boundary is transverse to \( X \).
(c) Every orbit of \( X \) outside \( H^+_\pm \) has one end point on \( \partial H^+ \) and the other on \( \partial H^- \). This also holds true for any smooth \( C^0 \)-approximation \( \tilde{X} \) of \( X \) (in particular \( \tilde{X} \) is still negatively transverse to \( \xi \)).

Given a (co-orientable) \( \Gamma_1 \)-structure \( \xi \) on a space \( G \), by an \emph{upper} (resp. \emph{lower}) \emph{completion} of \( \xi \) one means a foliation \( \mathcal{F} \) of \( G \times (-\epsilon, 1) \) (resp. \( G \times [-1, \epsilon) \)), for some positive \( \epsilon \), which is transverse to every fiber \( \{x\} \times (-\epsilon, 1) \) (resp. \( \{x\} \times [-1, \epsilon) \)), whose germ along \( G \times \{0\} \) is \( \xi \), and such that \( G \times \{t\} \) is a leaf of \( \mathcal{F} \) for every \( t \) close enough to \( +1 \) (resp. \(-1 \).

**Lemma 2.3.** Every co-orientable \( \Gamma_1 \)-structure on a simplicial complex \( G \) of dimension 1, \( r \geq 2 \), admits an upper (resp. lower) completion of class \( C^r \).

**Proof.** One reduces immediately to the case where \( G \) is a single edge. In that case, using a partition of unity, one builds a line field which fulfills the claim. This line field is integrable.

By (a), the \( \Gamma_1 \)-structure \( \xi \) admits an upper (resp. lower) completion over \( G_+ \) (resp. \( G_- \)), and thus also over an open neighborhood \( N_+ \) (resp. \( N_- \)) of \( G_+ \) (resp. \( G_- \)). By (b), there is a handlebody neighborhood \( H^\pm_\pm \) of \( G_\pm \), contained in \( N_\pm \) and whose boundary is transverse to \( X \).

So we have a foliation \( \mathcal{F} \) defined on a neighborhood of

\[
(M \times \{0\}) \cup (H^\pm_- \times [-1, 0]) \cup (H^\pm_+ \times [0, 1])
\]

which is transverse to \( X \) on \( M \setminus (H^\pm_- \cup H^\pm_+) \) and tangent to \( H^\pm_\pm \times \{t\} \) for every \( t \) close to \( \pm 1 \).

By (c), there is a diffeomorphism \( F : M \setminus Int(H^\pm_- \cup H^\pm_+) \to \Sigma \times [-1, +1] \) for some closed surface \( \Sigma \), which maps orbit segments of \( \tilde{X} \) onto fibers.

For a small \( \epsilon > 0 \), choose a function \( \psi : \mathbb{R} \to [-1, +1] \) which is smooth, odd, and such that:

- \( \psi(t) = 0 \) for \( 0 \leq t \leq 1 - 3\epsilon \) and \( \psi(1 - 2\epsilon) = \epsilon \);
- \( \psi \) is affine on the interval \( [1 - 2\epsilon, 1 - \epsilon] \).
- \( \psi(1 - \epsilon) = 1 - \epsilon \) and \( \psi(t) = 1 \) for \( t \geq 1 \);
- \( \psi' > 0 \) on the interval \( ]1 - 3\epsilon, 1[ \).

Let \( s : M \to M \times \mathbb{R} \) be the graph of the function whose value is \( \pm 1 \) on \( H'_2 \) and \( \psi(t) \) at the point \( F^{-1}(x, t) \) for \( (x, t) \in \Sigma \times [-1, +1] \). When \( \epsilon \) is small enough, it is easily checked that, for every \( x \in \Sigma \), the path \( t \mapsto s \circ F^{-1}(x, t) \) is transverse to \( F \) except at its end points. Then, \( \xi_1 := s^*F \) is homotopic to \( \xi \) and obviously fulfills the conditions required in proposition 2.1. \( \square \)

3. Giroux’s construction

We use here theorem III.2.7 from Giroux’s article [3], which states the following:

Let \( M \) be a closed 3-manifold (orientable or not). There exist a Morse function \( f : M \to \mathbb{R} \) and a co-orientable surface \( S \) which is \( f \)-essential in \( M \).

Giroux says that \( S \) is \( f \)-essential when the restriction \( f|S \) has exactly the same critical points as \( f \) and the same local extrema. In the sequel, we call such a surface a Giroux surface.

Giroux explained to us [3] how this notion is related to open book decompositions. In the above statement, the function \( f \) can be easily chosen self-indexing (the value of a critical point is its Morse index in \( M \)). Thus, let \( N \) be the level set \( f^{-1}(3/2) \). The smooth curve \( B := N \cap S \) will be the binding of the open book decomposition we are looking for. It can be proved that the following holds for every regular value \( a \), \( 0 < a \leq 3/2 \):

- the level set \( f^{-1}(a) \) is the union along their common boundaries of two surfaces, \( N_1^a \)
  and \( N_2^a \), each one being diffeomorphic to the sub-level surface \( S^a := S \cap f^{-1}(0, a) \);
- the sub-level \( M^a := f^{-1}(0, a] \) is divided by \( S^a \) into two parts \( P_1^a \)
  and \( P_2^a \) which are isomorphic handlebodies (with corners);
- \( S^a \) is isotopic to \( N_1^a \) through \( P_i^a \), for \( i = 1, 2 \), by an isotopy fixing its boundary curve \( S^a \cap f^{-1}(a) \).

This claim is obvious when \( a \) is small and the property is preserved when crossing the critical level 1. In this way the handlebody \( H_- := f^{-1}([0, 3/2]) \) is divided by \( S^{3/2} \) into two diffeomorphic parts \( P_i^{3/2} \), \( i = 1, 2 \), and we have \( N = N_1^{3/2} \cup N_2^{3/2} \). We take \( S^{3/2} \), which is isotopic to \( N_i^{3/2} \) in \( P_i^{3/2} \), as a page. The figure is the same in \( H_+ := f^{-1}([3/2, 3]) \). The open book decomposition is now clear.

**Proposition 3.1.** Let \( K \subset M \) be a compact connected co-orientable surface whose boundary is not empty. Then there exists an open book decomposition whose some page contains \( K \) in its interior.

**Proof.** (Giroux) According to the above discussion it is sufficient to find a Morse function \( f \) and a Giroux surface \( S \) (with respect to \( f \)) containing \( K \). Let \( H_0 \) be the quotient of \( K \times [-1, 1] \) by shrinking to a point each interval \( \{x\} \times [-1, 1] \) when \( x \in \partial K \times [-1, 1] \). After smoothing, it is a handlebody whose boundary is the double of \( K \). On \( H_0 \) there exists a standard Morse function \( f_0 \) which is constant on \( \partial H_0 \), having one minimum, the other critical points being of index 1. The surface \( K \times \{0\} \) can be made \( f_0 \)-essential. This function is then extended to a
global Morse function \( \hat{f}_0 \) on \( M \). At this point we have to follow the proof of Theorem III.2.7 in [13]. The function \( \hat{f}_0 \) is changed on the complement of \( H_0 \), step by step when crossing its critical level, so that \( K \times \{0\} \) extends as a Giroux surface in \( M \). \hfill \square

Let now \( \xi \) be a \( \Gamma_1 \)-structure meeting the conclusion of proposition 2.1, up to rescaling the interval to \( [−\epsilon, +\epsilon] \). Let \( \mathcal{F}_\varphi \) be the suspension foliation induced by \( \xi \) on \( \Sigma \times [−\epsilon, +\epsilon] \). Choose \( x_0 \in \Sigma \times \{0\} \); the segment \( x_0 \times [−\epsilon, +\epsilon] \) is transverse to \( \mathcal{F}_\varphi \). Let \( K \) be the surface obtained from \( \Sigma \times 0 \) by removing a small open disk centered at \( x_0 \). The foliation \( \mathcal{F}_\varphi \) foliates \( K \times [−\epsilon, +\epsilon] \) so that \( K \times \{t\} \) lies in a leaf, when \( t \) is close to \( ±\epsilon \), and \( \partial K \times [−\epsilon, +\epsilon] \) is foliated by parallel circles. We apply proposition 3.1 to this \( K \).

**Corollary 3.2.** There exists an open book foliation \( \mathcal{O} \) of \( M \) inducing the trivial foliation on \( K \times [−\epsilon, +\epsilon] \) (the leaves are \( K \times \{t\} \), \( t \in [−\epsilon, +\epsilon] \)).

Therefore, we have an open book foliation modified by suspension by replacing the above trivial foliation of \( K \times [−\epsilon, +\epsilon] \) by \( \bar{\mathcal{F}}_\varphi \), the trace of \( \mathcal{F}_\varphi \) on \( K \times [−\epsilon, +\epsilon] \). Let \( \mathcal{O}_\varphi \) be the resulting foliation of \( M \) and \( \xi_\varphi \) be its regular \( \Gamma_1 \)-structure. For proving theorem 1.2 (when \( r \geq 2 \)) it is sufficient to prove that \( \xi \) and \( \xi_\varphi \) are homotopic. This is done in the next section.

## 4. Homotopy of \( \Gamma_1 \)-Structures

We are going to describe a homotopy from \( \xi_\varphi \) to \( \xi \). Recall the tube \( T \) around the binding. For simplicity, we assume that each component of \( T \) is foliated by a standard Reeb foliation; the same holds true if \( T \) is foliated by Wood components (in the sense of [4]). Let \( T' \) be a slightly larger tube.

**Lemma 4.1.** There exists a homotopy, relative to \( M \setminus \text{int}(T') \), from \( \xi_\varphi \) to a new \( \Gamma_1 \)-structure \( \xi_1 \) on \( M \) such that:

1) \( \xi_1 \) is trivial on \( T \);
2) \( \xi_1 \) is regular on \( T' \setminus \text{int}(T) \) with compact toric leaves near \( \partial T \) and spiraling half-cylinder leaves with boundary in \( \partial T' \) (as in an open book foliation).

**Proof.** Recall from the introduction that we only use *thick* Reeb components. So there is a third concentric tube \( T'' \), \( T \subset \text{int}(T'') \subset \text{int}(T') \), so that \( T'' \setminus \text{int}(T) \) is foliated by toric leaves; and \( \text{int}(T) \) is foliated by planes.

On each component of \( \partial T \) we have coordinates \((x, y)\) coming from the framing of the binding, the \( x \)-axis being a parallel and the \( y \)-axis being a meridian. Let \( \gamma \) be a parallel in \( \partial T \). The \( \Gamma_1 \)-structure which is induced by \( \xi_\varphi \) on \( \gamma \) is singular but not trivial and the germ of foliation \( \mathcal{G} \) along the zero section in the normal line bundle \( A \cong \gamma \times \mathbb{R} \) is shown on figure 1.

The annulus \( A \) is endowed with coordinates \((x, z) \in \gamma \times \mathbb{R} \). The orientation of the \( z \)-axis, which is also the orientation of the normal bundle to the foliation \( \mathcal{O}_\varphi \) along \( \gamma \), points to the interior of \( T \). So the leaves of \( \mathcal{G} \) are parallel circles in \( \{z \leq 0\} \) and spiraling leaves in \( \{z > 0\} \). Take coordinates \((x, y, r)\) on \( T \) where \( r \) is the distance to the binding; say that \( r = 1 \) on \( \partial T'' \) and \( r = 1/2 \) on \( \partial T \). Let \( \lambda(r^2) \) be an even smooth function with \( r = 0 \) as unique critical point, vanishing at \( r = 1/2 \) and \( \lambda(1) < 0 < \lambda(0) \). Consider \( g : T'' \to A \), \( g(x, y, r) = (x, \lambda(r^2)) \).
It is easily seen that $\xi_\varphi|\text{int}(T'') \cong g^* G$. Let now $\bar{\lambda}(r^2)$ be a new even function coinciding with $\lambda(r^2)$ near $r = 1$, having negative values everywhere and whose critical set is $\{r \in [0, 1/2]\}$. Let $\bar{g} : T'' \to A$, $\bar{g}(x, y, r) = (x, \bar{\lambda}(r^2))$. A barycentric combination of $\lambda$ and $\bar{\lambda}$ yields a homotopy from $g$ to $\bar{g}$ which is relative to a neighborhood of $\partial T''$. The $\Gamma_1$-structure $\xi_1$ we are looking for is defined by $\xi_1|\text{int}(T'') = \bar{g}^*(G)$ and $\xi_1 = \xi_\varphi$ on a neighborhood of $M \smallsetminus \text{int}(T'')$. \hfill \Box

Recall the domain $K \times [-\varepsilon, +\varepsilon]$ from the previous section. After the following lemma we are done with the homotopy problem.

**Lemma 4.2.** There exits a homotopy from $\xi_1$ to $\xi$ relative to $K \times [-\varepsilon, +\varepsilon]$.

**Proof.** Let us denote $M' := M \smallsetminus \text{int}(K \times [-\varepsilon, +\varepsilon])$ which is a manifold with boundary and corners. It is equivalent to prove that the restrictions of $\xi_1$ and $\xi$ to $M'$ are homotopic relatively to $\partial M'$. Consider the standard closed 2-disk $D = D^2$ endowed with the $\Gamma_1$-structure $\xi_D$ which is shown on figure 2.
It is trivial on the small disk $d$ and regular on the annulus $D \setminus \text{int}(d)$. In the regular part, the leaves are circles near $\partial d$ and the other leaves are spiraling, crossing $\partial D$ transversely. One checks that the restriction of $\xi$ to $M'$ has the form $f^*\xi_D$ from some map $f : M' \to D$. We take $f[T : T \to d]$ to be the open book trivialization of $T$ (recall the binding has a canonical framing); $f|\partial K \times [-\varepsilon, +\varepsilon]$ to be the projection $pr_2$ onto $[-\varepsilon, +\varepsilon]$ composed with an embedding $i : [-\varepsilon, +\varepsilon] \to \partial D$ and $f$ maps each leaf of the regular part of $\xi_1$ to a leaf of the regular part of $\xi_D$. As $K$ does not approach $T$, we can take $f(\partial M') = i([-\varepsilon, +\varepsilon])$; actually, except near $T$, $f$ is given by the fibration over $S^1 = \partial D^2$ of the open book decomposition.

Once $\xi$ has Tsuibo’s form (according to proposition 2.1), the restriction of $\xi$ to $M'$ has a similar form: $\xi = k^*\xi_D$ for some map $k : M' \to D^2$. Recall that $M'$ is the union of two handlebodies and a solid cylinder $D^2 \times [-\varepsilon, +\varepsilon]$. Take $k$ to be $i \circ pr_3$ on the cylinder and $k$ to be constant on each handlebody. Observe that $f$ and $k$ coincide on $\partial M'$. As $D$ retracts by deformation onto the image of $i$, one deduces that $f$ and $k$ are homotopic relatively to $\partial M'$. □

This finishes the proof of theorem 1.2 when $r \geq 2$.

5. The case $C^{1+bv}$

A co-oriented $\Gamma^r$-structure $\xi$ on $M$ can be realized by a foliation $\mathcal{F}$ defined on a neighborhood of the 0-section in $M \times \mathbb{R}$; it is made of bi-foliated charts which are $C^\infty$ in the direction of the leaves and $C^r$ in the direction of the fibers. Consider such a box $\mathcal{U}$ over an open disk $D$ centered at $x_0 \in M$; its trace on the $x_0$-fiber is an interval $I$. Each leaf of $\mathcal{U}$ reads $z = f(x, t)$, $x \in D$, for some $t \in I$. Here $f$ is a function which is smooth in $x$ and $C^r$ in $t$, with $f(x_0, t) = t$; the foliating property is equivalent to $\frac{\partial f}{\partial t} > 0$. When $r = 1 + bv$, there is a positive measure $\mu(x, t)$ on $I$, without atoms and depending smoothly on $x$, such that:

\[
\frac{\partial}{\partial t} f(x, t) - \frac{\partial}{\partial t} f(x, t_0) = \int_{t_0}^t \mu(x, t).
\]

Proposition 5.1. Theorem 1.2 holds true for any class of regularity $r \geq 1$ including the class $r = 1 + bv$.

Proof. The only part of the proof which requires some care of regularity is section 2. Indeed, we have to avoid integrating $C^0$ vector fields. For proving lemma 2.3 with weak regularity we use the lemmas below which we shall prove in the case $r = 1 + bv$ only.

Lemma 5.2. Let $f : D \times I \to \mathbb{R}$ be a $C^r$-function as above. Assume $I = [-2\varepsilon, +\varepsilon]$ and $f(x, -2\varepsilon) > -1$ for every $x \in D$. Then there exists a function $F : D \times [-1, 0] \to \mathbb{R}$ of class $C^r$ such that:

1) $F(x, t) = f(x, t)$ when $t \in [-\varepsilon, 0]$,
2) $F(x, t) = t$ when $t$ is close to $-1$,
3) $\frac{\partial F}{\partial t} > 0$. 
Proof. Let $\mu(x,t)$ be the positive measure whose support is $[-\varepsilon, 0]$ such that formula $(\ast)$ holds for every $(x,t) \in D \times [-\varepsilon, 0]$ and $t_0 = 0$. There exists another positive measure $\nu(x,t)$, smooth in $x$ and whose support is contained in $]-1, -\varepsilon]$, such that

\[
(\ast\ast) \quad f(x,-\varepsilon) = -1 + \int_{-1}^{-\varepsilon} \left( \int_{-1}^{t} \nu(x,\tau) \right) dt.
\]

Then a solution is

\[
F(x,t) = -1 + \int_{-1}^{t} \left( \int_{-1}^{s} (\mu(x,\tau) + \nu(x,\tau)) \right) ds.
\]

Lemma 5.3. Let $A_1$ and $A_2$ two disjoint closed sub-disks of $D$. Let $F_1$ and $F_2$ be two solutions of lemma 5.2. Then there exists a third solution which equals $F_1$ when $x \in A_1$ and $F_2$ when $x \in A_2$.

Proof. Both solutions $F_1$ and $F_2$ differ by the choice of the measure $\nu(x,t)$ in formula $(\ast\ast)$, which is $\nu_i$ for $F_i$. Choose a partition of unity $1 = \lambda_1(x) + \lambda_2(x)$ with $\lambda_i = 1$ on $A_i$. Then $\nu(x,t) = \lambda_1(x)\nu_1(x,t) + \lambda_2(x)\nu_2(x,t)$ yields the desired solution.

The proof of proposition 6.1 is now easy. As already said, it is sufficient to prove lemma 6.3 in class $C^r$, $r \geq 1$. It is an extension problem of a foliation given near the 1-skeleton $T^r[1] \times \{0\}$ to $T^r[1] \times [-1, 0]$. One covers $T^r[1]$ by finitely many $n$-disks $D_j$. The problem is solved in each $D_j \times [-1, 0]$ by applying lemma 6.2. By applying lemma 6.3 one makes the different extensions match together.

6. Homotopy class of plane fields

It is possible to enhance theorem 1.1 by prescribing the homotopy class of the underlying co-oriented plane field (see proposition 6.1 below). The question of doing the same with respect to theorem 1.2 is more subtle (see proposition 6.3).

Proposition 6.1. Given a co-oriented $\Gamma_1$-structure $\xi$ on the closed 3-manifold $M$ and a homotopy class $[\nu]$ of co-oriented plane field in the tangent space $\tau M$, there exists a regular $\Gamma_1$-structure $\xi_{\text{reg}}$ homotopic to $\xi$ whose underlying foliation $\mathcal{F}_{\text{reg}} \cap M$ has a tangent co-oriented plane field in the class $[\nu]$.

Before proving it we first recall some well-known facts on co-oriented plane fields (see [4]). Given a base plane field $\nu_0$, a suitable Thom-Pontryagin construction yields a natural bijection between the set of homotopy classes of plane fields on $M$ and $\Omega^\nu_1(M)$, the group of (co)bordism classes of $\nu_0$-framed and oriented closed (maybe non-connected) curves in $M$. A $\nu_0$-framing of the curve $\gamma$ is an isomorphism of fiber bundles $\varepsilon : \nu(\gamma, M) \rightarrow \nu_0|\gamma$, whose source is the normal bundle to $\gamma$ in $M$. We denote $\gamma^\varepsilon$ the curve endowed with this framing. Moreover, given $\gamma^\varepsilon$, if $\gamma'$ is homologous to $\gamma$ in $M$ there exists a $\nu_0$-framing $\varepsilon'$ such that $(\gamma ')^{\varepsilon'}$ is cobordant to $\gamma^\varepsilon$. 
Proof of 6.1. We can start with an open book foliation $O_\varphi$ yielded by theorem 1.2. Let $\nu_0$ be its tangent plane field. Near the binding, the meridian loops (out of $T$) are transverse to $O_\varphi$ and homotopic to zero in $M$. As a consequence, each 1-homology class may be represented as well by a (multi)-curve in a page or by a connected curve out of $T$ positively transverse to all pages. We do the second choice for $\gamma^\varepsilon$, the $\nu_0$-framed curve whose cobordism class encodes $[\nu]$ with respect to $\nu_0$.

Hence we are allowed to turbulize $O_\varphi$ along $\gamma$. In a small tube $T(\gamma)$ about $\gamma$, we put a Wood component. Outside, the leaves are spiraling around $\partial T(\gamma)$. Let $O_{\varphi}\text{turb}$ be the resulting foliation. Whatever the chosen type of Wood component is, the $\Gamma_1$-structures of $O_{\varphi}\text{turb}$ and $O_\varphi$ are homotopic by arguing as in section 4. But the framing $\varepsilon$ tells us which sort of Wood component will be convenient for getting the desired class $[\nu]$ (see lemma 6.1 in [17]). □

In the previous statement, we have lost the nice model we found in theorem 1.2. Actually, thanks to a lemma of Vincent Colin [3], it is possible to recover our model, at least when $M$ is orientable (see below proposition 6.3).

Lemma 6.2. (Colin) Let $(B, p)$ be an open book decomposition of $M$ and $\gamma$ be a simple connected curve in some page $P$. Assume $\gamma$ is orientation preserving. Then there exist a positive stabilization $(B', p')$ of $(B, p)$ and a curve $\gamma'$ in $B'$ which is isotopic to $\gamma$ in $M$. When $\gamma$ is a multi-curve, the same holds true after a sequence of stabilizations.

The positive Hopf open book decomposition of the 3-sphere is the one whose binding is made of two unknots with linking number $+1$; a page is an annulus foliated by fibers of the Hopf fibration $S^3 \to S^2$. A positive stabilization is a “connected sum” with this open book. The new page $P'$ is obtained from $P$ by plumbing an annulus $A$ whose core bounds a disk in $M$ (see [7] for more details and other references).

Proof. If $\gamma$ is connected, only one stabilization is needed. We are going to explain this case only. A tubular neighborhood of $\gamma$ in $P$ is an annulus.

Choose a simple arc $\alpha$ in $P$ joining $\gamma$ to some component $\beta$ of $B$ without crossing $\gamma$ again. Let $\tilde{\gamma}$ be a simple arc from $\beta$ to itself which follows $\alpha^{-1} \ast \gamma \ast \alpha$. The orientation assumption implies that the surgery of $\beta$ by $\tilde{\gamma}$ in $P$ provides a curve with two connected components, one of them being isotopic to $\gamma$ in $P$. Let $P_\varepsilon$ be the page opposite to $P$ and $R : P \to P_\varepsilon$ the time $\pi$ of a flow transverse to the pages (and stationary on $B$). The core curve $C$ of the annulus $A$ that we use for the plumbing is the union $\tilde{\gamma} \cup R(\tilde{\gamma})$. And $A$ is $(+1)$-twisted around $C$ (with respect to its unknot framing) as in the Hopf open book. Let $H$ be the 1-handle which is the closure of $A \setminus P$. Surgering $B$ by $H$ provides the new binding. By construction, one of its components is isotopic to $\gamma$. □

Proposition 6.3. Let $O_\varphi$ be an open book foliation modified by suspension, whose its underlying open book is denoted $(B, p)$. Let $\nu_0$ be its tangent co-oriented plane field. Let $\gamma^\varepsilon$ be a $\nu_0$-framed curve in $M$ and $[\nu]$ be its associated class of plane field. Assume $\gamma$ is orientation preserving. Then there exists an open book foliation $O_{\varphi}\text{turb}$ with the following properties:

1) its tangent plane field is in the class $[\nu]$;

2) the suspension modification is the same for $O_{\varphi}\text{turb}$ as for $O_\varphi$ and is supported in $K \times [-\varepsilon, +\varepsilon]$;
3) as $\Gamma_1$-structures, $\mathcal{O}_\varphi$ and $\mathcal{O}'_\varphi$ are homotopic.

**Proof.** As said in the proof of 6.1, up to framed cobordism, $\gamma^\varphi$ may be chosen as a simple (multi)-curve in one page $P$ of $(B,p)$. Applying Colin’s lemma provides a stabilization $(B',p')$ such that, up to isotopy, $\gamma$ lies in the new binding. Observe that, if $K$ is in $P$, $K$ is still in the new page $P'$; hence 2) holds for any open book foliation carried by $(B',p')$. Once $\gamma^\varphi$ is in the binding, for a suitable Wood component foliating a tube about $\gamma^\varphi$, item 1) is fulfilled. Finally item 3) follows from item 2) and the proofs in section 4. □

### 7. Case of a $\Gamma_1$-structure with a twisted normal bundle

What happens when the bundle $\nu$ normal to $\xi$ is twisted? It is known that a necessary condition to regularization is the existence of a fibered embedding $i : \nu \to \tau M$ into the tangent fiber bundle to $M$. Conversely, assuming that this condition is fulfilled, we are going to state a normal form theorem analogous to theorem 1.2. Since no step of the previous proof can be immediately adapted to this situation, we believe that it deserves a sketch of proof.

**7.1.** In the first step (Tsuboi’s construction), we do not have “Morse position” with respect to a triangulation, since index and co-index of a singularity cannot be distinguished. Instead of lemma 2.2, we have the following statement.

*After some homotopy, $\xi$ has Morse singularities and admits a pseudo-gradient whose dynamics has no recurrence (that is, every orbit has a finite length).*

Here, by a pseudo-gradient, it is meant a smooth section $X$ of $\text{Hom}(\nu, \tau M)$, a *twisted vector field* indeed, such that $X \cdot \xi < 0$ except at the singularities (this sign is well-defined whatever a local orientation of $\nu$, or co-orientation of $\xi$, is chosen); such a pseudo-gradient always exists by using an auxiliary Riemannian metric.

**Sketch of proof.** Generically $\xi$ has Morse singularities. Let $X_0$ be a first pseudo-gradient, which is required to be the usual negative gradient in Morse coordinates near each singularity. Finitely many mutually disjoint 2-disks of $M$ are chosen in regular leaves of $\xi$ such that every orbit of $X_0$ crosses one of them. Following Wilson’s idea $[13]$, $\xi$ and $X_0$ are changed in a neighborhood $D^2 \times [-1,1]$ of each disk into a *plug* such that every orbit of the modified pseudo-gradient $X$ is trapped by one of the plugs. The plug has the mirror symmetry with respect to $D^2 \times \{0\}$. In $D^2 \times [0,1]$ we just modify $\xi$ by introducing a cancelling pair of singularities, center-saddle. □

Let $G$ be the closure of the one-dimensional invariant manifold of all saddles. It is a graph. We claim: $\nu|G$ is orientable. Indeed, we orient each edge from its saddle end point to its center end point. This is an orientation of $\nu|G$ over the complement of the vertices. It is easily checked that this orientation extends over the vertices. Thus $X$ becomes a usual vector field near $G$ and we have an arbitrarily small tubular neighborhood $H$ of $G$ whose boundary is transverse to $X$, and $X$ enters $H$. Now, the negative completion of $\xi|H$ can be performed as in lemma 2.3.

The complement $\bar{M}$ of $\text{int}H$ in $M$ is fibered over a surface $\Sigma$, the fibers being intervals ($\cong [-1,1]$) tangent to $X$. By taking a section we think of $\Sigma$ as a surface in $M \setminus H$. Since
is not co-orientable, Σ is one-sided and G is connected. Arguing as in section 4, after some homotopy, ξ becomes trivial on H and transverse to X on M, hence a suspension foliation corresponding to a representation ϕ : π1(Σ) → Diffc([−1, 1]).

7.2. In the second step (Giroux’s construction), we have to leave the open books and we need a twisted open book. It is made of the following:

- a binding B which is a 1-dimensional closed co-orientable submanifold in M;
- a Seifert fibration p : M \setminus B → [−1, +1] which has two one-sided exceptional surface fibers p−1(±1) and which is a proper smooth submersion over the open interval;
- when t goes to ±1, p−1(t) tends to a 2-fold covering of p−1(±1);
- near B the foliation looks like an open book.

The exceptional fibers are compactified by B as smooth surfaces with boundary. But, for t ∈ [−1, +1], p−1(t) is compactified by B as a closed surface showing (in general) an angle along B. Notice that, since B is co-orientable, a twisted open book gives rise to a smooth foliation where each component of the binding is replaced by a Reeb component, the pages spiraling around it.

Such an open book is generated by a one-sided Giroux surface, which is the union of the compactified exceptional fibers. Abstractly, a one-sided Giroux surface in M with respect to a Morse function f : M → R is a one-sided surface S such that f|S has the same critical points and the same extrema as f and fulfills the extra condition: for every regular value t ∈ R, f−1(t) ∩ S is a two-sided curve in the level set f−1(t). Starting with (S, f) where f is a self-indexing Morse function, a twisted open book is easily constructed. Its binding is the co-orientable curve f−1(3/2) ∩ S. In general such a one-sided Giroux surface (or twisted open book) does not exist on M; the obstruction lies in the existence of a twisted line subbundle of τM. Nevertheless, with a suitable assumption, we have an analogue of proposition 3.1:

Let i : ν → τM be an embedding of a twisted line bundle. Let K ⊂ M be a compact connected one-sided surface whose boundary is not empty. Assume the following: ν|K is twisted, ν|∂K is trivial and the normal bundle ν(K, M) is homotopic to i(ν)|K. Then there exists a twisted open book with one exceptional page containing K in its interior.

Sketch of proof. We give the proof only in the setting of [4.1] by taking K to be the closure of Σ \ d0 where d0 is a small closed 2-disk in Σ. Recall the fibration ρ : M → Σ. Let H′ be the handlebody made of H to which is glued the 1-handle ρ−1(d0). Let M′ be the complement of int H′. Consider a minimal system of mutually disjoint compression disks d1, ..., dg of H, so that cutting H along them yields a ball; g is the genus of H. Thus d0, d1, ..., dg is a minimal system of mutually disjoint compression disks of H′.

We claim: g + 1 is even. Indeed, by assumption there exists a non vanishing section of the bundle Hom(ν, τM). Thus, the number of zeroes of the pseudo-gradient X is even and the Euler characteristic χ(G) of the graph G is even. As G is connected, the genus g is odd, which proves the claim.

Now, one follows Giroux’s algorithm for completing K to a closed Giroux’s surface. On the surface ∂M′ the union of the attaching curves ∂d0, ∂d1, ..., ∂dg is not separating. Then, after some isotopy, for each i = 0, ..., g, ∂d_i crosses ∂K in exactly two points a_i, b_i linked by an arc α_i.
(resp. $\alpha_i'$) in $\partial d_i$ (resp. $\partial K$), so that $\alpha_i \cup \alpha_i'$ bounds a disk in $\partial M'$. Moreover, one can arrange that all the arcs $\alpha_0, ..., \alpha_g$ are parallel. Also we link $a_i, b_i$ by a simple arc in $d_i$. Now, each compression disk defines, simultaneously, a 1-handle which is glued to $K$ and a 2-handle which is glued to $M'$, yielding a proper surface $K_1$ in some 3-submanifold $M''$ of $M$, whose complement is a ball. The boundary of $K_1$ is made of $g + 2$ parallel curves in the sphere $\partial M''$. As this number is odd, Giroux described a process of adding cancelling pairs of 1- and 2- handles whose effect is to change $K_1$ into $K_2 \subset M''$ such that $\partial K_2$ is made of one curve only ([5], p. 676-677). Hence, $K_2$ can be closed into a Giroux’s surface.

**Theorem 7.3.** Let $\xi$ be a non co-orientable $\Gamma_1$-structure on $M^3$ whose normal bundle $\nu$ embeds into $\tau M$. Then $\xi$ is homotopic to a twisted open book foliation modified by suspension.

**Sketch of proof.** Let $K = \Sigma \setminus \text{int } D^2$ be the surface with a hole, where $\Sigma$ was built in the first step 7.1; it meets the required assumptions for building a twisted open book.

The twisted open book built in the second step gives rise to a foliation $\mathcal{O}$. Indeed, as the binding $B$ is co-orientable, it is allowed to spiral the pages around a tubular neighborhood of $B$. The tube itself is foliated by thick Reeb components. As in the co-orientable case, we can modify the open book foliation in a neighborhood of $K$ using the representation $\varphi$, yielding the foliation $\mathcal{O}_\varphi$ and its associated regular $\Gamma_1$-structure $\xi_\varphi$. We have to prove that $\xi$ and $\xi_\varphi$ are homotopic. We may suppose that $\xi$ is in Tsuboi form (7.1).

We observe that the total space of $\nu$ has a foliation $\mathcal{F}_0$ (unique up to isomorphism) transverse to the fibers, having the zero section as a leaf and whose all non trivial holonomy elements have order 2. It defines the trivial $\Gamma_1$-structure $\xi_0$ in the twisted sense. Using notation of 7.2, one can prove that $\xi|H'$ and $\xi_\varphi|H'$ are both homotopic to $\xi_0|H'$. Moreover, both homotopies coincide on the boundary $\partial H'$ (on $H'$, it is sufficient to think of the case when $\varphi$ is the trivial representation. Thus $\xi|H'$ and $\xi_\varphi|H'$ are homotopic relative to the boundary. □

7.4. Plane field homotopy class. By turbulizing $\mathcal{O}_\varphi$, it it possible to have the normal field in any homotopy class of embeddings $\nu \to \tau M$.

Indeed, a curve in $M$ is homotopic to a curve transverse to $\mathcal{O}_\varphi$ if and only if it does not twist $\nu$. But these homology classes are exactly those which appear as a first difference homology class when comparing two embeddings $j_1, j_2 : \nu \to \tau M$, since a closed curve which twists $\nu$ is not a cycle in $H_1(M, \mathbb{Z}_{\text{or}(\nu)}) \cong H^2(M, \mathbb{Z}_{\text{or}(\nu \otimes \tau M)})$.
