Formal Approach to Multimodal Control Design: Application to Mode Switching
Gregory Faraut, Member, IEEE, Laurent Piétrac, Member, IEEE, and Eric Niel

Abstract—A framework based on Supervisory Control Theory (SCT) is proposed to assist the design of multi-modal control for discrete-event systems (DESs). Our purpose handled modes which are conceptualized by using multi-model approach. Each mode represents a running part of the system, depending on the requirements to enforce and resources to activate. The resulted framework aims to design each mode independently first, and resolves conflicting connections between them secondly. The proposal carries out a formal way to build the final ready-to-use control laws. A flexible manufacturing system illustrates this approach.

Index Terms—Automata, discrete-event systems (DESs), mode switching, multimodel control design, multimodal system, supervisory control theory (SCT).

I. INTRODUCTION

INITIATED by Ramadge and Wonham [1], Supervisory Control Theory (SCT) has significantly improved results in the discrete-event systems (DESs) domain. Properties such as safety, liveness, controllability, observability and, more recently, diagnosability have been introduced to assess formally control architecture. Basically supported by finite-state machines, SCT applicability for industrial application schemes does not seems easy. In fact, the design of real control applications implies very large models, with two main problems. The first pertains to scalability because of state-space explosion: real system models may be too large to be computed. The second problem pertains to the interpretation of the models: larger models are difficult to understand even if computation is successful. To solve scalability, several approaches have been proposed in terms of control architecture: modular [2], [3], decentralized [4], [5], hierarchical [6], [7], and even hierarchical and distributed [8], [9].

Even if a decomposition is used to reduce complexity, these approaches always handle the whole process and the whole specification. However, for numerous systems, user requirements depend also upon specific instants. For example, sequential modes for hybrid systems (chemical batch processes [19]–[21] for cars also apply particular control laws according to the active operating mode: startup, ABS on/off, cruise control on/off,...). For each mode, some components of the whole system are engaged, and requirements may be very different from one to another.

In DES, numerous works are focused on multimodal control law. However, most of them applied compositional formalisms on modeling configurations: for instance state charts [22], mode charts [23], hierarchical finite-state machines, and mode automata [24]. In these approaches, the model of the process is not specifically representative of the state of the process, and thus, is unable to automatically detect (using the synthesis or validation) the issues about mode switching. Formal approach like SCT [25] seems to be more convenient for mode management by distinguishing process and specifications. With this approach, the authors of [26] have studied the problem to automatically find the restart state, after correction of an error. However, in these works, only the nominal mode of productivity is studied: the method does not assume that errors and/or corrective actions are included into the control. Our approach, quite the contrary, has the purpose to design all running modes of the system, including the actions of recuperation after a failure. Based on the works of [27] and [28], the proposed framework is able to take several modes into account. First, we define the model of the (controlled or not) and the models of specifications in a considered mode. This is an usual way in the industry to study and to design independently the mode between them. The models then

\begin{thebibliography}{10}
\bibitem{} Gregory Faraut, Member, IEEE, Laurent Piétrac, Member, IEEE, and Eric Niel.
\end{thebibliography}
are extended to include the mode switching [29]. The significant contribution, as presented in this article, is the identification of incompatibility for the mode switching, and the inconsistency (several states are possible to be reached by one commutation, meaning a lost of information) of the specifications. The proposed framework thus helps the designer throughout the design of control law of modes.

In Section III, we present a framework based on SCT devoted to functioning mode management. The proposed framework aims to design each functioning mode independently, and then simplify design and interpretation, considering for the discussed mode only the engaged components and associated requirements of that particular mode. The approach is illustrated on a conventional example in Section IV and is compared with the centralized approach. However, to give a better understanding of the proposition, Section II recalls basic notions of SCT.

II. SUPERVISORY CONTROL THEORY

Ramadge and Wonham’s theory [25] underpins the study of DES control. This theory is based on separation between the model representing what the system can do (the uncontrolled process), the model of what the system must or must not do (the liveness and safety properties of the process), the model of what the system does (the controlled process), and the model of what the system should do (the desired language).

The automaton $G = (Q, \Sigma, \delta, q_0, Q_m)$ models the uncontrolled process [30], with $Q$ the finite-state set, $\Sigma$ the finite alphabet of symbols (event labels), $\delta : Q \times \Sigma \rightarrow Q$ the partial transition function, $q_0$ the initial state, and $Q_m \subseteq Q$ the set of marked states. States exist for periods of time (duration), whereas events occur instantaneously, asynchronously, and at virtually random (unpredictable) times. For a machine, examples of states are “idle,” “operating,” “broken down,” and “under repair.” Examples of events are “machine starts to work,” “breaks down,” “completes work,” or “starts to repair.” Marked states are used to model ends of tasks, states to be reached or states in which the system can be stopped.

Let $\Sigma^*$ be the set of all finite sequences or strings of events in $\Sigma$, including the empty string $\epsilon$. The function $\delta$ is extended to $\delta : Q \times \Sigma^* \rightarrow Q$. Any subset of $\Sigma^*$ is called a language over $\Sigma$. The languages associated with $G$ are the closed behavior $L(G) = \{s \in \Sigma^* | \delta(q_0, s) \text{ is defined}\}$ and the marked behavior $L_m(G) = \{s \in \Sigma^* | \delta(q_0, s) \in Q_m\}$. $L(G)$ represents the set of all possible trajectories, i.e., all possible system behaviors, whereas $L_m(G)$ represents the subset of trajectories leading to a marked state.

Let us assume that automaton $G$ models the uncontrolled behavior of the process. This behavior is not satisfactory and must be restricted to a subset of $L(G)$ [31]. Let the specification represented by an automaton $E = (X, \Sigma, \xi, x_0, X_m)$ with $X$ the state set, $\Sigma$ the same alphabet as in $G$, $x_0$ the initial state and $X_m$ the set of marked states. This specification models the liveness and safety requirements of the process. The objective is to adjoint a supervisor, denoted by $S$, to interact with $G$. To do this, the alphabet $\Sigma$ is partitioned into two disjoint subsets $\Sigma_c$ and $\Sigma_{nc}$ which comprise controllable and uncontrollable events, respectively. The controllable events are the events that can be prevented from happening by supervisor $S$, the uncontrollable events cannot. Formally, the supervisor $S$ is a function from the language generated by $G$ to the power set (the set of all subsets) of $S$:

$L(G) \rightarrow 2^{2^S}$. Our goal is to find a controlled process, modeled by an automaton $H = (Y; \Sigma, \tau, y_0, Y_m)$, such that:

- The marked language of $H$ is included in that of $G$: $L_m(H) \subseteq L_m(G)$.
- This controlled process satisfies the specification: $L_m(H) \subseteq L_m(G \times E)$.
- This controlled process is controllable, i.e., a supervisor $S$ such that $L(S/G) = L(H)$ exists.

If $L(G \times E)$ is controllable with respect to $L(G)$, then $H = G \times E$. Else, we can determine [32] the automaton that generate the largest controllable sublanguage of $L(G \times E)$, called “supremal controllable sublanguage.” If this automaton exists, the controlled process is nonblocking and minimally restrictive.

III. MULTIMODAL DESIGN

A. Overview

In this paper, a multimodal standpoint with a representation by multimodel approach is adopted to design a system. This system is composed by different and numerous components (plants, actuators, sensors, etc.) activated to achieve tasks in accordance to functional and safe requirements. This system can also be critical so that it needs to have a high availability even if one of these components fails. This is only possible if a number of alternative components are available. These available components are capable of replacing the failed components and keeping the same quality of production.

The considered mechanism will be implemented for systems which can operate in one single mode (production, initialization, etc.) once. In automatic control within mode switching ability, our contribution comprises proposing a framework, in which:

- Each mode is studied independently and separately. In most cases, a mode is characterized by the components used, generating events involving a commutation, and by a set of requirements, modeled independently of the requirements of the others modes, having to be fulfilled when the system is working in this mode. In this independent study, the SCT theory is applied “conventionally” in each mode (limited to the centralized control structure in this paper).
- The intermodal framework includes the intermodal specifications, used to extend the behavior of modes and having all possible trajectories, and the switch specifications, used to limit the commutation phenomena, i.e., forbid undesired switch trajectories. Of course, this will depend on whether switch events can be observed and controlled or not.

The main problem is to determine the state of the models (process, controlled process and specification), when a mode of the system has to leave the initial mode to commute to another one, called the final mode. In fact, the commutation is possible if the initial mode is in a compatible state with the final mode. Compatible means the state of the shared components between initial and final mode are the same. It also means the requirements existing in both modes are still respected even if the system switches modes.

The following sections describe each of the steps necessary in order to build, in a formal way, the final control law for each
mode respecting requirements. To do so, we successively explain the intramodal framework—giving the internal behavior of each mode—and the intermodal framework allowing to check the connection between modes and identifying which ones of them are allowed or forbidden to finally obtain the control law.

To give a better understanding, Table II, shown at the end of this paper, refers to the notation used.

B. Definitions

A system is composed of different components. The dynamic of each component is the same regardless of the system mode. These dynamics include possible failures and recoveries. Such events will be used to model switching modes.

Definition 1: A set of components is denoted by \( C = \{C_1, C_2, \ldots, C_i\} \), where \( i \in \mathbb{N} \) and \( i \geq 1 \). A component \( C_i \) is modeled by an automaton \( G_{C_i} \) where \( G_{C_i} = (Q_{C_i}, \Sigma_{C_i}, \delta_{C_i}, q_{0_{C_i}}, f_{C_i}) \), with:

- \( Q_{C_i} \) is the state set of the component \( C_i \);
- \( \Sigma_{C_i} \) is the event set of the component \( C_i \), including two partitions:
  - \( \Sigma_{C_i}^{C} = \Sigma_{C_i}^{C} \cup \Sigma_{C_i}^{U} \) with \( \Sigma_{C_i}^{C} \cap \Sigma_{C_i}^{U} = \emptyset \); \( \Sigma_{C_i}^{C} \) and \( \Sigma_{C_i}^{U} \) are, respectively, the controllable and uncontrollable events of the component \( C_i \);
  - \( \Sigma_{C_i} = \Sigma_{C_i}^{C} \cup \Sigma_{C_i}^{U} \) with \( \Sigma_{C_i}^{C} \cap \Sigma_{C_i}^{U} = \emptyset \); \( \Sigma_{C_i} \) is the set of switch events; \( \Sigma_{C_i}^{C} \) are the other events;
- \( \delta_{C_i} \) is the transition function and includes \( \delta_{C_i}^{C} \) which represents the set of switch transitions;
- \( q_{0_{C_i}} \) is the initial state of the component \( C_i \);
- \( f_{C_i} \) is the marked states set of the component \( C_i \).

Definition 2: A set of modes is denoted by \( M = \{M_1, M_2, \ldots, M_n\} \), where \( n \in \mathbb{N} \) and \( n \geq 1 \) (by convention, we assume the initial active mode is \( M_1 \)). We define \( C_{M_i} \) as the set of components used in the mode \( M_i \), where \( C_{M_i} = C_{M_i}^{C} \cup C_{M_i}^{U} \cup C_{M_i}^{r} \) such that:

- \( C_{M_i}^{C} \) is the set of components representing the intramodal behavior of the process in the mode \( M_i \);
- \( C_{M_i}^{U} \) is the set of components that lead the system to enter into the mode \( M_i \);
- \( C_{M_i}^{r} \) is the set of components that lead the system to exit the mode \( M_i \);
- \( C_{M_i} = C_{M_i}^{C} \cup C_{M_i}^{U} \cup C_{M_i}^{r} \) is the set of switch components.

No particular relation is assumed to exist between \( C_{M_i}^{C}, C_{M_i}^{U}, C_{M_i}^{r} \) and \( C_{M_i} \) except that they are all included in \( C \); in particular, a component can be included in:

- \( C_{M_i}^{C} \), but not to be a switch component of \( C_{M_i}^{U} \).
- \( C_{M_i}^{U} \) and in \( C_{M_i}^{C} \). It means this component is used in the mode and is necessary to enter into this mode.
- \( C_{M_i}^{r} \) or \( C_{M_i}^{r} \). It means this component is necessary to represent the switch behavior of the mode \( M_i \) (enter or exit).

Fig. 1 is an example of switching modes. We have three modes, \( M_1, M_2 \) and \( M_3 \). The components \( C_1, C_2 \) and \( C_3 \) are used in mode \( M_1 \). From this nominal mode, a switch is possible to the degraded mode \( M_2 \), by the switch event \( f_2 \) generated if the component \( C_2 \) breaks down, or to \( M_3 \), by the switch event \( f_4 \) if it is the component \( C_2 \) that breaks down. Thus, the mode \( M_3 \) is composed of component \( C_1 \) representing its internal behavior, i.e., \( C_{M_3}^{C} = \{C_1\} \) and of the component \( C_{M_3}^{U} = C_{M_3}^{r} = \{C_2\} \) because it is this component that generates the event leading to a switch from the mode \( M_1 \) to \( M_3 \). In the same way, the mode \( M_2 \) is composed of the components \( C_1 \) and \( C_3 \) (with the component \( C_4 \)), but also with the components \( C_3 \) and \( C_{M_2}^{r} = \{C_2\} \) that generates the event \( r_4 \) responsible for the switch.

Definition 3: Let a mode automaton \( G^M \) representing the switch behavior of the system, described in requirements. Formally, this automaton is denoted by \( G^M = (Q^M, \Sigma^M, \delta^M, q_{0^M}, f_{M^M}) \) such that:

- \( Q^M = \{M_i\} \);
- \( \Sigma^M = \bigcup_{C_i \in C} \Sigma_{C_i} \);
- \( \delta^M : M \times \Sigma^M \rightarrow M \) is the transition function of mode automaton;
- \( q_{0^M} \) is the initial mode \( M_1 \);
- \( f_{M^M} \subseteq M \).

This automaton aims to easily add information on which mode the system is in. It also allows the addition of strategies to switch by modifying it.

C. Intramodal Design

The intramodal design, illustrated in Fig. 2, is very similar to the supervisory control theory used to synthesize the control law [31]. The objective of this first framework, a subpart of the general proposed framework, is to ensure the internal behavior enforcing the intramodal specification is correct and that each mode is reliable, well-built and optimal according to the requirements (illustrated by the green book). For each mode \( M_i \), the process \( G_{M_i} \), the model representing the internal behavior (in) of the mode \( M_i \), results from parallel composition [31] of automata \( G_{C_i} \), models of components used in this mode. It is defined on \( \Sigma_{in}^M = \bigcup_{C_i \in C_{M_i}} \Sigma_{C_i} \). The specification \( E_{in}^M \) is defined on the alphabet \( \Sigma_{in}^M \), results from the product composition of the model of each specification \( E_{in}^{C_i} \) to be compiled.
with in this mode. After designing the required $n$ modes, the designer obtains $n$ uncontrolled processes $G^M_{in}$, $n$ specifications $E^M_M$, and $n$ controlled processes $S^M_M / G^M_{in}$ (denoted $H^M_{in}$).

Each model of $H^M_{in}$ represents the control law of the mode $M_j$. Nevertheless, these models are not interconnected, and this is the main focus of the next section.

D. Intermodal Design

The intramodal framework focuses only on components used to represent the internal behavior and the requirements having to be fulfilled for each mode. This framework ensures the existence of one control law and that the requirements are respected. The running of the system remains flawless as long as it operates within one of these modes. However, as previously said in the introduction, the commutation phenomena are a very particular problem in mode management. The second framework aims to handle these phenomena correctly. This section focuses on the intermodal behavior of modes, and takes the behavior that could lead to switching between modes into account. The proposed framework is shown in Fig. 3.

This new framework includes successive steps in order to identify all trajectories connecting modes and, in some cases, to forbid them. The first step extends the mode’s behavior. The second one synthesizes these extended mode behaviors of mode by the extended intermodal specifications regarding these new dynamics resulted from the intermodal specifications. The next process tracking step identifies trajectories allow a switch from one mode to another. Concerning the steps process tracking (step three) and the merge function (step five), it is well-known that merging states in an automaton can cause nondeterminism [31]. The switch events are renamed in process tracking (Section III-D3) to avoid this. Thus, the knowledge about the switch events that produced them has been preserved.

In other words, the merge function has been anticipated in renaming all identified switch events during the procedure in step three. Using both of these functions allows the reduction of complexity without generating a nondeterministic automata. A second synthesis considering switch specifications (step four) is realized to forbid the undesired trajectories. The final models resulting from the fifth step are the control law of mode.

1) Extension of Process: The controlled process in the intramodal framework is built by composition of the components used in each mode and the requirements that have to be respected when the system is running in one of these modes. Nevertheless, assuming that the internal behavior is totally represented, it is not necessarily the case for the external behavior, i.e., all possible commutations between modes could be not totally known. Some components are indeed not taken into consideration in the intramodal framework for a particular mode, but could be important from a switch standpoint. The extension then takes all the components that are necessary to represent the internal and external behavior of modes into account. Extended models $G^M_{in}$ result in parallel composition of both included components $G^C_C$ in $G^M_M$ (and not only $G^C_C$), and the mode automaton $G^M_M$.

Definition 4: Let $G^M_M$ be such that

\[ G^M_M = (Q^M_M, \Sigma^M_M, \delta^M_M, I^M_M, F^M_M) \]

where $G^M_M = G^M_M \parallel G^C_C \parallel G^M_M$.

These models ensure that the whole behavior is represented and allow to detect all trajectories relying modes.

2) Synthesis With Extended Specification: The synthesis of the intramodal framework only deals with built specifications regarding taken components in the intramodal behavior of modes. In this step, we have to take the whole specification of the considered mode into account in order to fulfill the intermodal behavior of each mode. Thus, there are two types of specifications.

- Extended intramodal specifications. These specifications have to be extended according to the newly added components in the extension step. Indeed, some components do not represent the intramodal behavior of modes and may have an influence on intramodal specification. For this reason, the intramodal specification have to be extended. The specification $E^M_M$ represents extended intramodal specification.

- Intermodal specifications represent specifications which are not necessary in the intramodal behavior, but can modify the trajectory to switch. These specifications have to be taken into account also.

The synthesis procedure is applied in the same way as the synthesis in intramodal framework. For each mode, we obtain the model $H^M_M$ which represents both intramodal and intermodal behaviors and respects the requirements of the mode $M_j$.

3) Process Tracking: In fact, models $H^M_M$ are too rich in states: they also contain some states that do not correspond to the internal behavior or to a commutation between modes. It is a consequence of the parallel composition of the component models $G^C_C$ and the mode automaton $G^M_M$. These states will be removed in the last step of the intermodal framework (merge function), that may also cause an indeterminism (several transitions with the same event from a single state). To avoid that, we will add an information on each event occurrence (a label).
It is possible only if a single state exists in the final controlled process $H_{M_k}$ after a commutation from a single state in the initial controlled process $H_{M_j}$.

Formally, the procedure uses the next definitions to find the equivalent states between modes. However, the first definition is focused on subsets of $\Sigma$ necessary for others following definitions.

Definition 5: $\Sigma_{M_j}^M \subseteq \Sigma_{M_k}^M$ is the set of commutation events of the mode $M_j$: $\Sigma_{M_j}^M = \bigcup_{\alpha \in \Sigma_{M_j}} \Sigma_{M_j}^\alpha$, where $\Sigma_{M_j}$ (resp. $\Sigma_{M_k}$) is the event set that lead the system to enter into (resp. exit) the mode $M_j$.

We define the states set $Y_{M_j,\alpha} \cap M_k$ of $H_{M_k}$, where a switch event $\alpha$ exists and leads from the initial mode $M_j$ to the final mode $M_k$.

Definition 6:

$$Y_{M_j,\alpha} \cap M_k = \{ y \in Y_{M_j} | M_j, M_k \in Q^M, \alpha \in \Sigma_{M_j}^M \cap \Sigma_{M_k}^M \cap \Sigma_{M_j}^\alpha, \delta^M(M_j, \alpha) = M_k \text{, } \tau^M(\alpha, y) \text{ is defined} \}$$

Let the language $L_y^y_{M_j,\alpha} \cap M_k (H_{M_j})$ be the sublanguage of $L(H_{M_j})$ leading from the initial state $y_0$ of $H_{M_j}$ to a state $y$, where a switch event $\alpha$ can occur.

Definition 7:

$$L_y^y_{M_j,\alpha} \cap M_k (H_{M_j}) = \{ s \in \Sigma_{M_j}^M | y \in Y_{M_j} \cap M_k, \tau^M(\alpha, s) = y \}$$

The identification results in the extended projection function $P_{M_j,\alpha}$ defined as follows:

Definition 8: Let $P_{M_j,\alpha} : \Sigma_{M_j}^M \to \Sigma_{M_k}^M$ such that $\forall \sigma \in \Sigma_{M_j}^M$ and $\forall s \in \Sigma_{M_k}^M$.

$$P_{M_j,\alpha}(s) = \begin{cases} P_{M_j,\alpha}(s), & \text{if } \sigma \in \Sigma_{M_j}^M \cap \Sigma_{M_k}^M, \\ \varepsilon, & \text{otherwise} \end{cases}$$

In other words, this function takes a language defined on alphabet $\Sigma_{M_j}^M$ (representing the alphabet of the initial mode), and erases the events that are not included on alphabet $\Sigma_{M_k}^M$ (representing the alphabet of final mode). More details are given in [27] and [33]. In the next definition, this projection is used on $L_y^y_{M_j,\alpha} \cap M_k (H_{M_j})$ to find the projected language on the alphabet of the final mode $M_k$.

Definition 9: Let an initial mode be called $M_j$ and a final mode be called $M_k$. $P_{M_j,\alpha} \cap M_k (H_{M_j})$ is the language of $H_{M_j}$ that leads to a state $y$, where a switch event $\alpha$ occurs. $P_{M_j,\alpha} \cap M_k (H_{M_j})$ is the projected language on the alphabet of the final mode $M_k$, such that: $L_y^y_{M_j,\alpha} \cap M_k (H_{M_j}) = P_{M_j,\alpha} \cap M_k [L_y^y_{M_j,\alpha} \cap M_k (H_{M_j})]$.

Based on this definition, we can define two properties. First of all, if all languages $P_{M_j,\alpha} \cap M_k (H_{M_j})$ of $y \in Y_{M_j} \cap M_k$ are in $L(H_{M_k})$, this means at least one connection state exists in $L(H_{M_k})$. In this case, we say $H_{M_k}$ is compatible with $H_{M_j}$ (this does not mean that $H_{M_j}^M$ is compatible with $H_{M_k}^M$). It is not the case, specifications have to be modified.

Definition 10: $H_{M_j}$ is compatible with $H_{M_k}$ if and only if $\forall y \in Y_{M_j,\alpha} \cap M_k (L_y^y_{M_j,\alpha} \cap M_k (H_{M_j}) \subseteq L(H_{M_k}))$.

If $H_{M_j}$ is compatible with $H_{M_k}$, it is possible that from a single state of $H_{M_k}$, several states of $H_{M_j}$ are reachable. In this case, it is not possible to define a single state of connection. It is also possible that from several states of $H_{M_j}$, a single state of $H_{M_k}$ is reached. Thus, an information contained in the model $H_{M_j}$ has disappeared in the model $H_{M_k}$, which could lead to a problem when returning to the initial mode. If these two cases do not occur, there is no problem and all the switch events can be labeled with a subindex. We say $H_{M_k}$ is consistent with $H_{M_j}$ (this does not mean that $H_{M_j}^M$ is consistent with $H_{M_k}^M$).

Definition 11: Let $H_{M_j}$ be compatible with $H_{M_k}$. $H_{M_k}$ is consistent with $H_{M_j}$ if:

- $\forall y \in Y_{M_j,\alpha} \cap M_k \exists y_\emptyset \in Y_{M_k} \left( L_y^y_{M_j,\alpha} \cap M_k (H_{M_j}) \subseteq L_y^y (H_{M_k}) \right)$ with $L_y^y (H_{M_k}) = \{ s \in \Sigma_{M_k}^M | y \in Y_{M_k}, \tau^M(\emptyset, s) = y_\emptyset \}$.

- $\forall y_1, y_2 \in Y_{M_j,\alpha} \cap M_k (y_1 \neq y_2 \Leftrightarrow L_y^y_{M_j,\alpha} \cap M_k (H_{M_j}) \cap L_y^y \cap M_k (H_{M_k}) = \emptyset)$.

In the following procedure, we apply the above definitions to track trajectories representing commutations.

Procedure 1: For each $\delta^M(M_j, \alpha) = M_k$ of the mode automaton $G^M$:

1) For each $y \in Y_{M_j,\alpha} \cap M_k$ [definition 6]:
   a) We calculate $L_y^y_{M_j,\alpha} \cap M_k (H_{M_j})$ [definition 7];
   b) We calculate $L_y^y_{M_j,\alpha} \cap M_k (H_{M_k})$ [definition 9]. Two cases are possible.

   i) $(L_y^y_{M_j,\alpha} \cap M_k (H_{M_k}) \not\subseteq L(H_{M_k}))$. So, $H_{M_k}$ is not compatible with $H_{M_j}$ and we can stop the procedure for this transition [definition 10];

   ii) $(L_y^y_{M_j,\alpha} \cap M_k (H_{M_k}) \subseteq L(H_{M_k}))$: maybe $H_{M_k}$ is compatible with $H_{M_j}$. Two cases are possible:

   a) $\exists y_1, y_2 \in Y_{M_j} [ L_y^y_{M_j,\alpha} \cap M_k (H_{M_j}) \subseteq L_y^y \cap M_k (H_{M_k}) \text{ and } L_y^y_{M_j,\alpha} \cap M_k (H_{M_j}) \not\subseteq L_y^y (H_{M_k})]$ or $\exists y_1 \in Y_{M_j,\alpha} \cap M_k (y_1 \neq y_2 \Leftrightarrow L_y^y_{M_j,\alpha} \cap M_k (H_{M_j}) \cap L_y^y \cap M_k (H_{M_k}) = \emptyset)$; $H_{M_k}$ is not consistent with $H_{M_j}$ and we can stop the procedure for this transition [definition 11].

   b) else, maybe $H_{M_k}$ is consistent with $H_{M_j}$. $\delta^M(M_j, \alpha) = M_k$ is then considered as valid. The new name is operated on the transitions functions of $H_{M_j}$ and $H_{M_k}$ such that $\tau^M(y, \alpha) = \tau^M(y, \alpha)$ and $\tau^M(y, \alpha)$ and $\tau^M(y, \alpha)$ exist and are changed by $\tau^M(y, \alpha)$ and $\tau^M(y, \alpha)$ with $l$ a subindex. The alphabet of the newly built models is given by: $\Sigma_{M_k}^M = \Sigma_{M_j}^M \cup \{ \alpha \}$. 
2) After the last $y \in Y_{M_f} \cap {\delta_i}$, if the procedure was not stopped before this step, $H_{M_f}^j$ is consistent with $H_{M_f}^j$. We can go to the next transition $\delta_{M_f}^j(M_f, y) = M_f$.

When the switch events detected by an incompatibility or by an inconsistency has been listed, there are two methods to solve it. Either we go in the loop of the framework intermodal illustrated in Fig. 3 to modify the intermodal specifications, Section III-D2, or we create a new switch specification to forbid the undesired switch events which have been detected. This step of switch specification is the next step in the intermodal framework.

4) Synthesis With Switch Specifications: The switch specifications step is about trajectories detected as undesired during the process tracking, and not modified by the intermodal specifications. Building these models of specifications is really easy, because we use the new switch events label as we did in the last Section III-D3. In other words, the language of switch specifications is defined on the alphabet $\Sigma_\delta$ without the switch events we desire to forbid. Applying these specifications, represented by the models $P_{\text{out}}^j$, gives the new models $P_{\text{out}}^j$. At the end of this step, the models are under control and no model of the modes has more than one switch event with the same label, the undesired switch events have been forbidden and there is only one other switch event in another mode that has the same label for each switch event. The model of modes can now be reduced by using a merge function.

5) Merge Function: The merge function reduces the complexity of the model by keeping only the intramodal behavior of each mode and including the useful intermodal behavior. To obtain the smallest size of each mode, the mode automaton $G_M^j$ used during the extension step is used one more time. Each state of mode then has a name including the state where $\delta_{M_f}^j$. In other words, we know for each state the mode in which the system is in. As we are now only interested in the intramodal behavior of each mode, we just have to remove the behavior which does not represent the intramodal behavior and add an idle state representing the mode when it will be deactivated to meet the specification that only one mode can be active in the same time. To do this, we execute the next procedure.

Procedure 2: Let $P_{\text{in}}^{M_j}$ and $P_{\text{merge}}^{M_j}$ be automata, where $H_{\text{merge}}^{M_f}$ is the model reduced by the merge function of the model $P_{\text{in}}^{M_j}$. The procedure to merge states is described next.

1) We determine in $H_{\text{merge}}^{M_f}$, a merge set $Y_{\text{merge}}^{M_f} \subset Y_{\text{in}}^{M_f}$. The states included in $Y_{\text{merge}}^{M_f}$ are the insignificant states to the
mode. Insignificant state to the mode $M_j$ are all states which do not have $M_j$ as part of their name (this part was given by the mode automaton $G^M_j$). These states are certainly added during the extension of the different models.

2) All states in $Y_{\text{mer}}^{M_j}$ are replaced by one new state called $y_{\text{id}}^{M_j}$.

3) We remove all self-loops at $y_{\text{id}}^{M_j}$.

4) If the initial state is included in $Y_{\text{mer}}^{M_j}$, then $y_{\text{id}}^{M_j}$ is the new initial state.

5) If a marked state is included in $Y_{\text{mer}}^{M_j}$, then $y_{\text{id}}^{M_j}$ is a marked state.

This procedure results in models which only represent the internal behavior of each mode and an idle state needed for restricting it to one active mode at a time. Formally, the automaton $H_{\text{merge}}$ is defined as follows:

Definition 12: Let $Y_{\text{mer}}$ be the set of all states which do not have $M_j$ as part of their name.

$H_{\text{merge}} = (Y_{\text{merge}}^{M_j}, Y_{\text{merge}}^{M_j}, Y_{\text{merge}}^{M_j}, Y_{\text{merge}}^{M_j})$ such that:

• $Y_{\text{merge}}^{M_j} = (Y_{\text{mer}}^{M_j} \setminus Y_{\text{mer}}^{M_j} \cup \{y_{\text{id}}^{M_j}\}$.

• $Y_{\text{merge}}^{M_j} = \bigcup_{C_{i} \in C_{M_j} \setminus M_j} Y_{\text{mer}}^{M_j}$.

• $y_{\text{id}}^{M_j} \in Y_{\text{mer}}^{M_j}$.

• $Y_{\text{merge}}^{M_j} = \{y_{\text{id}}^{M_j}, y_{\text{id}}^{M_j}\}$ if $y_{\text{id}}^{M_j}$ is a new state.

The aim of the steps process tracking and merge function are to avoid the nondeterminism involving the reduction complexity of models of mode. Between the last two steps, we can use the synthesis (step four) again to forbid the undesired trajectories. The final models resulted in the fifth step are the control law of mode.

IV. Example

A. Requirements

Consider the manufacturing system illustrated in Fig. 4(a), the system comprises four components and one buffer. The components are used to process a part and the buffer is used as a storage between the components with a maximal capacity of 1. The components $C_1$ are modeled by the automaton denoted $G^{C_1}$ and are shown Figs. 4(b) and (c). The events $s_1$ and $e_1$ represent a new task and the end of the task, respectively. While all these events are observable, events $s_2$ and $r_1$ are controllable and $e_2$ and $f_1$ are not. The system has four modes, such as $M = \{d_1, d_2, d_3, d_4\}$. Fig. 4(d) shows the model of the mode automaton $G^M$, which represents the switch behavior between modes. The first one, which is the initial mode, is the nominal mode $n$. The other modes are the degraded modes $d_1$, $d_2$, and $d_3$, which, respectively, depend on whether the component $C_1$, $C_2$, or $C_1$ and $C_2$ fail. In the case of malfunction, the component $C_3$ is replaced by the component $C_4$ and the component $C_2$ by the component $C_4$. This malfunction is modeled with the event $f_2$, while the repairing is modeled with the event $r_2$. So we have: $C_{n1} = C_{n2} = C_{n3} = C_{n4} = \{C_1, C_2\}$, $C_{d_1} = \{C_1, C_2\}$, $C_{d_2} = \{C_1, C_2\}$, $C_{d_3} = \{C_1, C_2\}$, $C_{d_4} = \{C_1, C_2\}$.

B. Intramodal Design

The modal decomposition of the system, where modes use components necessary to run, is modeled in Fig. 4(e). These models must be controlled according to the requirements defined by a specification automaton, like the model of the nominal specification $F^M_{\text{in}}$ representing the requirement of the buffer, shown in Fig. 4(f). It is unlikely that $L(G^M \times F^M_{\text{in}})$ is not controllable with respect to $L(G^M_{\text{in}})$, thus we use the supremal controllable sublanguage of $L(H^M_{\text{in}})$ to control our four modes, as illustrated in Fig. 4(g).

C. Intermodal Design

The first step is an extension of each mode with the components not already included in the internal behavior but which are
necessary to represent the switch behavior. This extension is illustrated Fig. 5(a) by a modal decomposition standpoint. The model $E^{d_3}$ representing the extended specification for the degraded mode $d_3$ is represented in Fig. 5(b). It includes the extended intramodal specification that is the buffer but expressed on the alphabet $\Sigma^{d_3}$ (and not $\Sigma^{d_1}$ like in the intramodal design). This specification also includes an intermodal requirement—the activation or the deactivation of the machines 1 and 3 following if the system is in the mode nominal $d_1$ or degraded $d_3$. This second specification was not present in the intramodal design because it has no effect on the internal behavior. The extended controlled process $H^{d_3}$ of the degraded mode $d_3$ is illustrated in Fig. 5(c). The next step is the process tracking to characterize the switch events and identify those to imply a deadlock.

Fig. 6(a) represents the model $H_{d_3}^{c_1}$ for the degraded mode $d_3$ and is the result of the process tracking step. At the end of this step, some problems are identified throughout the switch events sets $r_1, r_2, r_3, r_4$ and $r_1, r_2, r_3, r_4$. In each set, the projection of their language results in the same switch event in the final mode. This is an incompleteness between requirements, i.e., it misses information in the requirements. This information is about when the system can repair the machine 1 with regards to machine 3. This missing requirement has to be added by modifying the model of the intermodal specification. The modified intramodal specification for the degraded mode $d_3$ is shown Fig. 6(b).

The intermodal specification once modified and the process tracking step reused, only events $r_1, r_5, r_1, r_6$ remain problematic, as illustrated in Fig. 7(a), by the new model $H_{d_3}^{c_1}$, which includes the added requirements. Nevertheless, these requirements do not solve the incompleteness for these events. A closer look showed that the incompleteness due to these events is caused by the fact that the final mode does not have the behavior of machine 3 and, thus, does not know the buffer can be reduced by this machine 3. This may sound strange since the state in final mode exists, but the connection allowing the commutation does not.

The easiest way for the designer to correct this incompleteness is to forbid these events in the model of the switch specification, as displayed Fig. 7(b), representing the model $E^{c_1}_{\text{merge}}$. Thanks to rename command in the process tracking step, it is really easy to design the model of the switch specifications. The last figure, as displayed in Fig. 7(c), represents the model $H_{d_3}^{c_1}_{\text{merge}}$ after the application of the merge function for the degraded mode $d_3$. This merge function merges all states that do not have $d_3$ as part of their name. This merge results a new idle state, which is the new initial state for degraded modes. The models $H_{d_3}^{c_1}_{\text{merge}}$ are the final control law for each mode and ensure a reliable commutation between modes.

D. Comparison

In this section, the classical centralized approach is compared with our proposed multimodel approach. The Table I, gives the

The size of the different models. Each model has three numbers, meaning, respectively, the number of states (in the set of states), the number of events (in the set of events), and the number of transition in the automaton.

Through the intramodal study, Table I shows the different models are much smaller than the models built in centralized approach. The number of transitions is by example divided by a value comprised between 2 and 7 depending on the mode.
considered. This reduction gives an easier way for the designer to perform a good interpretation of these models, which is one of the aims of this work.

During the intermodal study, the last models of the controlled process, i.e., the models \(H_{\text{inter}}^{M_j} \) are approximately three times smaller that their equivalent models \(H_j \) built in the centralized approach, when we compare the number of states and the number of transitions. The number of events is a little bit bigger due to the process tracking step when some switch events are labeled. A comparison on the built models through the intermodal framework (the models \(G^{M_j}, E^{M_j} \) and \(H^{M_j} \)) show they are a similar size, but with a reduced complexity because the number of transitions is halved. A negative point is the study of the degraded mode \(d_3 \). Indeed, in this mode, all components are considered to build the (uncontrolled) process. This is the worst case that could happen for the framework, because the model of the process in the mode \(d_3 \) is the same as the process in the centralized approach: \(G^{d_3} = G \). This also is the case for the models of specifications \(E^{d_3} = E \), and the model of controlled process: \(H^{d_3} = H \). This is because in our example the single specification \(E \) is also the single specification in mode \(d_3 \). This is also the worst case for specifications.

Are these models necessary? The models of the intramodal framework allow the designer, in charge of the synthesis, to discuss with the users of the studied system. These models have to be the most clear that it is possible to reach, and this is clearly the case for the framework. The models \(G^{M_j}, E^{M_j} \) and \(H^{M_j} \) built in the intermodal study are only used by the designer that do not work, at this moment, with models simpler than in the centralized approach. On the contrary, his work is more complicated because he has to use more models. In the same way, the final models \(H_{\text{inter}}^{M_j} \) (Interg) are intended to the communication between the designer and the users, and then have to be as simplest as possible, that effectively the case with this framework. With these results, we think our objectives about the simplification of the models, to be easier to analyze, are for a big part reached.

V. CONCLUSION

The main contribution of this paper is to present an advanced framework using a multimodal standpoint and allowing to design a system by multimodel approach. The multimodal standpoint is an usual way in industry to design a system. The proposed framework uses a multimodel approach allowing to decompose the system in numerous control laws (one by mode). The first step of the framework is an intramodal study where each mode is studied independently. The second step, and the major contribution of this work, focuses on formal way to design complete modes including its different switch dynamics, to identify some incompatibilities during the mode switching and forbid these incompatibilities by using SCT. Being an offline study, this work gives a formal method to design a control law from scratch while meeting all requirements the system needs. Current research involves defining strategies when incompatible states have been recognized using uncontrollable switch events and when the supramodal controllable does not give satisfaction on the set of requirements.
