Abstract

The eukaryotic voltage-dependent anion channel (VDAC) is a pore-forming protein originally discovered in the outer membrane of mitochondria. It has been established as a key player in mitochondrial metabolite and ion signaling. In addition, in recent years, it has also been proposed that VDAC is present in extra-mitochondrial membranes, and it has been related to cytoskeletal structures. However, little is known about the presence and intracellular localization of VDAC subtypes in mammalian gametes.

In this study we confirm the synthesis of VDAC1 and 2 subtypes in germinal vesicle (GV) and meiosis II (MII) stage porcine oocytes as well as their protein expression. A shift in the abundance of immunoreactive 32 kDa VDAC protein between GV and MII stage oocytes was observed with anti-VDAC2 antibody. Furthermore, subcellular localization by confocal laser microscopy demonstrated fluorescent labeling of VDAC1 over the entire oocyte surface, suggesting the presence of VDAC1 in the porcine oocyte plasma membrane and around the cortical area. Anti-VDAC2 immunostaining yielded ring-like clusters of structures distributed on the cortical area in some GV but not in MII stage oocytes. These results are the first data obtained for VDAC in mammalian female gametes and provide the basis for studying protein-protein interactions, distribution and possible functions of VDAC subtypes during maturation and fertilization of mammalian oocytes.

Key words

immunoblotting, indirect immunofluorescence, oocyte, RT-PCR, voltage-dependent anion channel

1. Introduction

Voltage-dependent anion channels (VDAC) are a widespread class of pore-forming proteins (30-35 kDa) mainly found in the outer mitochondrial membranes in most eukaryotic organisms (for reviews see [1,2]). In addition to mitochondrial localization, in the past few years several reports demonstrated the presence of VDAC in the plasma membrane and caveolae-like domains, sarcoplasmic/endoplasmic reticulum, nuclear envelope and endosomes (for reviews see [3,4]).

VDAC have conserved sequences, and three different VDAC genes encoding distinctly expressed isoforms are known to exist in vertebrates [4,5]. Little is known in mammals about tissue-specific distribution, intracellular localization and the specific role of each isoform [5-7]. The existing information derives mainly from recombinant proteins expressed in model organisms like yeast or mutant mice [5,8-10]. This paucity of information is due to the fact that to date mainly VDAC1 has been purified and characterized from different animal tissues, in contrast to VDAC2 which was until now only obtained from bovine spermatozoa [11].

The basic, known function of VDAC is to form a diffusion pore with highly conserved characteristics in the outer mitochondrial membrane (OMM). The OMM functions as a link between mitochondrial metabolism and the rest of the cell. The involvement of VDAC in metabolic pathways and interactions with other supramolecular structures has been investigated [2,4]. VDAC has been implicated to play a significant role in the programmed cell death pathway (for review see [12]). Other recent roles attributed to VDAC were the participation in calcium trafficking in the cell and the interaction with cytoskeletal proteins [4,13-15].

Currently, there is only scant information regarding the expression and the function of VDAC proteins in gametes. In a previous study we reported the presence of VDAC in the outer dense fibers (ODF) of the bovine sperm flagellum [16] and their involvement in the regulation of essential sperm functions [17]. Furthermore, we have obtained and characterized highly enriched VDAC2 from bovine spermatozoa [11].

Steinacker et al. (2000) reported the localization of VDAC in the plasma membrane of *Xenopus laevis* oocytes [18]. The expression and subcellular distributions of Porin 1 and 2 (VDAC1 and 2) were also reported in ovaries of *Drosophila melanogaster* [19,20]. Wang et al., also identified VDAC1 and 2 in two-dimensional electrophoresis analysis of human ovary [21] relating it with a possible role in the atresia of follicles.

At present there is no evidence regarding the presence and the function of VDAC in mammalian oocytes. This work provides the first report of the expression and localization of endogenous VDAC in immature and mature porcine oocytes as well as the purification of VDAC2 from porcine oocytes.

2. Materials and methods

2.1. Collection of oocytes and in vitro maturation Ovaries of pre-pubertal gilts were transported at 37 °C from a local abattoir in physiological saline solution containing 100 mg/ml Kanamycin. Cumulus-oocyte complexes were aspirated from non-atretic follicles (3-6 mm diameter) and only oocytes with evenly granulated cytoplasm and several layers of cumulus cells were selected. The *in vitro* maturation was performed following the method described by Romar [22]. For all experiments, granulosa cell-free immature oocytes (germinal vesicle, GV) and mature oocytes (meiosis II, MII) were used.

2.2. RT-PCR The total cellular RNA extracted from 10 porcine oocytes using an RNeasy mini-kit (Qiagen, Hilden, Germany) was reversibly transcribed into the first-strand cDNA through Omniscript Reverse Transcriptase (Qiagen). The subsequent amplification of the desired genes was performed using Taq DNA polymerase (Eppendorf, Hamburg, Germany) according to the manufacturer's protocol. The primer sequences derived from porcine cDNA sequences (GenBank) were constructed as follows for: *VDAC1*, (5'-CAAAATCTGAGAATGGACTGGAA-3' and 5'-TTGGTGAGAAGGATGAATCAAAG-3') and for *VDAC2*, (5'-AAATCAAAGCTGACAAGGAA-3' and 5'-GACTTTTGCAGAAATGGAAG-3'). As a control for amplification 5' and 3' primers for the GAPDH gene were used (5'-CCAGAAGACTGTGGATGGCC-3' and 5'-CTGACGCCTGCTTCACCACC-3'). The amplification was conducted for 35 cycles at 94 °C for 45 s, annealing temperature (57 °C) for 45 s, and 72 °C for 90 s with a final step of 72 °C for 5 min.

2.3. Protein detection by immunoblotting Oocytes were incubated at 70 °C in a minimum volume of 0.9% NaCl for 1 h, then dissolved 1:1 (v/v) in oocyte sample buffer (5% SDS; 100 mM Tris-HCl, pH 7; 25 mM EDTA; 12% glycerol; 2% bromophenol blue; 10% β-mercaptoethanol) and vortexed for 5 min followed by a last heating step at 95 °C. SDS-PAGE was performed according to Laemmli [23] in 12% (v/v) polyacrylamide gels loaded with an extract from 300 oocytes per lane.

Proteins were subjected to immunoblotting following a published protocol [24]. The antibodies used were AS P1/6 (anti-VDAC1), monoclonal anti-human type I porin (P31HL, Calbiochem, Darmstadt, Germany) and AS P2/45 (anti-VDAC2) at appropriate dilutions. Characterization and specificity of the antibodies has been previously described [16].

2.4. Purification and protein identification by mass spectrometry of oocyte VDAC

Protein samples were prepared from immature oocytes (3300 cells) solubilized in Triton X-100 extraction buffer (2% v/v Triton X-100; 150 mM NaCl; 50 mM Tris-HCl, pH 7.4; 2 mM DTT; 1 mM EDTA; 10 mM benzamidine; 0.2 mM PMSF). The suspension was incubated for 90 min at 4 °C and finally centrifuged at 13800xg for 45 min. The supernatant (extract A) was stored at -80 °C until use. The remaining sediment was subjected to a second solubilization treatment as described above (extract B). The proteins from extract A and B were diluted 1:1 with 2% Triton X-100 extraction buffer. Each extract was applied to a dry hydroxyapatite-celite (2:1 w/w) column [25]. The first two ml of the pass-through (VDAC-containing fraction) were collected separately in 1 ml fractions and stored at -20 °C until use. Both extracts were subjected to semi-preparative SDS-PAGE (12% separating polyacrylamide gels) according to Laemmli [23] and proteins were visualized by staining with SilverQuest (Invitrogen, Karlsruhe, Germany). Protein bands were excised and subsequently subjected to MALDI-TOF mass spectrometry analysis (ChromaTec, Greifswald, Germany). Peptide mass fingerprinting database searching was carried out using available online software (<http://www.matrixscience.com/>).

2.5. Immunocytochemical localization of VDAC proteins For immunofluorescence microscopy, porcine oocytes were fixed in 3.7% (w/v) paraformaldehyde (Sigma, Munich, Germany) in phosphate-buffered-saline (PBS, 120 mM NaCl, 4 mM KH₂PO₄, 10 mM Na₂HPO₄, pH 7.4) for 30 min at room temperature, washed three times for 5 min

in PBS drops and blocked for 1 h with PBS supplemented with 1% skimmed milk powder (EuroClone, Milano, Italy; MP-PBS). Incubation with primary antibody P31HL (anti-VDAC1, Calbiochem), AS P1/6 (anti-VDAC1) and anti-VDAC2 antibody (Santa Cruz, Heidelberg, Germany) was performed for 60 min followed by three washes in 0.1% MP-PBS. Secondary FITC-conjugated antibodies were applied for 30 min: anti-mouse IgG (Sigma) for P31HL antibodies; anti-rabbit IgG (Sigma) for AS P1/6; and anti-goat IgG (Santa Cruz) for anti-VDAC2 antibodies. During the last 5 min of incubation, propidium iodide (100 µg/ml, Sigma) was added to detect maturation stages. Finally, labeled oocytes were mounted onto slides, examined and recorded using a laser scanning confocal microscope (LSM 510, Zeiss Axioplan imaging, Gottingen, Germany). The microscope was equipped with an Argon and HNe1 laser. For the assessment of intracellular localization of VDAC in immature oocytes, the paraformaldehyde-fixed cells were permeabilized for 5 min in 0.1% (v/v) Triton X-100 (Serva, Heidelberg, Germany) in PBS. The antibodies used were monoclonal anti-human type I porin, P31HL (Calbiochem), AS P1/6 (anti-VDAC1), AS P2/45 (anti-VDAC2) and anti-VDAC2 antibody (Santa Cruz) at appropriate dilutions.

3. Results

3.1. RT-PCR RT-PCR revealed that VDAC1 and VDAC2 mRNAs were expressed in porcine oocytes (Figure 1). Amplification of the coding sequences was detected in GV (VDAC1 lane A, VDAC2 lane B) and MII (VDAC1 lane C, VDAC2 lane D) stage oocytes. The primer pairs generated amplicons of 219 bp (VDAC1) and 231 bp (VDAC2) and the positive control GAPDH showed an amplification product of 248 bp in GV and MII (GAPDH, lane A-D). All amplicons were sequenced on both strands (MWG Biotech, Ebersberg, Germany) and confirmed by blasting.

3.2. Protein detection by immunoblotting Figure 2 shows immunoblot results using protein extracts obtained from 300 GV and 300 MII stage oocytes. VDAC proteins detected with the antiserum P1/6 (anti-VDAC1, lanes 1 and 2) and AS P2/45 (anti-VDAC2, lanes 3 and 4) demonstrate the presence of the two VDAC isoforms, VDAC1 and VDAC2, in GV and MII oocyte protein extractions. A strong immunoreaction at the approximate molecular weight of 32 kDa was visible in GV (lane 1) and MII oocytes (lane 2) using anti-VDAC1 antibodies. In contrast, anti-VDAC2 immunodetection presented a different staining pattern between immature and mature oocytes. In immature cells a polypeptide band of approximately 30 kDa was observed; however, a faint immune reaction with a 50-55 kDa peptide was also visible (lane 3). In mature oocytes a single, strong immune reaction was observed at the molecular mass range of 50-55 kDa (lane 4), while the 30 kDa immunoreactive protein band was missing. In control experiments with the respective pre-immune sera, no immunoreactions were noticed (data not shown).

3.3. Purification and protein identification by mass spectrometry of oocyte VDAC The purification procedure of porcine oocyte VDAC was adapted from the method described for mammalian VDAC protein [25]. Proteins from immature porcine oocytes (n = 3300) were isolated by a two-step sequential extraction (extract A and B) as described in Material and Methods.

In extract A, no VDAC protein was detected (data not shown). Extract B contained a single faint protein band of 30-32 kDa in the first fraction (data not shown), while a higher amount was found in the second fraction (Figure 3). The protein band from fraction 2 was excised from the gel and subjected to MALDI-TOF MS followed by PMF analyses. The number of peptides matched covered 31% of the VDAC2 (*Sus scrofa*) protein.

3.4. Immunocytochemical localization of VDAC proteins in porcine oocytes In Figure 4 (A-C), GV stage non-permeabilized oocytes were prepared and assayed with anti-VDAC antibodies. Anti-VDAC1 antiserum, AS P1/6, and monoclonal anti-human type 1 VDAC antibodies, P31HL (Calbiochem), yielded a dense dot-like arrangement of fluorescent labeling primarily confined to the oocyte surface (Figure 4, A and B). For the polyclonal antibody AS P1/6, additional staining of the zona pellucida was observed (Figure 4 A, arrow). No distinct labeling of the oocyte surface was observed in control oocytes, which were treated only with the second antibody and the respective pre-immune serum or IgG_{2a} (Figure 4, C). VDAC2 antibodies (Santa Cruz) displayed no fluorescent labeling; however, some cells exhibited signs of lesions and disturbance of cell integrity (data not shown).

For the assessment of intracellular VDAC polypeptides, membrane-permeabilized oocytes (GV and MII stage) were probed with anti-VDAC antibodies. Oocytes were completely scanned and photographed in three planes; however, mainly the equatorial plane data was included since it gave the most descriptive information.

As shown in Figure 4 for GV stage oocytes (D), the antiserum against VDAC1, AS P1/6 (D), presented a dense immunofluorescence labeling around the cortical area of the oocyte. Identical results were observed when immature oocytes were probed with another anti-VDAC1 antibody, P31HL (Calbiochem, data not shown). The assessment of MII porcine oocytes with both anti-VDAC1 antibodies yielded the same immunofluorescence pattern that has been observed in GV stage porcine oocytes (data not shown).

By using anti-VDAC2 antibodies from Santa Cruz, immunolabeling was observed in most of the GV oocytes tested (Figure 4, E). In these immunofluorescence-positive cells, variable spherical clusters, not evenly distributed throughout the cortical area, were detected (details observed in the oocyte cortical area of Figure 4, F). However, when porcine MII oocytes were tested with anti-VDAC2 antibodies from Santa Cruz, no specific reaction was observed (data not shown). The anti-VDAC2 antibody (AS P2/45) displayed no specific fluorescence labeling in immature and mature porcine oocytes (data not shown).

4. Discussion

In previous studies, we reported the expression, localization and functional characterization of VDAC isoforms in bovine testis and spermatozoa [11,16,26]. Furthermore, we presented new results that indicate the participation of VDAC proteins in essential sperm functions [17]. In relation VDAC in mammal oocytes have not yet been investigated.

Using RT-PCR, we demonstrated for the first time the expression of VDAC1 and VDAC2 within immature (GV) and *in vitro*-matured (MII) porcine oocytes. The amplification products detected in porcine oocytes corresponded to the published coding sequence. The presence of additional sequences corresponding to an unspliced variant,

as has been described previously for Porin 2 (VDAC2) in *Drosophila melanogaster*, remains to be elucidated [19].

Specific antibodies generated against VDAC1 and VDAC2 allowed investigation of the expression pattern of VDAC proteins in oocytes. Immunoblot analyses demonstrated the expression of VDAC1 in GV and MII maturation stages. Testing of immature porcine oocytes with anti-VDAC2 antibodies yielded VDAC2 protein having the same molecular weight range of about 30-32 kDa as has been reported for sperm VDAC2 [16]. Additionally, we noticed a faint immunoreactive band with a higher molecular weight of approximately 50-55 kDa. Interestingly, in mature oocytes (MII) only a single, strong immunoreaction with anti-VDAC2 antibodies was observed with the 50-55 kDa protein band while the original immunoreactive 30-32 kDa VDAC protein disappeared. This result enhances the hypothesis of the expression of two VDAC2 sub-isoforms, with different polypeptide lengths, and with a pattern of similar post-translational modifications [11]. Guarino et al. (2006) suggested that a high molecular weight VDAC protein in drosophila ovaries could be the product of mRNA still containing intron sequences.

We sought to further investigate the identity of the immunoreactive protein bands by purifying porcine oocyte VDAC proteins to apparent homogeneity and subsequent sequencing of the polypeptides using hydroxyapatite/celite purification [25] and MALDI TOF MS analyses, respectively. To obtain sufficient material for sequencing, high amounts of granulosa cell-free oocytes and a two-step protein extraction were necessary. Here we report, to our knowledge for the first time, the purification of the 30-32 kDa VDAC2 protein from mammalian immature oocytes.

The VDAC1 and the VDAC2 immuno-related 50-55 kDa polypeptide, identified by immunological methods in immature porcine oocytes, could not be detected in the VDAC protein-containing hydroxyapatite/celite throughput. Presumably, the amount of these proteins was too low or the proteins were retained in the hydroxyapatite/celite column [27].

Having identified VDAC proteins in mature and immature porcine oocytes, the subcellular distribution of these proteins was studied. The cytochemical analyses of nonpermeabilized oocytes with anti-VDAC1 antibodies could reveal the presence of VDAC1 in the plasma membrane region. Very similar staining patterns were obtained with the two different anti-VDAC1 antibodies. However, AS P1/6 (antiserum), additionally displayed immunofluorescence of the zona pellucida. Compared with the specific staining pattern of the monoclonal anti-VDAC1 antibody P31HL (Calbiochem), this observation most probably is due to nonspecific binding to this extracellular oocyte matrix.

The fluorescence pattern of anti-VDAC1 antibodies is reminiscent of the cytological staining observed in *Xenopus laevis* oocytes [18]. Furthermore, the dot-wise labeling pattern at the cell surface suggests a plasma membrane localization of VDAC1. Because the oocytes assayed in our study were not permeabilized, we assume that the VDAC1 epitopes detected by the two antibodies are localized at the extracellular plasma membrane domain of the oocyte. The first evidence for an extra-mitochondrial localization of VDAC protein in the plasma membrane of human B lymphocytes was published in 1989 [28]. Several reports on the presence of VDAC as an integral membrane protein of various kinds of cells and organelles supported this study [2,3,29-31]. Our results confirm the localization of VDAC1 in the plasma membrane of porcine oocytes; however, no information on the function of plasma membrane-bound VDAC1

in oocytes is yet available. Several studies suggest that VDAC in the plasma membrane of somatic cell types act as anion channels involved in volume regulatory mechanisms [32,33]. The participation of VDAC1 in the volume regulatory process of mammalian spermatozoa was reported recently for gametes [17]. VDAC2 was not observed in the oocyte plasma membrane, suggesting separate localizations and functions of both isoforms in the oocyte.

After having found that anti-VDAC 1 antibodies bind to the outer surface of the oocyte plasma membrane, we were interested to identify VDAC proteins in the ooplasm of immature and mature porcine oocytes. Using confocal microscopy, it was possible to detect VDAC1 and VDAC2 proteins in different localizations of the porcine ooplasm. VDAC1 was clearly observed at the cortical area of immature and mature oocytes. Thus, the distribution of VDAC1 proteins seemed to be stable throughout the meiotic maturation. In the literature, it has been reported that in the GV stage of mammalian oocytes, actin filaments are distributed as a relatively thick, uniform area around the cell cortex and are also found near the germinal vesicle. After germinal vesicle breakdown (GVBD), microfilaments are predominantly found at the cortex of the cell and around the female chromatin [34]. The interaction of VDAC with other cellular proteins, especially those of the cytoskeleton, has been reported in recent years [15,35]. G-actin has been demonstrated to modulate VDAC gating in *Neurospora crassa* [14], whereas in HeLa cells the dynein light chain Tctex1 was shown to regulate VDAC [13]. Furthermore, VDAC were identified as binding sites for microtubule-associated protein 2 (MAP2) in the outer membrane of rat brain mitochondria [15,36]. The localization of VDAC1 at the cortical area of the oocyte might indicate an interaction of VDAC1 with cytoskeleton proteins that are predominantly found in this area of the cell.

The observed pattern of VDAC1 distribution could also suggest a mitochondrial localization. The presence of VDAC protein on the outer membrane of mitochondria from eukaryotic cells is well established [37,38]. During porcine oocyte maturation, the distribution of oocyte mitochondria was reported in the perinuclear area in GV stage oocytes, and large mitochondrial foci form and relocate to the inner cytoplasm in mature oocytes [39]. In mouse oocytes, mitochondria are clustered at the periphery of the large nucleus and the cortical area, but they disperse through the cytoplasm during maturation. This pattern of distribution may be related to the high energy requirement in the cortex, as the oocyte requires the support of cumulus cells at this stage [39].

Staining patterns observed with anti-VDAC2 antibodies differed from that of the VDAC1 isoform. In immature porcine oocytes, VDAC2 antigen was detected as distinct but not evenly distributed spherical clusters throughout the cortical area of the ooplasm. Thus, it can be speculated that VDAC1 and VDAC2 are present in different intracellular compartments of the oocyte. Our results implicate that in oocytes VDAC subtypes might be involved in the regulation of different cell functions (e.g. cell maturation or apoptosis). However, the exact localization and role of VDAC in the regulation of particular oocyte functions remain to be investigated.

In mature oocytes, the labeling pattern of VDAC2 protein completely disappeared after *in vitro* maturation, apparently indicating an interrelation of VDAC2 distribution or integrity with the cell's developmental stage. Nevertheless, the lack of immunoreactivity observed in mature oocytes could be also explained with a post-translational change of the conformation of VDAC2 protein that hinders binding of the antibody to the native protein. It has been shown previously that some of the oocyte organelles exhibit dramatic changes during meiotic progression. Although VDAC were

originally thought to be only located in the OMM, several investigations reported the presence in other cell compartments, e.g. nuclear envelope, endosomes, sarcoplasmic/endoplasmic reticulum, caveolae and other organelles of somatic cells [3,4,40-42]. The distribution of caveolae in *Caenorhabditis elegans* oocytes [43] resembles that observed in our immunofluorescence studies with anti-VDAC2. However, preliminary double staining experiments, containing anti-VDAC2 and anti-Caveolin 1 antibodies, showed only a partial overlapping of both proteins. More research is essential to determine VDAC localization in these or other organelles in mammalian oocytes.

Anti-VDAC2 antibodies clearly exhibited different labeling patterns within immature oocytes. In the future it will be of great interest to study if the difference observed in VDAC2 labeling is conditioned to individual characteristics of each oocyte (e.g. oocyte quality). The identification of quality markers for oocyte fertilization capacity would be of great help in clinical applications and *in vitro* production.

The data obtained for VDAC2 using immunofluorescence are in line with the immunoblot experiments performed in this study, where shifts of apparent molecular masses of VDAC antigens during maturation were detected. The immunoreactive band at 30-32 kDa was no longer found after oocyte maturation, and a strong immunoreaction was observed in the 50-55 kDa molecular weight range. The 50-55kDa anti-VDAC antigen, which is evidently the only VDAC2-related protein in the ooplasm of mature oocytes, could possibly represent a homodimerization/oligomerization product of these integral membrane proteins [44-46] or a tight complex of VDAC with other polypeptides [35]. However, it is tempting to speculate that either alterations of intracellular distribution of VDAC2 or protein-protein interactions of VDAC isoforms are causally related to the shift of apparent molecular masses during the maturation of oocytes.

The identification and localization of VDAC isoforms in different compartments of maturing porcine oocytes unveiled in this study could be the basis for better understanding of the molecular mechanisms of oocyte functions as well as the basis for novel clues concerning the role of VDAC proteins in the regulation of physiological processes of cells.
