Abstract Sickle cell anaemia (SCA; HbSS) is characterised by its clinical variability, which is only partly explained by known genetic factors. Environmental factors are known to contribute to acute problems but their importance in chronic complications has not been analysed. We have studied 93 children with SCA in a single institution, who underwent transcranial Doppler scanning and steady-state blood tests in 2006. These data were correlated with each individual's exposure to pollution from dust (PM₁₀), nitric oxide (NO) and nitrogen dioxide (NO₂). This exposure was derived from patient postcodes and detailed street-level maps of average pollutant levels in 2006. All the pollutants correlated closely with each other. Increased exposure to pollution correlated with a significant reduction in total bilirubin levels, with a trend towards lower levels of lactate dehydrogenase and aspartate transaminase. There was

significant correlation between extracranial internal carotid artery blood velocity and PM₁₀ exposure. These studies suggest that chronic exposure to air pollutants could explain some variability in SCA. The lower levels of bilirubin and other markers of haemolysis with increased exposure to air pollutants could be mediated by increased exposure to NO.

Keywords Sickle cell anaemia · Air quality · Nitric oxide · Transcranial Doppler scan · Haemolysis

Introduction

Sickle cell anaemia (SCA) is an inherited condition characterised by episodes of acute pain, acute lung problems and progressive organ damage [1]. In children, one of the main problems is the increased risk of stroke, typically associated with the narrowing of intracerebral blood vessels [2]. The clinical picture varies widely between individuals, with some children having very few problems and others being severely affected. It is not known why the disease varies so much, although genetic factors are significant and have been extensively studied [3]. Environmental factors are also likely to be important but have received little attention. We have recently started to analyse these effects on the large population of people with sickle cell disease in South London. We found that windy weather and low humidity were associated with increased hospital admissions [4]. We have also recently shown that air quality affects acute complications of sickle cell disease, with high levels of ozone (O₃) causing more episodes of acute pain. Interestingly, we also found that high levels of carbon monoxide and NO were linked to fewer hospital admissions [5].

Most patients with sickle cell disease in the UK and other developed countries live in urban areas with variable and often poor air quality. It seems likely that air quality has significant effects on the pathophysiology and chronic complications of SCA, as has been demonstrated for many other diseases [6]. Our previous study looked only at the effect of daily variation of air quality on admission to hospital with acute pain [5]. This study tests the hypothesis that mean annual exposure to PM₁₀, NO and NO₂ correlates with some chronic complications in children with sickle cell disease, including frequency of hospital admissions, haematological parameters and cerebrovascular disease. The study involved children less than 16 years of age for two reasons: the cerebrovascular circulation is routinely assessed using transcranial Doppler (TCD) ultrasound in this age group, and children live most of their lives close to home, allowing postcode to act as a reasonable surrogate marker of exposure to pollutants. Understanding the effects of air quality may also allow more evidence-based advice to be given on housing needs and illuminate pathological mechanisms in SCA.

Patients, materials and methods

Patient population

The study was based on children with SCA attending the Paediatric Sickle Cell Clinic at King's College Hospital who also lived in greater London. The data were anonymised prior to analysis and no extra blood samples or tests were performed. The study was discussed with the Research Ethics Committee at King's College Hospital, who decided that formal ethical approval was not necessary. Children were included in the study if they had a confirmed diagnosis of SCA (haemoglobin (Hb), family and DNA studies), underwent routine TCD scan and steady-state blood tests in 2006 and were documented to be living at the same address from 2005 to 2006. Patients receiving regular blood transfusions were excluded, as were those living outside London for whom air quality maps were not available. Patients are seen in clinic routinely every 3–12 months, and steady-state blood tests are performed annually.

Data collection

Relevant data were collected from written and electronic patient records. This included assessment of haemolysis (Hb, reticulocyte count, bilirubin, lactate dehydrogenase (LDH), aspartate transaminase (AST)), steady-state haematology (Hb, white cell, neutrophil and platelet counts), cerebral blood velocities from TCD scans and clinical complications (attendances at Accident and Emergency and days spent in

hospital in 2006, use of hydroxyurea). The postcode was recorded routinely at each clinic attendance. The data were recorded anonymously on a secure study database.

Transcranial Doppler scanning

Intracerebral blood velocity was measured according to the protocol used in the STOP study [7] in the vascular laboratory at King's College Hospital. TCD measurements were first attempted between the ages of 2 and 4 years.

Air quality mapping

The Environmental Research Group at King's College London predicts London's air pollution using a combined modelling–measurement approach. It uses a kernel modelling technique to describe the initial dispersion of pollutants and then calculates the contribution of various sources to total air pollution concentrations by applying the model concentration field and adjusting for the source strength. A number of source types are taken into account: detailed treatment of the road network, gas combustion sources, railway sources and Heathrow airport, plus the effect of the combined road traffic emissions plus all other source types from more distant locations. The model uses hourly sequential meteorological data from the London Heathrow site. Measurements from the London Air Quality Network, which operates a series of air quality monitoring stations across London, are used to validate the model.

Local levels of NO, NO₂ and PM₁₀ were mapped using the model, although equivalent maps of O₃ levels were not available. These maps were used to assign a mean exposure to pollutants for 2006 to each child, based on the postcode of their home. In the UK, postcodes consist of five to eight numbers and letters, which uniquely designate a small group of houses in the same street.

Analysis

The mean annual exposure to NO, NO₂ and PM₁₀ was not normally distributed and was analysed by Spearman's rank correlation (ρ), using Statistical Package for Social Sciences (SPSS), version 14.0 (SPSS Inc., Chicago, IL, USA). Mean annual pollution exposure for categorical variables was analysed using the Mann–Whitney *U* test.

Results

Patients

One hundred seven children with SCA who lived in greater London underwent TCD scanning and blood testing in

2006 at King's College Hospital. Of these, 14 had known cerebrovascular disease and were on transfusion programmes and were not analysed further. The 93 children studied had a mean age of 8.9 years (2.5–16.4 years) and included 38 girls (41%). Ten patients were taking hydroxyurea because of recurrent acute pain or acute chest syndrome and were included in the analyses.

Air quality

Mean annual exposure to the three pollutants analysed varied widely across the different postcodes. The mean annual exposure to pollutants was: NO₂ 38.9 µg/m³ (median 40, range 26–51), NO 24.6 µg/m³ (median 24.5, range 8–52), PM₁₀ 22.3 µg/m³ (median 22.2, range 20–26). All three pollutants were very closely correlated with each other (NO₂ vs NO $\rho = 0.98$, $P < 0.001$; NO₂ vs PM₁₀ $\rho = 0.93$, $P < 0.001$; NO vs PM₁₀ $\rho = 0.94$, $P < 0.001$), suggesting that they are all related to a similar aspect of air quality.

Hospital attendance

The number of days spent in hospital varied from 0 to 26 (median 0, mean 1.96) and the number of A&E attendances ranged from 0 to 4 (median 0, mean 0.37). There was no detectable effect of exposure to pollution for NO, NO₂ or PM₁₀ on hospital use in 2006 on a number of different analyses. For example, for each pollutant, patients were divided in to two halves: those exposed to lowest levels and those exposed to highest levels. There was no difference in hospital admissions or A&E attendance between these halves for any of the pollutants (Mann–Whitney U test). Taking hydroxyurea is a marker of more severe clinical problems,

and there was no difference in the mean annual exposure to pollutants in the ten children taking hydroxyurea compared to those who were not (Mann–Whitney U test).

Routine laboratory measures

There was no significant correlation between exposure to NO, NO₂ or PM₁₀ and haemoglobin, white cell count, platelet count, and alanine transaminase (Spearman's rank correlation; Table 1).

Measures of haemolysis

Exposure to NO, NO₂ and PM₁₀ correlated negatively and significantly with total bilirubin levels (Fig. 1). There was a non-significant trend towards increasing pollution exposure being correlated with decreasing levels of LDH, AST and reticulocyte count (Table 1).

Transcranial Doppler measurements

There was significant positive correlation between exposure to all three pollutants and blood velocity in the extracranial internal carotid artery (eICA). There was a non-significant negative relationship between exposure to pollution and intracerebral blood flow in the intracranial carotid artery, middle cerebral, anterior cerebral (ACA) and posterior cerebral arteries. (Table 1).

Conclusions

This study is the first attempt to assess the effects of air quality on steady-state measurements and chronic com-

Table 1 Summary of data showing Spearman rank correlation (r) and two-tailed significance (P) between air pollutants, blood parameters and transcranial Doppler measurements of blood velocity

Statistically significant results are shown in bold.

Fig. 1 **a** Scatter plot of exposure to nitric oxide (NO in microgramme per cubic metre) against bilirubin (μ M). **b** Scatter plot of dust exposure (PM_{10} in microgramme per cubic metre) and blood velocity (cm/s) in the extracranial internal carotid artery (**b**). The lines were interpolated by linear regression

plications of SCA. There are inevitably a number of limitations and confounding factors. Postcode can only act as an approximate estimate of annual exposure to pollutants, and many other factors will be important, including exposure to indoor pollutants such as tobacco smoke [8]. Equally, this study only looked at pollution exposure over a 12-month period, and some complications may occur over a longer time period and be related to environmental factors several years previously. We were also not able to analyse the effect of O_3 exposure due to unavailability of maps of annual exposure at the time of the study, and we previously found this to have an important effect on increased episodes of acute pain [7]. However, despite these limitations, this study is the first to

try and identify the importance of air quality on chronic complications in SCA and showed some potentially important effects.

All three pollutants showed significant negative correlation with total bilirubin. The significance of this is unclear, although a similar non-significant trend was seen for other markers of haemolysis, with LDH, reticulocytes and AST all decreasing with increasing exposure to pollution, whilst haemoglobin shows positive correlation with NO. Haemolysis is implicated in the pathogenesis of vascular complications in SCA, with evidence that increased levels of free plasma haemoglobin cause a functional deficiency of NO [9], which contributes to a number of complications including cerebrovascular disease, priapism and leg ulcers [10, 11]. It is interesting that increased exposure to environmental NO is possibly associated with decreasing haemolysis and potentially beneficial effects. This is consistent with clinical evidence of benefit from low-dose NO exposure [12] and our previous study demonstrating decreased episodes of acute pain in SCA on days with high levels of environmental NO [7].

The other significant finding in our study was a positive correlation between blood flow in the extracranial internal carotid artery and exposure to NO, NO_2 and PM_{10} . This relationship was strongest between PM_{10} and eICA blood velocity, with a weaker effect for NO and NO_2 , consistent with the primary relationship being with PM_{10} . The significance of increased eICA blood velocity in SCA is not established, with no evidence that it is predictive of stroke risk as has been shown for intracranial blood vessels. However, there is evidence that extracranial cerebrovascular disease is a cause of stroke in some children [13], and our study suggests that dust exposure may be contributory to this. Consistent with this, previous studies in adults without sickle cell disease have shown an association between increased exposure to PM_{10} and increased risk of infarctive stroke [14] and myocardial infarction [15]. It has been proposed that exposure to small particles might contribute to atherosclerotic plaque development and disruption due to demonstrable associations between PM_{10} levels and measures of inflammation [16], thrombosis [17] and autonomic excitation [18]. These same mechanisms might reasonably be expected to apply in children with SCA.

This study provides further evidence that air quality and environmental factors contribute to the complications of SCA. Mapping annual exposure to pollutants offers a way of analysing the effects of air quality on complications of SCA, and the findings in this study need to be confirmed in larger, prospective longitudinal studies. These effects may become more important in time due to climate change and deteriorating air quality.
