Abstract

**Background:** Intraocular ranibizumab (Lucentis®, Novartis, Basel Switzerland) is the primary choice in the treatment of neovascular age-related macular degeneration (AMD). VEGF is known to be a survival factor for neuronal cells. Therefore, blockage of all VEGF isoforms by ranibizumab could induce retinal dysfunction.

**Methods:** Using isolated bovine retinas the electroretinogram (ERG) was recorded as a transretinal potential using Ag/AgCl electrodes while the retinas were perfused with an oxygen pre-incubated nutrient solution. For 45 min ranibizumab was applied at a concentration of 0.2mg/mL and alternatively the solvent carrier without the active agent. The ERG was monitored before, during and after exposure.

**Results:** The concentration of 0.2mg/mL ranibizumab induced a not significant b-wave reduction of 22.32 % after exposure (p = 0.13). For the a-wave amplitude only a reduction of 4 % was detected (p = 0.18). The solvent carrier induced no significant reduction of the a- and b-wave amplitudes (p = 0.30 and p = 0.979, respectively).

**Conclusion:** In our *ex vivo* model, the isolated perfused vertebrate retina, ranibizumab has been proven to be a safe compound at the concentrations applied. The stability of the ERG-amplitudes rules out a considerable retinal dysfunction after an injection of up to 1mg ranibizumab.
Introduction:

Ranibizumab (Lucentis®, Novartis, Basel, Switzerland) is the humanized fragment of the murine monoclonal antibody that binds all the active isoforms of the vascular endothelial growth factor (VEGF-A) leading to a containment of the neovascular process, the cause of wet age-related macular degeneration (AMD).[1, 2] Wet AMD leads to a rapid and irreversible loss in central vision and is one of the leading causes of blindness in the western world.[3] The development of the anti-vascular growth factor therapy (anti-VEGF) offered a substantial progress and is currently the primary choice in the treatment of neovascular AMD.[4]

Improvement in visual acuity by 15 or more letters has been observed in 33.8-40.3% of patients treated with ranibizumab in pivotal clinical trials.[5, 6] The MARINA study also could show that ranibizumab-treated patients suffering from minimally classic or occult CNV were more likely to improve in vision-related quality of life through 24 months.[7]

On the one hand ranibizumab inhibits the effects of VEGF, angiogenesis and vascular permeability, on the other hand, VEGF plays a central role in the trophic maintenance of the choriocapillaris and in protecting retinal neurons from apoptosis in the eye.[8] While the intravitreous administration of anti-VEGF agents reduces the severity of systemic adverse events, potential concerns about retinal toxicity remain due to the intravitreal injection and to the long-term maintenance therapy that some patients may require.

Clinical trials showed no evidence for retinal toxicity and a therapy with up to 0.5mg ranibizumab intravitreally was well-tolerated for more than two years.[5, 6] But concerns persist, as the pharmaceutical phial of lucentis contains 0.23 mL of a 10mg/mL ranibizumab solution, which makes an accidental injection of more than 0.5mg ranibizumab possible.

The present study was designed to investigate the effects of ranibizumab on the parameters of the electroretinogram using the isolated perfused vertebrate retina technique, an electrophysiological ex vivo technique for evaluation of the safety profile of ranibizumab.[9,
This is the first electrophysiological report about testing the effects of ranibizumab on retinal function.
Materials and Methods:

Materials

Aspartate, glucose and other chemicals were purchased from Merck at pro analysis grade. Ranibizumab, Lucentis®, was provided from Novartis (Basel, Switzerland). The solvent carrier was made under sterile conditions at the pharmacy of the University Hospital Tübingen in guidance of Novartis. The solvent carrier and ranibizumab was stored at 4°C.

Methods

Superfused vertebrate retina assay: Bovine eyes were obtained directly post mortem and were transported in darkness in a serum-free standard medium containing 120 mM NaCl, 2 mM KCl, 0.1 mM MgCl₂, 0.15 mM CaCl₂, 1.5 mM NaH₂PO₄, 13.5 mM Na₂HPO₄ und 5 mM glucose. The preparation was performed as described previously.[10]

The electroretinogram was recorded in the surrounding nutrient medium via two silver/silver-chloride electrodes on either side of the retina. The recording chamber containing a piece of retina was placed in an electrically and optically insulated box. The perfusion velocity was controlled by a roller pump and set to 1 mL/min. The temperature was kept constant at 30°C. The perfusing medium was pre-equilibrated and saturated with oxygen. The retina was dark-adapted and the electroretinogram was elicited at intervals of five min using a 1-Hz single white xenon flash (xenon tube; Grass Technologies, West Warwick, RI 02893 U.S.A.) for stimulation. The flash intensity was set to 6.3 mlux at the retinal surface using calibrated neutral density filters (Kodak Wratten Filter; Kodak, Stuttgart, Germany).

The duration of light stimulation was 10 microseconds controlled by a timer (Photopic Stimulator PS33 Plus; Grass Technologies, West Warwick, RI 02893 U.S.A). The ERG was filtered and amplified (100-Hz high pass filter, 50-hz notch filter, 100 000 x amplification) using a Grass Amplifier P122 (Grass Technologies, West Warwick, RI 02893 U.S.A).
data were processed and converted with an analog-to-digital data acquisition board (PCI-MIO-16XE-50; National Instruments, Austin, Tex, U.S.A) in a desktop computer (PC compatible).

The retina was superfused with the serum-free nutrient solution and stimulated repeatedly until stable amplitudes were recorded. A concentration of 0.2mg/mL ranibizumab was added to the nutrient solution, and responses were recorded for 45 min. Thereafter, perfusion with standard solution was resumed for another 75 min to observe the b-wave recovery. According to the described procedure one pilot experiment was performed to evaluate the effects of ranibizumab at a concentration of 0.1mg/mL to simulate the impact of the clinical dose, 0.5mg ranibizumab, on the b-wave amplitude. The b-wave amplitude was measured from the trough of the a-wave to the peak of the b-wave (Fig. 1a).

To investigate the effects of ranibizumab on the photoreceptors under scotopic conditions (6.3 mLx flash light intensity), the b-wave was suppressed by adding 1 mM aspartate to the nutrient solution. Under these conditions, the influence of ranibizumab on the photoreceptor potential P III was analyzed. Aspartate is an inhibitor of synaptic transmission at the level of the first retinal synapse and enables the recording of unmasked photoreceptor potential P III by abolishing the b-wave (Fig. 1b).[11] We recorded stable photoreceptor potential P III for 30 minutes. Thereafter, ranibizumab was added in a concentration of 0.2mg/mL to the aspartate containing nutrient solution for 45 minutes. The changes of the a-wave amplitude during the application of ranibizumab were recorded and the recovery was followed up for 75 minutes under perfusion with the aspartate containing nutrient solution.

To test the effects of the solvent carrier on the a- and b-wave amplitude the solvent carrier without the active agent ranibizumab was used as a control. Equivalent amounts of the solvent carrier were applied to the nutrient solution for 45 min under the same conditions as during the testing of the ranibizumab. Subsequently, the a- and b-wave recovery was observed for 75 min.
Data analysis: The percentage reduction of the a-wave and b-wave amplitude was calculated before and after application of ranibizumab. The a- and b-wave recovery was compared with the a- and b-wave amplitude before application of ranibizumab and the solvent carrier, respectively. For the statistical analysis the software “Origin 6.0” (Microcal) was used. Significance was estimated by the Student’s t-test and levels of p ≤ 0.05 were considered as statistically significant.
Results:

The perfusion of the isolated bovine retina was performed under stable environmental conditions. Osmotic pressure, temperature, and pO2 remained unchanged during perfusion. In our experimental setting stable ERG amplitudes were reached within two hours of perfusion. We showed that the superfused retinal preparations responded constantly to light stimulation in our experimental setup for more than ten hours.[9]

Ranibizumab was effective in the treatment of neovascular AMD at an intravitreal dose of 0.5mg dissolved in 0.05 mL solvent carrier per human eye according to a concentration of 0.1mg/mL. To investigate the safety and the retinal tolerance we tested a higher dose of ranibizumab. According to the volume of the vitreous humour of approximately 5 mL, the averaged intraocular concentration of ranibizumab was calculated to 0.2mg/mL.

The concentration of 0.2mg/mL ranibizumab failed to induce a significant decrease of the b-amplitudes of the isolated perfused bovine retinas, although a non-significant b-wave reduction of 22.32 % was found directly after exposure (p = 0.13, Fig. 2A). After exposure the b-wave amplitude recovered completely during the washout reaching the mean value of b-wave amplitudes before the application of ranibizumab and no delayed decrease of the b-wave amplitudes could be observed (p = 0.36, Fig. 2A).

In contrast, the same amount of the solvent carrier reduced the b-wave amplitude only about 2.9 % (p = 0.979, Fig. 3A). In addition, the b-wave amplitude remained stable throughout the washout after the exposure with the solvent carrier (p = 0.99, Fig. 3A).

A reduction of the b-wave amplitude alone cannot specify the site of action of any drug on retinal function, which is added to the nutrient solution. Additionally, we investigated the effects of ranibizumab on the photoreceptor potential P III and a-wave amplitude, respectively, using aspartate.[11]

After the addition of 1 mM aspartate, the b-wave amplitude was reduced continuously and unmasked photoreceptors potential could be recorded. The concentration of 0.2mg/mL
ranibizumab was added to the nutrient solution containing aspartate. After 45 min exposure the a-wave amplitude showed only a slight reduction of 4 % (p = 0.18, Fig. 2B). Similarly, throughout the washout the a-wave amplitude remained unaltered (p = 0.43, Fig. 2B).

In addition, the equal amount of the solvent carrier induced only a not significant reduction of the a-wave amplitude of about 8 % after 45 min exposure (p = 0.30, Fig. 3B). At the washout the a-wave amplitude slightly recovered and the a-wave amplitude remained stable throughout the washout (p = 0.69, Fig. 3B).

One pilot experiment was performed testing the effects of 0.1mg/mL on the b-wave amplitude (Fig. 4). During the exposure a reduction of the b-wave amplitudes could be not detected. During the washout the b-wave amplitudes were measured unchanged to the b-wave amplitudes before the application of ranibizumab.
Lüke et al.

Discussion:

The ERG is a sensitive parameter of retinal integrity and function. The changes of the ERG in the model of the isolated and perfused bovine retina reflected toxic effects of the drug directly and exclusively on retinal function, in which especially a reduced b-wave indicates an evident dysfunction of retinal neurons.[9, 12] A detailed localization of the effected neuronal layer by the applied drug is enabled by a separate investigation of the photoreceptor function using aspartate.[11]

The aim of our study was to evaluate the tolerability of the retina to ranibizumab. We tested a higher concentration according to an intravitreal injection of about 1mg ranibizumab to evaluate the safety profile of ranibizumab also in the case of an accidental injection of a higher dose than 0.5mg ranibizumab, which was the recently evaluated, tested and proposed dose for the treatment of wet AMD.[5, 6] An accidental injection of more than 0.5mg ranibizumab is possible, because the pharmaceutical phial of lucentis contains 0.23 mL. Deducting the remnants in the phial and a reflux of the solution after injection we calculated a potentially excessive injected amount to 0.1 mL and 1mg ranibizumab, respectively. In 5 mL vitreous humour the applied 1mg ranibizumab would become diluted to the tested concentration of 0.2mg/mL ranibizumab.

However, it must also be considered that the spatial distribution inside of the vitreous humour is not uniform and the retina near the area of the injection would be exposed to a higher concentration than the average calculated concentration of 0.1mg/mL, which would be expected after an injection of the usual applied dose of 0.5mg ranibizumab. In addition, the intravitreal concentration of the active agent varies after injection. For example, in monkeys 0.5mg ranibizumab in 0.05 mL leads to a peak vitreous concentration (\(C_{\text{max}}\)) of 169 µg/mL ranibizumab six hours after intravitreal administration.[13]

The pivotal clinical trials did not observe an evidence for retinal toxicity during the standard therapy with 0.5mg ranibizumab every four weeks in the treatment of wet AMD during an
observation period of two years. Taking into account these considerations, we tested the effects of ranibizumab on the electroretinogram at a higher dose to evaluate the safety profile of intraocular ranibizumab.

Our study revealed no significant decrease of the a- and b-wave amplitude during the exposure of the tested concentration. We found only a not significant reduction of the b-wave amplitude, which indeed seems to be induced by the active agent ranibizumab itself, because the equivalent amount of the solvent carrier did not alter the b-wave. Ranibizumab seems to affect selectively the inner retinal network indicated by the selective b-wave reduction. An alteration of the b-wave amplitude at the concentration of 0.1mg/mL according to the clinical dose of 0.5mg ranibizumab could not be observed. The photoreceptor function itself remained unaltered.

Recently, we tested the effects of bevacizumab (Avastin®, Roche Pharma, Vienna, Austria), which is the full-length humanized anti-VEGF monoclonal antibody and also proposed in the treatment of wet AMD. For avastin, we found a not significant reduction for the a- and b-wave amplitude during the exposure with the threefold dose of bevacizumab (0.8mg/mL according to a dose of 3.75mg), which is recommended to be applied intravitreally[14]. The observed alterations of the a- and b-wave were most likely induced by the solvent carrier. These findings are not surprising as the solvent carrier of bevacizumab was developed for intravenous cancer therapy and not for intravitreal injections.[15]

In this study, we could demonstrate that the solvent carrier of ranibizumab has no effects on the a-wave as well as on the b-wave amplitude. The origin of the slight dysfunction of the inner retina during the exposure of 0.2mg/mL ranibizumab remained unclear, but was fully reversible after exposure.

However, we consider that an injection of the lower and usually injected dose of 0.5mg ranibizumab in the treatment of wet AMD seems to be safe, because a concentration of 0.2mg/mL did not lead to a significant reduction of the b-wave amplitude. In the case of the
accidental injection of a higher concentration equivalent to an injected dose of 1mg ranibizumab the effects on retinal function seem to be slight and transient. As higher doses have not yet been tested in our model, no reliable conclusion can be made on the retinal toxicity of doses higher than 1.0mg ranibizumab.

The clinical experiences and trials confirm our results that an intravitreal injected dose of 0.5mg ranibizumab seems to be safe, which was shown for an observation period of two years with an injection of 0.5mg ranibizumab every four weeks.[5, 6] Clinical experiences with escalating injected doses of 0.3 up to 2mg of ranibizumab showed a mild ocular inflammation as most common post injection adverse event.[16 – 18] In these trials the maximum well tolerated dose of ranibizumab was estimated to 0.5mg and a stronger ocular inflammation was observed at higher applied doses. An electrophysiological assessment is missing and was not done in these studies.[16 - 18] So far, no electrophysiological data are available for ranibizumab. We think that this additional safety study adds important information to the known clinical data. Especially, in respect to the upcoming of further indications beyond wet AMD the safety profile of ranibizumab should be known since it was shown that ranibizumab was also effective in the treatment of common retinal diseases like the macular oedema induced by diabetes or retinal vein occlusion.[19, 20]

In conclusion, the isolated superfused retina is well defined to evaluate short-term effects on retinal function. Significant short-term toxic effects were not detected at the tested concentration of 0.2mg/mL. This concentration accords to the twofold dose of ranibizumab, which is used in the treatment of wet AMD, and so we could show that ranibizumab seems to be safe also in the case of an accidental injection of more than 0.5mg.
