Co-crystallisation of the Et₄N⁺ or *n*-Bu₄N⁺ salts of the thiocyanate anion with *o*-, *m*- and *p*-diiodoperfluorobenzene or the *sym*-trifluorotriiodobenzene allowed for the isolation of six different salts which were structurally characterized by single crystal X-ray diffraction. Halogen bonding interactions are observed between the neutral iodinated molecules acting as halogen bond donors and the S or N ends of the thiocyanate anion, with a variety of bonding modes (terminal as well as bridging), and characterised by short I⋯(N,S) contacts and linear C–I⋯(N,S) motifs. On the other hand, the I⋯N≡C angles present deviations from linearity (145–170°) while the I⋯S–C angles are close to 90°, revealing a type II halogen bond interaction with the S atom acting as pseudo halogen. The observation of structures where only the S or the N atom are engaged in halogen bonding suggests that the two coordination modes are close in energy, as confirmed by DFT calculations and ELF analysis which give also a rationale for the observed structural preferences. This bidentate nature of the SCN[−] anion in halogen bonding interactions is reminiscent of its various coordination modes with the Cd²⁺ cation, best understood in terms of the hard–soft acid–base concept.

Introduction

Halogen bonding in the solid state, albeit known for many years,¹ is currently the subject of an intense research effort.² It describes a directional, attractive interaction between covalently bound halogen atoms and Lewis bases and exhibit many similarities with hydrogen bonding,³ with which it can even successfully compete.⁴ The electrostatic contributions to this interaction result from the anisotropic charge distribution around the halogen, with a positive potential that develops at the halogen in the region *trans* to the C–X bond,^{5,6} a region which then plays a role similar to the hydrogen atom in hydrogen bonding. The effects are strongest with the heaviest, most polarisable halogens (Br, I) and are further enhanced when electron-withdrawing groups are attached to the carbon atom. This directional interaction thus appears as an efficient tool for supramolecular chemistry and crystal engineering, and has been extensively developed in the last ten years by Resnati and Metrangolo,^{7,8} who used iodoperfluorocarbon molecules as halogen bond donors, facing them with a broad range of organic Lewis bases.⁹ Other efficient halogen bond acceptors were found in metal complexes with terminal ligands such as halide, oxo or nitrido groups but also carbonyl or cyanide ones, as recently reviewed by Brammer.¹⁰ In many cases, the investigated interactions involved neutral donor and acceptor molecules. Since the halogen bond interaction is essentially of electrostatic origin, one

can easily anticipate that charge assistance in salts might strongly increase its strength, provided that the positive charge is on the halogen bond donor moiety, the negative charge on the halogen bond acceptor moiety.¹¹ Such electrostatic effects have been clearly evidenced (i) in pyridinium salts with the halogen atom on the pyridine ring acting as halogen bond donor,^{12,13} (ii) in cation radical salts of halogenated tetrathiafulvalenes with the halogen atom interacting with the counter ion such as halides,¹⁴ polyhalides (I₃[−], IBr₂[−], ...), halometallates or cyanometallates such as [Ag(CN)₂][−] or [Ni(CN)₄]^{2−}.¹⁵ In these situations, extremely short intermolecular distances between the halogen atom and the Lewis base were indeed observed, confirming also the strong electrostatic contribution to the interaction.

The intermediate situation where the halogen bond donor molecule is neutral while the halogen bond acceptor is anionic has been also investigated and iodinated conjugated molecules such as diiodoacetylene, tetraiodoethylene, perfluoro mono or di-iodobenzene have been shown^{16,17} to form extended networks when associated with halide anions (Cl[−], Br[−], I[−]). Similar structures were also reported with the *sym*-trifluoro-triiodobenzene.^{18,19} This topic of anion coordination and anion-templated assembly under halogen bonding control has been very recently reviewed.²⁰ A beautiful extension of this work was reported by Metrangolo and Resnati with neutral ditopic molecules capable of simultaneous binding of both the anion (through halogen bonding) and the cation (with a crown ether moiety) of simple salts.²¹ Non-conjugated iodoperfluoroalkanes also proved to be very efficient²² as exo-receptors for naked anions while CBr₄ was successfully engaged with dibromocuprate salts.²³ In most cases, the halide anion is able to halogen-bond to several donor molecules (up to four) simultaneously, affording polymeric networks with various connectivities and dimensionalities.^{7,20} Such polymeric anionic networks were also included by Yamamoto and Kato in electro-crystallization experiments with non-halogenated tetrathiafulvalenium salts to afford ternary

systems incorporating the partially oxidized donor molecules, and the anionic networks comprised of halide anions halogen bonded to neutral iodinated molecules.^{24,25}

Most examples described so far of such halogen interactions with this *neutral donor/anionic acceptor* scheme concerned simple halide anions. ¹⁹F NMR investigations²² of the upfield shift shown by the $-\text{CF}_2\text{I}$ signal of 1,2-diiodotetrafluoroethane ($\text{I}-\text{CF}_2\text{CF}_2-\text{I}$) upon addition of a three-fold excess of various anions (I^- , Br^- , Cl^- , NO_3^- , SCN^- , CN^-) showed that the strongest effect of halogen bonding were indeed observed with the most polarisable I^- anion while the SCN^- anion appeared as a much weaker halogen bond acceptor, within the series $\text{I}^- > \text{Br}^- > \text{Cl}^- > \text{CN}^- > \text{SCN}^- > \text{NO}_3^-$. The ability of the thiocyanate anion to interact with halogen bond donors in the solid state was however recently demonstrated by Bock and Holl, who described its halogen bonding interaction with neutral donor molecules bearing four iodine atoms, that is tetraiodoethylene,²⁶ tetraiodothiophene²⁷ and N-methyltetraiodopyrrole²⁸ (Scheme 1). Analyses of the three crystal structures revealed for the SCN^- anion a bitopic character, with both the nitrogen and the sulfur atoms engaged in halogen bonding interaction with these poly-iodo conjugated molecules. On the other hand, Kochi reported that the crystallization of $n\text{Bu}_4\text{NSCN}$ with CBr_4 affords a 1:1 complex where CBr_4 is halogen bonded only to the sulfur atom while the nitrogen atom is “free”.²⁹ As an element of comparison, hydrogen bonded systems to the SCN^- anion were shown by Guru Row *et al.* to involve both the nitrogen and the sulfur atoms in its ammonium salts.³⁰

The SCN^- salts mentioned above exhibit several remarkable peculiarities, that is (i) unexpected strong deviations from linearity for the $\text{C}\equiv\text{N}\cdots\text{I}$ angles, (ii) presence of several iodine atoms “coordinating” the sulfur one and (iii) acute ($91\text{--}100^\circ$) $\text{C}-\text{S}\cdots\text{I}$ angles. In our recent investigations of the halogen bonding interaction of halide anions (Cl^- , Br^-) with the 1,3,5-trifluoro-2,4,6-triiodobenzene,¹⁸ a detailed topological analysis of the electron localization function^{31,32} (ELF) had shown a perfect match between the organic iodine valence shell electrons, with a “belt”-shape arrangement around the $\text{C}-\text{I}$ axis, and the spherical halide anions (Cl^- , Br^-). We wanted to apply the same theoretical analysis on the thiocyanate anion as halogen bond acceptor in order to possibly rationalise the actual geometries found in the solid state. As halogen bond donors, besides the examples shown in Scheme 1^{26–28} or molecules like CBr_4 ,²⁹ other iodo-aromatics activated with fluorine atoms such as *o*-, *m*- or *p*-diodoperfluorobenzene or the *sym*-trifluorotriiodobenzene^{18,19,33} (Scheme 2) have proven very efficient halogen bond donors, towards pyridines, amines as well as halide anions. They have been faced here with the SCN^- anion, in order to expand the available library of thiocyanate salts engaged in halogen bonding in the hope to observe some recurrent geometrical trends in association with activated iodine atoms.

Scheme 1

Scheme 2

We describe here six novel thiocyanate salts, as Et_4N^+ or $n\text{-Bu}_4\text{N}^+$ salts, with these perfluoroiodobenzene derivatives, and analyse their solid state characteristics, with an emphasis on the halogen bond patterns they adopt, while a rationale is provided by a detailed topological analysis of the electron localization function (ELF).³⁴

Results and discussion

Crystal growth and structure analysis

Either the Et_4N^+ or the $n\text{-Bu}_4\text{N}^+$ thiocyanate salts were mixed in a 1:1 ratio with either the *o*-, *m*- or *p*-diodoperfluorobenzene or the *sym*-trifluorotriiodobenzene (Scheme 2). Concentration and cooling of the solutions afforded crystalline material (Table 1) in six out of the eight investigated systems, since $n\text{-Bu}_4\text{NSCN}$ with *o*- and *m*-diodoperfluorobenzene did not afford in our hands any crystalline material but oils. The actual stoichiometry of the salts was deduced from elemental analyses and single-crystal X-ray diffraction experiments. They exhibit different stoichiometries (Table 1) despite a starting 1:1 composition. They will be described in the following according to the structural motifs they develop in the solid state.

The thiocyanate anion as a bidentate anion in 3b, 4a and 4b

Salt **3b** adopts a 1:1 stoichiometry and is formulated as $(n\text{-Bu}_4\text{NSCN})(p\text{-C}_6\text{F}_4\text{I}_2)$. It crystallises in the monoclinic system, space group $P2_1/n$, with the anion, the cation and the neutral $p\text{-C}_6\text{F}_4\text{I}_2$ molecule in general position in the unit cell. Molecules of $p\text{-C}_6\text{F}_4\text{I}_2$ are separated from each other by the bulky tetra-butylammonium groups and the shortest intermolecular $\text{I}\cdots\text{I}$ contacts exceed 4.7 \AA . On the other hand, they are associated into chains running along *b* (Fig. 1), through coordination of both the nitrogen and the sulfur atoms of the SCN^- anion.

The structural characteristics of these two halogen bonding interactions are collected in Table 2 and point to strong interactions as the $\text{I}\cdots\text{N}$ and $\text{I}\cdots\text{S}$ intermolecular distances are particularly short when compared with the sum of the van der Waals radii ($\text{I}\cdots\text{N}$: 3.68 \AA , $\text{I}\cdots\text{S}$: 3.72 \AA) or with the sum of the

Fig. 1 A view of the chains formed by the ditopic p -C₆F₄I₂ molecules and the SCN[−] anion in **3b**.

non-isotropic radii developed by Nyburg and Faerman³⁵ [$r_{\min}(\text{I}) + r_{\max}(\text{N}) = 1.76 + 1.60 = 3.36 \text{ \AA}$; $r_{\min}(\text{I}) + r_{\max}(\text{S}) = 1.76 + 2.03 = 3.79 \text{ \AA}$]. Furthermore, these chains exhibit structural features which are characteristic of the other examples described below, that is a relatively linear $\text{I} \cdots \text{N} \equiv \text{C}$ contact which contrasts with the acute $\text{I} \cdots \text{S} - \text{C}$ angle close to 90° . This structure represents the best possible adaptation between the symmetric, ditopic p -C₆F₄I₂ halogen bond donor molecule and the ditopic, unsymmetric SCN[−] halogen bond acceptor anion.

Salt **4a** adopts the same 1:1 stoichiometry, with one Et₄N⁺SCN[−] for one tritopic $\text{sym-C}_6\text{F}_3\text{I}_3$ molecule. It crystallises in the monoclinic system, space group $P2_1/n$ with the three entities in general position in the unit cell (Fig. 2). The $\text{sym-C}_6\text{F}_3\text{I}_3$ molecules are organised into columns running along a with a head-to-tail arrangement within the columns. Halogen bonding interactions develop into layers perpendicular to a , with halogen-bonded chains of alternating $\text{sym-C}_6\text{F}_3\text{I}_3$ and SCN[−] running along c (Fig. 3). Their structural characteristics collected in Table 2 are comparable to those observed in **3b**. Note also that one iodine atom of the $\text{sym-C}_6\text{F}_3\text{I}_3$ molecule is not engaged in any halogen bond, but rather acts as an *acceptor* in a short $\text{I} \cdots \text{H} - \text{C}$ hydrogen bond involving a methylene group of the Et₄N⁺ cation, with the following characteristics: $\text{I} \cdots \text{H}$: 2.095 \AA ; $\text{I} \cdots \text{H} - \text{C}$: 147.6° ; $\text{C} - \text{I} \cdots \text{H}$: 128.5° . Note this acute value for the $\text{C} - \text{I} \cdots \text{H}$ angle, which contrasts strongly with the linear $\text{C} - \text{I} \cdots (\text{S}, \text{N})$ interaction. Indeed, in the hydrogen bond interaction, the iodine atom acts as a nucleophile through its lone pairs delocalised in an

Fig. 4 Projection view of the unit cell of **4b** showing the halogen-bonded chains running along *b*. The *n*-Bu₄N⁺ cation has been omitted for clarity.

The corresponding tetrabutylammonium salt **4b** is found to crystallise with a different stoichiometry, that is (*n*-Bu₄N⁺SCN[−])₂(*sym*-C₆F₃I₃) with two thiocyanate salts for one single *sym*-C₆F₃I₃ molecule. As a consequence of this stoichiometry, we are now in the situation of three iodine atoms as halogen bond donors combined with potentially four halogen bond acceptor atoms (2 × S + 2 × N). As shown in Fig. 4, the three iodine atoms of the *sym*-C₆F₃I₃ molecule are now engaged in halogen bonds, two of them with one SCN[−] anion to form chains running along *b* while the third iodine atom is linked to the nitrogen atom of the second SCN[−] anion, through a slightly longer I...N distance.

The thiocyanate anion as a polydentate anion in **2a**, **1a** and **3a**

More complex structures are found with the three Et₄N⁺SCN[−] salts isolated with the *o*-, *m*- and *p*-C₆F₄I₂ molecules. Despite a 1:1 stoichiometry, **2a**, formulated as (Et₄N⁺SCN[−])(*m*-C₆F₄I₂), does not exhibit the chain motif encountered above with I...N and I...S interactions but rather two I...S interactions while the nitrogen atom of the thiocyanate anion does not act as halogen bond acceptor. **2a** crystallises in the monoclinic system, space group *C2/c* with one SCN[−] anion and *m*-C₆F₄I₂ molecule in general position while two crystallographically independent Et₄N⁺ cations are found, both located on the two-fold axis, with one of the two further disordered on two positions. The *m*-C₆F₄I₂ molecules are organised into parallel (1 0 1) layers. As shown in Fig. 5, within a (1 0 1) layer, the thiocyanate anion is halogen bonded to the *m*-C₆F₄I₂ molecule through two I...S interactions while the nitrogen atom does not take part into halogen bonding, indicating that it might not be such a strong halogen bond acceptor in comparison with the sulfur atom in the SCN[−] anion, a feature already observed once by Kochi in the *n*Bu₄N⁺SCN[−] salt with CBr₄.²⁹

The complex **1a** crystallises in the orthorhombic system, space group *Pbca* and involves two *o*-C₆F₄I₂ molecules in general position for one Et₄N⁺SCN[−], also in general position in the unit cell. The *o*-C₆F₄I₂ molecules are organised into columns running along *a* composed alternately of the two crystallographically independent molecules (Fig. 6). These columns are linked together in the *b* direction (Fig. 7) through three halogen bond

Fig. 5 A view of one (1 0 1) layer in **2a** showing the thiocyanate anions pointing out of the plane. Hydrogen atoms have been omitted for clarity.

interactions involving the nitrogen and twice the sulfur atom of the SCN[−] anion.

Finally, the most complex salt obtained with *p*-C₆F₄I₂, **3a**, crystallises in the monoclinic system, space group *P2/a* and is formulated as (Et₄N⁺SCN[−])₂(*p*-C₆F₄I₂)₅, that is, with five *p*-C₆F₄I₂ molecules for two Et₄N⁺SCN[−] salts. Furthermore, two *p*-C₆F₄I₂ molecules are in general position while six others are located on inversion centres or two-fold axes. A projection view of this complex structure along *b* (Fig. 8) shows a segregation of the neutral and charged moieties similar to that observed in **1a** (Fig. 6). Each of the two SCN[−] anions is halogen bonded to five different *p*-C₆F₄I₂ molecules (Fig. 9), three on the sulfur atom and for the first time two on the nitrogen atom, with the shortest N...I distance associated with the largest C–I...N angle (Table 2). This unexpected structure around the nitrogen atom can be explained in a crude manner as the contribution of the mesomeric form C, shown in Scheme 3.

In the six structures described above, we observe that the thiocyanate anion adopts specific halogen bond motifs

Scheme 3 Lewis description of three mesomeric forms of the SCN[−] anion. The grey ellipsoids represent the lone pairs around the S and N atoms.

characterized by systematic linear C–I⋯(N,S) contacts, in agreement with earlier results showing the alignment of the electron depletion zone in the extension of the C–I bond. The geometrical features observed by Bock and Holl,^{26–28} and Kochi²⁹ in their earlier work are confirmed, that is a linear C–I⋯(N, S) contact while the I⋯N≡C angle deviates notably from linearity

(145–170°) and acute I⋯S–C angles (<90°) are systematically observed. Furthermore, examples were found where the sulfur atom is “coordinated” two times (in **2a**) or even three times (in **3a**) simultaneously, showing that formally, the three lone pairs on the S atom in the Lewis description of the SCN[−] anion can act as halogen bond acceptors. On the other hand, we note here two examples where the nitrogen atom behaves in an unexpected way, either by staying free of any halogen bond (in **2a**) or by linking simultaneously to two different iodine atoms at the same time (in **3a**). It therefore appears that the two N and S atoms in the SCN[−] anion most probably exhibit a very comparable tendency to engage into halogen bonds. Theoretical calculations were performed to rationalise these experimental solid state observations, as detailed below. In order to allow comparisons with our earlier results concerning the halogen bonding of halide anions (Cl[−], Br[−]) with the *sym*-trifluorotriiodobenzene,¹⁸ the calculations were similarly performed here for the same *sym*-C₆F₃I₃ molecule, interacting through one iodine atom with either the N or S end of the SCN[−] anion.

Theoretical study of the *sym*-C₆F₃I₃⋯NCS[−] complex

The energetic values, geometrical optimizations and frequency calculations of *sym*-C₆F₃I₃ and NCS[−] in both coordination modes (C–I⋯N or C–I⋯S) have been calculated using DFT methods. One complex is found for each coordination mode. Interestingly, both complexation energies are very similar, −16.97 and −16.43 kcal/mol for C–I⋯N and C–I⋯S, respectively, although the equilibrium geometrical parameters are substantially different. Hence, coordination through the N atom yields an I⋯N equilibrium distance of 2.599 Å and an angle I⋯N≡C of 151.3° while the complex formed through the S atom presents an I⋯S equilibrium distance of 3.007 Å and an angle I⋯S–C of 103.2° (Fig. 10). In both cases, the C–I⋯X (X = N, S) angles present a linear rearrangement. The calculations are carried out in a gas-phase environment and, therefore, the charge transfer process is overestimated, leading to calculated I⋯(S,N) distances notably shorter than the experimentally observed ones. This trend has already been observed in the calculated interaction with halide anions where counterions or simultaneous participation into two, three, four or five halogen bonds should be taken into account in order to get comparable results.

Further insight into the geometrical differences between both interaction modes can be gained considering the variation of the complexation energy with regard to I⋯X distance, from 2.3 to 3.3 Å, and C–I⋯X angles, from 90 to 180° (Fig. 11). The C–I⋯N interaction mode presents a relatively flat minimum surface for *r*(I⋯N) between 2.5 and 2.8 Å and for α(I⋯N≡C) between 130 and 180° whereas the minimum in the C–I⋯S interaction is found for *r*(I⋯S) distances between 2.9 and 3.2 Å and a α(I⋯S–C) angle between 90 and 110°.

A topological characterization of weak interactions, such as hydrogen bonds can be obtained using the theory of Atoms-in-Molecules³⁶ (AIM) and the analysis of the ELF. Hence, both halogen bonding modes are characterized by the presence of a (3,−1) bond critical point (bcp) on the topology of the electronic density with similar values of the density (0.037, 0.031 in a.u.) and Laplacian (0.093, 0.047) for C–I⋯N and C–I⋯S interactions at the respective bcp coordinates. The topological partition

Fig. 10 DFT optimized geometrical parameters for interaction of *sym*-C₆F₃I₃ with SCN[−], through the I...N (top) or I...S interaction (bottom).

Fig. 11 Complexation energy maps calculated at DFT level for I...X distances (on the abscissa) and I...X-C angles (on the ordinate) for the I...N (left) and I...S (right) coordination modes.

of the ELF gradient field yields basins of attractors that can be identified as corresponding to atomic cores (C) and valence electrons (V). According to the number of core basins in contact (the synaptic order), valence basins can be characterized as monosynaptic, disynaptic *etc.* Monosynaptic basins, labeled V(A) correspond to lone pairs while disynaptic basins, labeled V(A,B) are associated to the bonding region between atoms A and B. Bifurcation points between ELF valence basins of different monomers have been proposed in order to characterize hydrogen bonding interactions.³⁷ For the halogen bonds considered in this work the bifurcation points of C-I...N and C-I...S complexation modes corresponding to V(I)UV(N) and V(I)UV(S) connections have values of $\eta(r) = 0.187$ and $\eta(r) = 0.270$, respectively. These values are similar to hydrogen bonds of medium strength.

Further insight can be obtained by analyzing the two electronic factors playing a key role for the C-I...N,S interactions: (i) charge transfer from the anion to the C₆F₃I₃ molecule and (ii) shape and orientation of the N and S lone pairs. The amount of charge transferred can be estimated theoretically using different approaches. Natural bond orbital (NBO) analysis on both complexes gives a transfer from NCS[−] to C₆F₃I₃ of 0.13e and 0.26e for C-I...N and C-I...S complexes, respectively. Other methodologies to calculate the charge transfer are based on topological approaches and yield very similar values: 0.14e and 0.27e using the AIM theory (based on the electron density) and 0.12e and 0.21e using the ELF for C-I...N and C-I...S complexes, respectively. Hence, the smaller electronegativity of S compared to N allows for a more efficient charge transfer to the halogen bond donor and leads to a larger stabilization of the complex. The second factor can be best analyzed by means of the ELF, which localises electron pairs within the geometrical space and integrates the amount of electron density of each electron pair providing an understanding of the different geometric structures. The ELF analysis of isolated NCS[−] shows one monosynaptic valence basin for N and S containing 3.83e and 5.79e, respectively (see Fig. 12). This electron population can be interpreted as a superposition of mesomeric structures B and C described previously (Scheme 3). Inspection of the shape of V(N) and V(S) basins reveals clear differences between both

Fig. 12 ELF plot (isocontour value of 0.80) for NCS[−] (a), C₆F₃I₃...NCS[−] (b) and C₆F₃I₃...S-CN[−] (c). Core basins in purple, monosynaptic basins in orange and disynaptic basins in green.

Scheme 4 Anisotropic electronic distribution around the halogen (X) atom and geometric features of type I and type II motifs.

terminal lone pairs. While V(N) is compact and lying on the molecular axis, V(S) is much more voluminous and adopts a nearly toroidal shape around the core electrons of S. As it can be observed in Fig. 12, the interaction between $C_6F_3I_3$ and NCS^- takes place between the lone pairs V(N) and V(S) for the N or S coordination modes, respectively, and the halogen bond donor through the sigma “hole” located in the prolongation of the C–I bond. The more compact nature of V(N) allows a closer approach to the I nucleus in a nearly linear way while the shape of V(S) enforces a much longer I...S distance and a nearly 90° approach to the I nucleus. It should be noted that V(S) also presents a small sigma “hole” in the back side of the S–C bond similar to V(I) which prevents the linear approach to the halogen bond donor. This interaction pattern is actually closely related to the so-called type II interaction between halogens described by Desiraju (Scheme 4).⁵

Indeed, the sulfur atom plays here the role of the halogen bond acceptor atom in a strong, type II, halogen...halogen interaction. This ability of the sulfur atom of the SCN^- anion to interact sideways as a halogen bond acceptor group has been observed only very recently in metal thiocyanate complexes where the NCS^- anion is N-bonded to the metal, giving M–NCS motifs and leaving the sulfur atom at the periphery available for interaction with halogen bond donors. Indeed, salts

of cationic diiodotetrathiafulvalenes with either isolated $[Cr(isoq)_2(NCS)_4]^-$,³⁸ or polymeric $[Cd_3(NCS)_8]^{2-}$ moieties³⁹ exhibit short I...S contact with C–I...S angles essentially linear while the I...S–C angles are systematically around 90° .

Conclusions

In the examples reported earlier,^{26–29} the halogen bond donor molecules reported had each four iodine (Scheme 1) or bromine (CBr_4) atoms available for halogen bonding to the SCN^- anion, affording structures where the thiocyanate anion was systematically linked to at least three to five iodine atoms. Using here benzene derivatives with only two or three activated iodine atoms, we were able to enhance the selectivity of the halogen interaction, and to discriminate more precisely the respective ability of the sulfur and nitrogen atom to engage in such halogen bond interactions. The analysis of the six structures described here combined with the theoretical calculations clearly shows the ambivalent character of the SCN^- anion and demonstrates the ability of the sulfur and nitrogen ends to interact with halogen bond donors with comparable strength. This ambivalent character of the SCN^- anion towards halogen bonding is strongly reminiscent of its similar behaviour toward metal coordination, particularly with group 12 (Zn, Cd, Hg) d^{10} metal cations, which are best understood in terms of the hard–soft acid–base concept developed by Pearson, Basolo and Burmeister.⁴⁰ Indeed, while the Zn tetrahedral thiocyanate complexes tend to be N-bonded, the tetrahedral Hg complexes are almost always S-bonded. The Cd^{2+} cation in between becomes “schizophrenic”,⁴¹ exhibiting both S and N bonding modes and a variety of coordination numbers, exactly as observed here when faced with halogen bond donor molecules such as the iodo aromatics collected in Schemes 1 and 2.

Experimental

The four neutral molecules *o*-, *m*- or *p*-diiodoperfluorobenzene and the *sym*-trifluorotriiodobenzene were either commercially available (*p*- and *o*-diiodoperfluorobenzene) or prepared according to published procedures (*m*-diiodoperfluorobenzene,⁴² *sym*-trifluorotriiodobenzene⁴³). Crystallisation experiments for the Et₄NSCN salts **1a–d** were performed by mixing equimolar quantities (0.125 mmol) of Et₄NSCN and the aromatic in EtOH (3 mL). Slow addition of water and cooling to 4 °C afforded the title compounds as colourless crystals. The *n*Bu₄NSCN salts **3b** and **4b** were obtained from slow evaporation of CH₂Cl₂ solutions containing *p*-diiodoperfluorobenzene (0.1 g, 0.25 mmol) or *sym*-trifluorotriiodobenzene (0.1 g, 0.2 mmol) with, respectively, one or two equiv. *n*Bu₄SCN.

Crystallography

X-Ray data collections (Table 3) were performed, either on an APEXII, Bruker-AXS diffractometer at 100(2) K for **1a**, **2a**, **3a** and **4a**, or on an Enraf-Nonius Kappa-CCD diffractometer at 293(2) K for **3b** and **4b**, both with graphite-monochromated Mo K α radiation ($\lambda = 0.71073$ Å). Structures were solved by direct methods (SHELXS-97⁴⁴ or SIR-97)⁴⁵ and refined by full matrix least-squares methods (SHELXL-97), as implemented in the WinGX software package.⁴⁶ Absorption correction was applied. Hydrogen atoms were introduced at calculated positions (riding model), included in structure factor calculations, and not refined.

Theoretical methods

All calculations have been carried out by means of the GAUSSIAN03 package.⁴⁷ All DFT calculations were performed at the B3LYP level using the 6-311G(d,p) basis set for iodine and 6-311++G(d,p) basis set for the other atoms.^{48,49} Complexation energies are defined as $[E(\text{sym-C}_6\text{F}_3\text{I}_3 \cdots \text{SCN}^-) - E(\text{sym-C}_6\text{F}_3\text{I}_3) - E(\text{SCN}^-)]$. The basis set superposition error for the optimized structures of *sym*-C₆F₃I₃ with SCN[−], through the I \cdots N or I \cdots S interaction is 2.65 kcal/mol and 0.60 kcal/mol, respectively. No BSSE correction to the complexation energies was applied. Energy maps were carried out at the same level of theory by means of optimizations, fixing the I \cdots X distances and I \cdots X–C angles in both coordination modes as indicated in Fig. 11. The AIM and ELF topological analyses have been carried out using the TopMod program developed by Silvi *et al*⁵⁰ using a cubic grid with a step size of 0.1. Graphic representations of ELF have been obtained using the Amira software.⁵¹
