Abstract

The theory of Petri Nets provides a general framework to specify the behaviors of real-time reactive systems and Time Petri Nets were introduced to take also temporal specifications into account. We present in this paper a forward zone-based algorithm to compute the state space of a bounded Time Petri Net: the method is different and more efficient than the classical State Class Graph. We prove the algorithm to be exact with respect to the reachability problem. Furthermore, we propose a translation of the computed state space into a Timed Automaton, proved to be timed bisimilar to the original Time Petri Net. As the method produce a single Timed Automaton, syntactical clocks reduction methods (Daws and Yovine for instance) may be applied to produce an automaton with fewer clocks. Then, our method allows to model-check T-TPN by the use of efficient Timed Automata tools.

KEYWORDS: Time Petri Nets, Timed Automata, Bisimulation, Reachability Analysis, Zones.

1 Introduction

Framework

The theory of Petri Nets provides a general framework to specify the behaviors of real-time reactive systems and time extensions were introduced to take also temporal specifications into account. The two main time extensions of Petri Nets are Time Petri Nets (TPN) (Merlin 1974) and Timed Petri Nets (Ramchandani 1974). While a transition can be fired within a given interval for TPN, in Timed Petri Nets, transitions are fired as soon as possible. There are also numerous ways of representing time. TPN are mainly divided in P-TPN, A-TPN and T-TPN where a time interval is relative to places (P-TPN), arcs (A-TPN) or transitions (T-TPN). Finally, Time Stream Petri Nets (Diaz and Senac 1994) were introduced to model multimedia applications.

Concerning the timing analysis of these three models ((T,P,A)–TPN), few studies have been realized about model-checking.
Recent works (Abdulla and Nylén 2001; de Frutos Escrig et al. 2000) consider Timed Arc Petri Nets where each token has a clock representing its “age”. Using a backward exploration algorithm (Abdulla and Jonsson 1998; Finkel and Schnoebelen 1998), it is proved that the coverability and boundedness are decidable for this class of Petri Nets. However, they assume a lazy (non-urgent) behavior of the net: the firing of a transition may be delayed even if its clock’s value becomes greater than its latest firing time, disabling the transition.

In (Rokicki 1993; Rokicki and Myers 1994), Rokicki considers an extension of labeled Petri Nets called Orbitals Nets: each transition of the TPN (safe P-TPN) is labeled with a set of events (actions). The state space is built using a forward algorithm very similar to Alur and Dill region based method. Rokicki finally uses partial order method to reduce time and space requirements for verification purpose. The semantics used is not formally defined and seems to differ from another commonly adopted proposed by Khansa (Khansa et al. 1996) for P-TPN.

In this paper, we consider T-TPN in which a transition can be fired within a time interval. For this model, boundedness is undecidable and works report undecidability results, or decidability under the assumption of boundedness of the T-TPN (as for reachability, decidability (Popova 1991)).

Related Works

State Space Computation of a T-TPN. The main method to compute the state space of a T-TPN is the State Class Graph (Menasche 1982; Berthomieu and Diaz 1991). A class $C$ of a T-TPN is a pair $(M, D)$ where $M$ is a marking and $D$ a set of inequalities called the firing domain. The variable $x_i$ of the firing domain represents the firing time of the enabled transition $t_i$ relatively to the time when the class $C$ was entered in and truncated to nonnegative times. The State Class Graph preserves markings (Berthomieu and Vernadat 2003) as well as traces and complete traces but can only be used to check untimed reachability properties and is not accurate enough for checking quantitative real-time properties. An alternative approach has been proposed by Yoneda et al. (Yoneda and Ryuba 1998) in the form of an extension of equivalence classes (atomic classes) which allow CTL model-checking. Lilius (Lilius 1999) refined this approach so that it becomes possible to apply partial order reduction techniques that have been developed for untimed systems. Berthomieu and Vernadat (Berthomieu and Vernadat 2003) propose an alternative construction of the graph of atomic classes of Yoneda applicable to a larger class of nets. In (Okawa and Yoneda 1997), Okawa and Yoneda propose another method to perform CTL model-checking on T-TPN, they use a region based algorithm on safe T-TPN without $\infty$ as latest firing time. Their algorithm is based on the one of (Alur and Dill 1994) and aims at computing a graph preserving branching properties. Nevertheless, the algorithm used to construct the graph seems inefficient (their algorithm do code regions) and no result can be exploited to compare with other methods.
From T-TPN to TA. Several approaches aim at translating a Time Petri Net into a Timed Automaton in order to use efficient existent tools on TA. In (Cortès et al. 2000), Cortès et al. propose to transform an extension of T-TPN into the composition of several TA. Each transition is translated into an automaton (not necessarily identical due to conflict problems) and it is claimed that the composition captures the behavior of the T-TPN. In (Cassez and Roux 2004), Cassez and Roux propose another structural approach: each transition is translated into a TA using the same pattern. The authors prove the two models are timed bisimilar. In (Sava and Alla 2001), Sava and Alla compute the graph of reachable markings of a T-TPN. The result is a TA. However, they assume the T-TPN is bounded and does not include $\infty$ as latest firing time. No proof is given of the timed bisimilarity between the two models. In (Lime and Roux 2003), Lime and Roux propose a method for building the State Class Graph of a bounded T-TPN as a TA. They prove the T-TPN to be timed bisimilar to the generated TA.

Considering the translation of T-TPN into TA, in order to study model’s properties, raises the problem of the model-checking feasibility of the resulting TA. The model-checking complexity on TA is exponential in the number of clocks of the TA. The proposed transformation in (Cassez and Roux 2004; Cortès et al. 2000) is to build as many TA as the number of transitions of the T-TPN. Consequently, there are as many clocks as in the initial T-TPN. It has also to be considered that reduction method (Daws and Yovine 1996) can not be applied to the resulting TA: the parallel composition has to be computed first. Nevertheless, the construction of TA is straightforward and linear in the number of transitions of the T-TPN. Concerning the method in (Lime and Roux 2003), the resulting TA has a lower number of clocks. The method we propose produces an automaton with more clocks than the previous method but its computation is faster.

Such translations show that TCTL and CTL are decidable for bounded T-TPN and that developed algorithms on TA may be extended to T-TPN.

Contributions

This paper is devoted to presenting an alternative approach to the state space construction of a T-TPN. The method is mainly based upon the region graph algorithm of Alur and Dill on Timed Automaton. We propose to use a derived method using zones to compute the state space of the T-TPN. The algorithm is proved to be exact with respect to the reachability problem and we propose to translate the state space it computes into a Timed Automaton, bringing so the power of TA model-checking algorithms to T-TPN.

We first recall the semantics of T-TPN and present a forward zone-based algorithm that computes the state space of a T-TPN. Next, we present the labeling of the state space that produces a TA we proved to be timed bisimilar to the original T-TPN. We then compare our method to other used methods on T-TPN and show its advantages. Finally, some applications are proposed.
2 Time Petri Nets

2.1 Definitions

Time Petri Nets (T-TPN) are a time extension of classical Petri Nets. Informally, with each transition of the Net is associated a clock and a time interval. The clock measures the time since the transition has been enabled and the time interval is interpreted as a firing condition: the transition may fire if the value of its clock belongs to the time interval.

Formally:

Definition 1 (T-TPN)

A Time Petri Net is a tuple \((P, T, \cdot, \cdot, \cdot, \cdot, \alpha, \beta, M_0)\) defined by:

- \(P = \{p_1, p_2, \ldots, p_m\}\) is a non-empty set of places,
- \(T = \{t_1, t_2, \ldots, t_n\}\) is a non-empty set of transitions,
- \(\cdot : T \rightarrow \mathbb{N}^P\) is the backward incidence function,
- \(\cdot : T \rightarrow \mathbb{N}^P\) is the forward incidence function,
- \(M_0 \in \mathbb{N}^P\) is the initial marking of the Petri Net,
- \(\alpha : T \rightarrow \mathbb{Q}_{\geq 0}\) is the function giving the earliest firing times of transitions,
- \(\beta : T \rightarrow \mathbb{Q}_{\geq 0} \cup \{\infty\}\) is the function giving the latest firing times of transitions.

A Petri Net marking \(M\) is an element of \(\mathbb{N}^P\) such that for all \(p \in P\), \(M(p)\) is the number of tokens in the place \(p\).

A marking \(M\) enables a transition \(t\) if: \(M \geq \cdot t\). The set of transitions enabled by a marking \(M\) is \(\text{enabled}(M)\).

A transition \(t_k\) is said to be newly enabled by the firing of a transition \(t_i\) if \(M - \cdot t_i + \cdot t_k\) enables \(t_k\) and \(M - \cdot t_i\) did not enable \(t_k\). If \(t_i\) remains enabled after its firing then \(t_i\) is newly enabled. The set of transitions newly enabled by a transition \(t_i\) for a marking \(M\) is noted \(\uparrow \text{enabled}(M, t_i)\).

\(v \in (\mathbb{R}_{\geq 0})^T\) is a valuation of the system. \(v_i\) is the time elapsed since the transition \(t_i\) has been newly enabled.

The semantics of T-TPN is defined as a Timed Transition Systems (TTS). Firing a transition is a discrete transition of the TTS, waiting in a marking, the continuous transition.

Definition 2 (Semantics of a T-TPN)

The semantics of a T-TPN is defined by the Timed Transition System \(S = (Q, q_0, \rightarrow)\):

- \(Q = \mathbb{N}^P \times (\mathbb{R}_{\geq 0})^T\)
- \(q_0 = (M_0, 0)\)
- \(\rightarrow \in Q \times (T \cup \mathbb{R}_{\geq 0}) \times Q\) is the transition relation including a discrete transition and a continuous transition.

- The continuous transition is defined \(\forall d \in \mathbb{R}_{\geq 0}\) by:

\[(M, v) \xrightarrow{e(d)} (M, v') \iff \begin{cases} v' = v + d \\ \forall k \in [1, n] M \geq \cdot t_k \Rightarrow v' \leq \beta(t_k) \end{cases}\]
The discrete transition is defined \( \forall t_i \in T \) by:

\[
(M, v) \overset{t_i}{\rightarrow} (M', v') \iff \alpha(t_i) \leq v_i \leq \beta(t_i)
\]

\[
M' = M - \bullet t_i + \bullet t_i
\]

\[
\forall k \in [1, n], v_k' = \begin{cases} 
0 & \text{if } t_k \in \uparrow enabled(M, t_i) \\
v_k & \text{otherwise}
\end{cases}
\]

### 2.2 The State Class Method

The main method for computing the state space of a Time Petri Net is the State Class Method introduced by Berthomieu and Diaz in (Berthomieu and Diaz 1991).

**Definition 3 (State Class)**

A State Class \( C \) of a T-TPN is a pair \( (M, D) \) where \( M \) is a marking and \( D \) a set of inequalities called the firing domain. The variable \( x_i \) of the firing domain represents the firing time of the enabled transition \( t_i \) relatively to the time when the class \( C \) was entered in.

The State Class Graph is computed iteratively as follows:

**Definition 4**

Given a class \( C = (M, D) \) and a firable transition \( t_j \), the successor class \( C' = (M', D') \) by the firing of \( t_j \) is obtained by:

1. Computing the new marking \( M' = M - \bullet t_j + \bullet t_j \).
2. Making variable substitution in the domain: \( \forall i \neq j, x_i \leftarrow x_i' + x_j \).
3. Eliminating \( x_j \) from the domain using for instance the Fourier-Motzkin method.
4. Computing a canonical form of \( D' \) using for instance the Floyd-Warshall algorithm.

In the state class method, the domain associated with a class is relative to the time when the class was entered in and as the transformation (time origin switching) is irreversible, absolute values of clocks cannot be obtained easily. The produced graph is an abstraction of the state space for which temporal information has been lost and generally, the graph has more states than the number of markings of the T-TPN. Transitions between classes are no longer labeled with a firing constraint but only with the name of the fired transition: the graph is a representation of the untimed language of the T-TPN.

### 2.3 Limitations of the State Class Method

As a consequence of the State Class Graph construction, sophisticated temporal properties are not easy to check. Indeed, the domain associated with a marking is made of relative values of clocks and the function to compute domains is not bijective. Consequently, domains can not easily be used to verify properties involving constraints on clocks.
In order to get rid of these limitations, several works construct a different State Class Graph by modifying the equivalence relation between classes. To our knowledge, proposed methods (Berthomieu and Vernadat 2003) depend on the property to check. Checking LTL or CTL properties will lead to construct different State Class Graphs.

Another limitation of methods and proposed tools to check properties is the need to compute the whole state space while only the reachability of a given marking is needed (e.g. for safety properties). The graph is then analyzed by a model-checker. The use of T-TPN observers is even more costly: actually, for each property to be checked, a new State Class Graph has to be built and the observer can dramatically increase the size of the state space.

In the next section we will present another method to compute the state space of a bounded T-TPN. It will be used in a later section to propose a Timed Automaton that is timed bisimilar to the original T-TPN. As the graph has exactly as many nodes as the number of reachable markings of the T-TPN, we obtain a compact representation of the state space which may be efficiently model-checked using TA tools.

3 A Forward Algorithm to Compute the State Space of a Bounded T-TPN

The method we propose in this paper is an adaptation, proved to be exact, of the region based method for Timed Automaton (Alur and Dill 1994; Rokicki 1993). This algorithm starts from the initial state and explores all possible evolutions of the T-TPN by firing transitions or by elapsing a certain amount of time.

First, we define a zone as a convex union of regions as defined by Alur and Dill (Alur and Dill 1994). For short, considering $n$ clocks, a zone is a convex subset of $(\mathbb{R}_{\geq 0})^n$. A zone could be represented by a conjunction of constraints on clocks pairs: $x_i - x_j \sim c$ where $\sim \in \{<, \leq, =, \geq, >\}$ and $c \in \mathbb{Z}$.

3.1 Our Algorithm: One Iteration

Given the initial marking and initial values of clocks (null vector), timing successors are iteratively computed by letting time pass or by firing transitions.

Let $M_0$ be a marking and $Z_0$ a zone. The computation of the reachable markings from $M_0$ according to the zone $Z_0$ is done as follows:

- Compute the possible evolution of time (future): $\bar{Z}_0$. This is obtained by setting all upper bounds of clocks to infinity.
- Select only the possible valuations of clocks for which $M_0$ could exist, i.e. valuations of clocks must not be greater than the latest firing time of enabled transitions:

$$Z_0' = \bar{Z}_0 \cap \left\{ x_i \leq \beta_i \mid t_i \in \text{enabled} (M_0) \right\}$$

So, $Z_0'$ is the maximal zone starting from $Z_0$ for which the marking $M_0$ is legal according to the T-TPN semantics.
• Determine the firable transitions: $t_i$ is firable if $Z'_0 \cap \{ x_i \geq \alpha_i \}$ is a non empty zone.
• For each firable transition $t_i$ leading to a marking $M_{0i}$, compute the zone entering the new marking:

$$Z_i = (Z'_0 \cap \{ x_i \geq \alpha_i \}) [X_c := 0],$$

where $X_c$ is the set of clocks of newly enabled transitions.

This means that each transition which is newly enabled has its clock reset. Then, $Z_i$ is a zone for which the new marking $M_{0i}$ is reachable.

### 3.2 Convergence Criterion

To ensure termination, a list of zones is associated with each reachable marking. It will keep track of zones for which the marking was already analyzed or will be analyzed. At each step, we compare the zone currently being analyzed to the ones previously computed. If the zone is included in one of the list there is no need to go further because it has already been analyzed or it will lead to compute a subgraph.

### 3.3 Unboundedness in T-TPN

An algorithm to enumerate reachable markings for a bounded T-TPN could be based on the described algorithm but, generally, it will lead to a non-terminating computation. Though the number of reachable markings is finite for a bounded T-TPN, the number of zones in which a marking is reachable is not necessarily finite (see figure 1).

![Time Petri Net with an unbounded number of zones](image)

Let us consider the infinite firing sequence: $(T_3, T_3)^\ast$. The initial zone is $\{ x_1 = 0 \land x_2 = 0 \land x_3 = 0 \}$ (where $x_i$ is the clock associated with $T_i$), the initial marking $M_0 = (P_1, P_2, P_3) = (1, 1, 0)$. By letting time pass, $M_0$ is reachable until $x_2 = 1$. When $x_2 = x_1 = 1$ the transition $T_2$ has to be fired. The zone corresponding to clock values is: $Z_0 = \{ 0 \leq x_1 \leq 1 \land x_1 = x_2 = 0 \}$. By firing $T_2$ and then $T_3$, the net returns to its initial marking. Entering it, values of clocks are: $x_1 = 2$, $x_2 = 0$ and $x_1 - x_2 = 2$. Indeed, $T_1$ remains enabled while $T_2$ and $T_3$ are fired and $x_2$ is reset when $T_3$ is fired because $T_3$ is newly enabled. Given these new values, the initial marking can exists while $x_2 \leq 1$ i.e. for the zone: $Z_1 = \{ 2 \leq x_1 \leq 3 \land x_1 - x_2 = 2 \}$.
By applying infinitely the sequence \((T_2, T_3)\), there exists an infinite number of zones for which the initial marking is reachable.

Actually, the number of zones is not bounded because infinity is used as latest firing time \((T_1)\). If infinity is not used as latest firing time, all clocks are bounded and so, the number of different zones is bounded (Alur and Dill 1994). The “naive” algorithm is then exact and can be used to compute the state space of a bounded T-TPN.

Consequence 1
For a bounded T-TPN without infinity as latest firing time, this forward analysis algorithm using zones computes the exact state space of the T-TPN.

In the next section, we propose a more general algorithm which computes the state space of a T-TPN as defined in section 2, i.e. with infinity as latest firing time allowed.

### 3.4 General Algorithm

A common operator on zones is the \(k\text{-approx}\) operator. For a given \(k\) value, the use of this operator allows to create a finite set of distinct zones. The algorithm proposed is an extension of the one presented in the previous section. It consists in applying the \(k\text{-approx}\) operator on the zone resulting from the last step:

\[
Z_i = k\text{-approx}(\{Z' \cap \{x_i \geq \alpha_i\}\})[X_e := 0]
\]

This approximation is based on the fact that once the clock associated with an unbounded transition \([\alpha, \infty[\) has reached the value \(\alpha\), its precise value does not matter anymore.

Unfortunately recent works on Timed Automaton (Bouyer 2002; Bouyer 2003) proved that this operator generally leads to an overapproximation of the reachable localities of TA. However, for a given class of TA (diagonal-free), there is no overapproximation of the reachable localities.

Results of Bouyer are directly extensible for T-TPN. As computation on zones only involved diagonal-free constraints, the following theorem holds:

**Theorem 1**

A forward analysis algorithm using \(k\text{-approx}\) on zones is exact with respect to T-TPN marking reachability for bounded T-TPN.

A detailed proof is available in (Gardey et al. 2003).

### 3.5 Example

Let us consider the T-TPN of figure 1.

We associate the clock \(x_i\) with the transition \(T_i\) of the T-TPN and recall that clocks associated with each transition count the time since the transition has been newly enabled.
The algorithm starts from the initial state: \( l_0 = (M_0, Z_0) \), with \( M_0 = (1 \ 1 \ 0) \) and \( Z_0 = \{x_1 = x_2 = 0\} \). At marking \( M_0 \), transitions \( T_1 \) and \( T_2 \) are enabled.

The first step is to compute the possible future, i.e. the maximal amount of time for which the marking \( M_0 \) may exist:

\[
\exists x_1, x_2 \in [0, \infty) \cap \{x_1 \leq \infty \land x_2 \leq 1\}
\]

From this zone, two transitions are firable: \( T_1 \) and \( T_2 \).

**Firing of \( T_1 \)**

- the new marking is \( M_1 = (0 \ 1 \ 0) \)
- the new zone is obtained by intersecting the previous zone \( Z_0 \cap \text{Inv}(M_0) \) with the guard \( x_1 \geq 0 \), deleting clocks of transitions that are no longer enabled in \( M_1 \) \((x_1)\) and resetting clocks of newly enabled transitions (none).

\[
Z_1 = \{x_1 = x_2 \in [0, 1]\} \cap \{x_1 \geq 0\} \quad \text{(intersect with guard)}
\]

\[
= \{x_1 = x_2 \in [0, 1]\}
\]

\[
= \{x_2 \in [0, 1]\} \quad \text{(delete } x_1)\]

**Firing of \( T_2 \)**

- the new marking is \( M_3 = (1 \ 0 \ 1) \)
- the new zone is obtained by intersecting the previous zone \( Z_0 \cap \text{Inv}(M_0) \) with the guard \( x_2 \geq 1 \), deleting clocks of transitions that are no longer enabled in \( M_3 \) \((x_2)\) and resetting clocks of newly enabled transitions \((x_3)\).

\[
Z_3 = \{x_1 = x_2 \in [0, 1]\} \cap \{x_2 \geq 1\} \quad \text{(intersect with guard)}
\]

\[
= \{x_1 = x_2 = 1\}
\]

\[
= \{x_1 = 1\} \quad \text{(delete } x_2)\]

\[
= \{x_1 = 1 \land x_3 = 0\} \quad \text{(reset } x_3)\]

We got two new states to analyze: \((M_1, Z_1)\) and \((M_3, Z_3)\). We apply the same algorithm to these two states.

Considering \((M_1, Z_1)\):

\[
Z'_1 = Z_1 \cap \text{Inv}(M_1) = \{x_2 \in [0, 1]\} \cap \{x_2 \leq 1\}
\]

\[
= \{x_2 \in [0, 1]\}
\]

\(T_2\) is firable and leads to the new state: \((M_2, Z_2)\) with \( M_2 = (0 \ 0 \ 1) \) and \( Z_2 = \{x_3 = 0\} \). Analyzing \((M_2, Z_2)\) leads to the new state \((M_1, \{x_2 = 0\})\). As \( x_2 = 0 \) \( \subseteq Z_1 \), the algorithm stops and get a new state to analyze: \((M_3, Z_3)\).

Considering \((M_3, Z_3)\):

\[
Z'_3 = Z_3 \cap \text{Inv}(M_3) = \{x_1 - x_3 = 1, x_1 \in [0, \infty]\} \cap \{x_1 \leq \infty \land x_3 \leq 1\}
\]

\[
= \{x_1 - x_3 = 1 \land x_3 \leq 1\}
\]

\(T_3\) and \(T_1\) are firable...
The analysis is performed until no new states are created. We then build the following graph of reachable markings.

Figure 2. Graph of reachable markings

In this section we have presented an algorithm that exactly computes the reachable markings of a bounded T-TPN with $\infty$ as latest firing time. The graph computed is not suitable to verify time logic properties. So, in the next section we present a transformation of the graph into a Timed Automaton we proved to be timed bisimilar to the original T-TPN. Consequently, model-checking methods on TA become available for the model-checking of T-TPN.

4 Marking Timed Automaton of Time Petri Net

We first recall the definition of Timed Automata, introduced by Alur and Dill (Alur and Dill 1994) and their semantics.

4.1 Timed Automaton: Definitions

Timed Automata are an extension of classical automata providing timing constraints. A transition can occur if clocks valuations satisfy constraints called “guard”. Actions on clocks (reset for instance) are associated with transition. The system can idle in a locality if valuations of clocks satisfy some constraints called “invariant”.

**Definition 5 (Constraints)**

Let $V$ be a set of clocks, $C(V)$ is the set of timing constraints upon $V$ i.e. the set of expressions $\delta$ defined by:

$$\delta := v \sim c \mid v - v' \sim c \mid \neg \delta_1 \mid \delta_1 \land \delta_2$$

with $v, v' \in V$, $\sim \in \{<, \leq, =, \geq, >\}$ and $c \in \mathbb{N}$.

**Definition 6 (TA)**

A Timed Automaton is a tuple $(L, l_0, C, A, E, Inv)$ defined by:

- $L$ a finite set of locations,
- $l_0 \in L$ the initial location,
- $C$ a finite set of positive real-valued clocks,
- $A$ a finite set of actions,
• $E \subset L \times C(C) \times A \times 2^C \times L$ a finite set of transitions. $e = (l, \gamma, a, R, l')$ is the transition from location $l$ to location $l'$ with the guard $\gamma$, the label $a$ and the set of clocks to reset $R$.

• $Inv : L \times C(C) \rightarrow \{true, false\}$, a function assigning to each location an invariant.

The semantics of a Timed Automaton is given by a Timed Transition System (TTS).

**Definition 7 (Semantics of a TA)**
The semantics of a Timed Automaton is the Timed Transition System $S = (Q, Q_0, \rightarrow)$ where:
- $Q = L \times (\mathbb{R}_{\geq 0})^C$,
- $Q_0 = (l_0, 0)$,
- $\rightarrow$ is the transition relation including a discrete transition and a continuous transition.

• The discrete transition is defined $\forall a \in A$ by:
  
  $$(l, v) \xrightarrow{a} (l', v') \text{ iff } \exists (l, \gamma, a, R, l') \in E \text{ such as : } 
  \begin{cases} 
  \gamma(v) = true \\
  v' = v[R \leftarrow 0] \\
  Inv(l')(v') = true
  \end{cases}$$

• The continuous transition is defined $\forall d \in \mathbb{R}_{\geq 0}$ by:
  
  $$(l, v) \xrightarrow{\epsilon(d)} (l, v') \text{ iff } v' = v + d \\
  \forall t' \in [0, d], \ Inv(l)(v + t') = true$$

### 4.2 Labeling algorithm

The algorithm given in section 3 represents the marking graph of the T-TPN. We show here that it can easily be labeled to generate a Timed Automaton timed bisimilar to the T-TPN.

Let $G = (M, T)$ be the graph produced by the algorithm where:
- $M$ is the set of reachable markings of the T-TPN: $M_0, \ldots, M_p$
- $T$ is the set of transitions: $T_0, \ldots, T_q$

The Timed Automaton will be obtained by associating to each marking an invariant and to each transition a guard and some clocks assignments.

#### 4.2.1 Invariant

First, an invariant is associated with each marking $M_k$. By construction, in each marking, only the possible evolution of time is computed: the entering zone is intersected with the set of constraints $\{x_i \leq \beta_i\}$, where $x_i$ are clocks of transitions enabled by the marking $M_k$. Then, the invariant associated with each marking $M_k$ is defined by:

$$I(M_k) = \{x_i \leq \beta_i \mid t_i \in enabled(M_k)\}$$
4.2.2 Guard

Each transition $T_k$ of the graph $G$ corresponds to the firing of a transition $t_i$. Then we label $T_k$ by:

- the action name $t_i$,
- the guard: $x_i \geq \alpha_i$,
- the clocks assignments: $x_k \leftarrow 0$ for all clocks $x_k$ associated with a newly enabled transition $t_k$

4.3 Marking Timed Automaton

The Timed Automaton we obtain is then defined as follows:

**Definition 8 (Marking Timed Automaton)**

- $L = \{M_0, \ldots, M_p\}$ is the set of localities i.e. the set of reachable markings of the T-TPN.
- $l_0 = M_0$ is the initial locality.
- $C = \{x_1, \ldots, x_q\}$ is the set of clocks i.e. the set of all clocks associated with a transition.
- $A = \{t_1, \ldots, t_q\}$ is the set of actions i.e. the transitions of the T-TPN.
- $E \subset L \times C(C) \times A \times 2^C \times L$ is the finite set of transitions. Let $e = (M_i, \gamma, a, R, M_j)$ a transition, $e$ is defined as follows:

  - $a = t_k$
  - $\gamma = x_k \geq \alpha_k$
  - $R = \{x_i \mid t_i \in \uparrow enabled(M_i, t_k)\}$

- $Inv : L \times C(C) \rightarrow \{true, false\}$, with:

  $$Inv(M_i) = \{x_i \leq \beta_i \mid t_i \in enabled(M_i)\}$$

**Example**

Considering the T-TPN of figure 1, the resulting Timed Automaton is:

```
Figure 3. Time Marking Automaton
```
4.4 Bisimulation

Definition 9
As defined in the time transition system for a T-TPN T, we note \( \mathcal{Q}_T \) the set of states of T. \( \mathcal{Q}_A \) is the set of states of a TA A.

Definition 10
Let \( \mathcal{R} \subset \mathcal{Q}_T \times \mathcal{Q}_A \) be the relation between a state of the Timed Automaton and a state of the Time Petri Net defined by:

\[
\begin{align*}
\forall (M, v) \in \mathcal{Q}_T, (M, v)\mathcal{R}(l, \bar{v}) & \iff (M = M(l)) \land (v = \bar{v})
\end{align*}
\]

where \( M \) is the function giving the associated marking of a TA state \( l \).

Two states are in relation if their “markings” and their clocks valuations are equals.

Theorem 2
\( \mathcal{R} \) is a bisimulation:

For all \( (M, v), (l, \bar{v}) \) such that \( (M, v) \mathcal{R} (l, \bar{v}) \):

- \( (M, v) \xrightarrow{t} (M', v') \mathcal{R} (l', \bar{v}') \iff (l, \bar{v}) \xrightarrow{t} (l', \bar{v}') \)

- \( (M, v) \xrightarrow{\delta} (M, v') \mathcal{R} (l, \bar{v}') \iff (M', v') \mathcal{R} (l', \bar{v}') \)

Proof

Continuous transition – time elapsing.
Let \( (M, v_T) \in \mathcal{Q}_T, (l, v_A) \in \mathcal{Q}_A, \) and \( \delta \in \mathbb{R}^{\geq 0} \).

We prove that if the T-TPN can idle in a state, this is allowed on the constructed TA i.e. if the system can idle for any \( \delta \) such that \( \forall k \in [1, n] M \geq t_k \Rightarrow v_T(t_k) + \delta \leq \beta(t_k) \) then the automaton verifies: \( \forall t \in [0, \delta] Inv(l)(v_A + t) = true \).

By construction, the invariant of the location \( l \) is obtained by the conjunction of the latest firing times of enabled transitions. So \( Inv(l) = \bigwedge \{ x_i \leq \beta(t_i) \} \) where \( t_i \in enabled(M(l)) \). \((M, v_T)\) and \((l, v_A)\) are in relation so \( v_T = v_A \). As \( v_T(t_i) + \delta \leq \beta(t_i) \) then for all \( t \in [0, \delta] v_A(t_i) + t \leq \beta(t_i) \). This means that \( \forall t \in [0, \delta] Inv(l)(v_A + t) = true \).

To conclude, the automaton can idle in the state and \( (M, v_T + \delta) \mathcal{R}(l, v_A + \delta) \).

Symmetrically, we prove that if the TA can idle for a time \( \delta \), the T-TPN can idle for the same time \( \delta \).

According to the semantics of T-TPN, a continuous transition can occur if and only if \( \forall t_k \in enabled(M) \), \( v_T(t_k) + \delta \leq \beta(t_k) \). As \((M, v_T)\) and \((l, v_A)\) are in relation, \( v_T = v_A \). The TA can idle in the state for all \( t \in [0, \delta] v_A(t_i) + t \leq \beta(t_i) \) by construction of the invariant. Then, \( t = \delta \) prove the result.

The T-TPN can idle in the marking and \( (M, v_T + \delta) \mathcal{R}(l, v_A + \delta) \).
Concerning continuous transitions, $R$ is a bisimulation.

**Discrete transition – firing a transition $t_i$** Let $(M, v_T) \in Q_T$ and $(l, v_A) \in Q_A$ be two states in relation.

We prove that if a transition is fireable for the T-TPN, it is fireable for the TA and the two resulting states are in relation.

A transition $t_i$ of the T-TPN can be fired if: $M \geq t_i$ and $\alpha(t_i) \leq v_T(t_i) \leq \beta(t_i)$.

The resulting marking is $M' = M - t_i + t_i^*$ and the resulting valuation is $v_T'(t_k) = 0$ for all newly enabled transition $t_k$, all others valuations remain unchanged.

The corresponding action is allowed on the constructed TA if and only if:

$$\exists (l, \gamma, a, R, l') \in E \text{ such as: } \begin{cases} \gamma(v) = true \\ v_A = v_A[R \leftarrow 0] \\ Inv(l')(v_A') = true \end{cases}$$

As $t_i$ is fireable, it exits by construction a transition of the TA from $l$, such that $M(l) = M$, to a location $l'$ such that $M(l') = M'$. The guard is by construction, $\gamma = x_i \geq \alpha(t_i)$. Thus, as $t_i$ is fireable $\gamma(v_A) = true$.

Also by construction, the clocks to be reset are the same clocks to be reset for the T-TPN. Thus, $v_A' = v_T'$.

As clocks newly enabled are set to 0, they verifies the inequalities $x_j \leq \beta(t_j)$ in the invariant of $l'$. All other clocks stay unchanged: $v_A'(t_j) = \beta(t_j)$ for all other enabled clocks. Thus, $Inv(l')(v_A') = true$.

So the transition on TA is allowed and $(M', v_T'R)(l', v_A')$.

**Symmetrically**, we prove that if $t_i$ is fireable for the TA, it is fireable for the T-TPN.

The two resulting states are in relation.

A transition $e = (l, t_i, \gamma, R, l')$ of the TA can occur and leads to a new state $(l', v_A')$ if and only if $\gamma(v_A) = true$ and $Inv(l')(v_A') = true$. Then $v_A' = v_A[R \leftarrow 0]$.

The corresponding action is allowed on the T-TPN and leads to a new state $(M', v_T')$ if and only if:

$$\begin{cases} M \geq t_i \\ M' = M - t_i + t_i^* \\ \alpha(t_i) \leq v_T \leq \beta(t_i) \\ \forall \text{ transitions } t_k \begin{cases} 0 \text{ if } t_k \in \uparrow enabled(M, t_i) \\ v_T(t_k) \text{ otherwise} \end{cases} \end{cases}$$

By definition of the Marking Timed Automaton, if $t_i$ is fireable for the TA, it is for the T-TPN. So $M \geq t_i$ and the resulting marking is by definition $M' = M - t_i + t_i^*$. $(l, v_A)$ and $(M, v_T)$ are in relation so $v_T = v_A$.

As, $\gamma(v_A) = true$ and $Inv(l)(v_A) = true$ so, $\alpha(t_i) \leq v_T(t_i) \leq \beta(t_i)$.

By construction, the clocks to be reset are the clocks of newly enabled transitions i.e. the clocks of $R$. So $v_A' = v_T'$.

To conclude, $t_i$ is fireable for the T-TPN and $(M', v_T')$ and $(l', v_A')$ are in relation.

$R$ is a bisimulation for discrete transitions.

5 Performances

We have implemented the algorithm to compute all the reachable markings of a bounded T-TPN using DBM (Difference Bounded Matrices) to encode zones. The tool implemented (MERCUTIO) is integrated into ROMEO (Romeo 2003), a software for T-TPN edition and analysis.

As boundedness of T-TPN is undecidable, MERCUTIO offers stopping criteria: number of reached markings, computation time, bound on the number of tokens in a place. It also provides an on-the-fly reachability test of markings and export the automaton in Kronos or UPPAAAL syntax. Concerning the on-the-fly reachability test, MERCUTIO also provides a trace (sequence of transitions and interval in which they are fired) leading to the marking.

5.1 Comparison with other methods

We present here a comparison (Table 1) of three methods to compute the state space of a T-TPN:

- the method proposed in this paper with our tool MERCUTIO.
- the State Class Graph computation (BERTHOMIEU) with the tool TINA.
- the State Class Timed Automaton (LIME and ROUX) with the tool GPN.

Computations were performed on a Pentium 2 (400MHz) with 320MB of RAM. Examples 1 to 5 come from real-time systems (parallel tasks [1], periodic tasks [2–3], producer-consumer [4–5, 8–12]). Examples 7 and 8 are the classical level crossing example (3 and 4 trains).

For this set of examples and for all nets we have tested, our tool performs better than TINA and than GPN. For example 12, GPN ran out of memory.

</table>

Number of: 1 clocks of the original T-TPN, 2 clocks of the TA, 3 nodes of the TA, 4 transitions of the TA.

5.2 Reducing the number of clocks

A major issue in model checking TA is the number of clocks in the automaton. Time computation is exponential in the number of clocks. Consequently, obtaining an automaton with a reduced number of clocks is of importance.

The algorithm we propose assigns a clock to each transition. Thus, the resulting automaton has as many clocks as transitions of the T-TPN. However we have underlined that for each location, only a reduced number of clocks (active clocks) really matter for the timing evolution of the T-TPN.

Daws and Yovine in (Daws and Yovine 1996) proposed a syntactical method to reduce the number of clocks of a TA. As a single Timed Automaton is build with our method (no need to compute parallel composition) we applied this reduction. The table 2 presents the comparison between the clocks of (1) the Timed Automaton obtained, (2) the Timed Automaton obtained after syntactical clocks reduction (we used OPTIKRON from KRONOS (Yovine 1997)), (3) the State Class Timed Automaton using GPN that ensures a minimal number of clocks using classes.

These results are all the more encouraging that, reducing the number of clocks is made syntactically and is made at no cost comparatively to the state space computation. The State Class Timed Automaton always as a lower number of clocks but its construction is not as fast as our method: the Timed Automaton has lower clocks at the price of a greater size. For example 12, we have not succeeded in computing the State Class Timed Automaton (out of memory).

6 Applications

We propose in this section some applications of our method to model-check T-TPN.
6.1 Model checking of Quantitative Properties

Since they were introduced, Timed Automata are an active research area and several methods and tools have been developed to analyze them. Tools like UPPAAL (Larsen et al. 1997) or KRONOS (Yovine 1997) successfully implement efficient algorithms and data structures to provide model-checking on TA (TCTL model-checking for instance): numerous case studies have been performed with real reactive systems.

Concerning T-TPN, few studies were realized and properties that can be checked are mainly safety untimed properties (reachability). Time or untimed properties are mainly verified over T-TPN using “observers”. Basically, properties are transformed in an additional T-TPN motif called “observer”, and then, the problem is transformed into a reachability test. Such methods are not easy to use: (1) modeling the property with an observer is not easy (it exists some generic observers (Toussaint et al. 1997), but for few properties), (2) the observer’s size may be as large as the initial T-TPN, (3) due to the increase of the T-TPN’s size, computing the state space will be more time expensive.

The method we propose here, is to use existent TA tools to perform model-checking of T-TPN. As a Timed Automaton is produced, model-check a T-TPN (LTL,CTL) becomes possible and verifying quantitative time property (TCTL) is possible. Moreover, as the automaton constructed is a Timed Automaton with diagonal free constraints, model checking could be done using on-the-fly algorithms on TA (UPPAAL(Larsen et al. 1997), KRONOS(Yovine 1997)).

Example

Let us consider the classical level crossing example. The system is modeled using the three patterns of the figure 4. This model is made of a controller (4(a)), a barrier model (4(b)) and four identical trains (4(c)). The resulting Petri Net is obtained by the parallel composition of these T-TPN.

The property “the barrier is closed when a train crosses the road” is a safety property and is interpreted as a reachability test: we want to check if there exists a state such that for any train $i$: $M(\text{On}_i) = 1$ and $M(\text{Closed}) = 0$. This could be checked directly on the computed graph using MERCUTIO or using UPPAAL to test the property. In UPPAAL, the property is expressed as: $\text{E}<>((M[\text{On}_1]==1 \text{ or } M[\text{On}_2]==1 \text{ or } M[\text{On}_3]==1 \text{ or } M[\text{On}_4]==1) \text{ and } M[\text{Closed}]==0)$. In both cases, the result is False, proving that no train may cross the road while the barrier is not closed.

Using the automaton, it is possible to model time properties. For instance, “when the train $i$ approaches, the barrier closes within delay $\delta$” may be checked. In TCTL this property is expressed by: $M(\text{close}_i) = \uparrow 1 \Rightarrow \forall \delta \leq \delta M(\text{closed}) = 1$. $M(\text{close}_i) = \uparrow 1$ means that only states for which $M(\text{close}_i) = 1$ in the state and $M(\text{close}_i) = 0$ for all the preceding states. To check this property on the TA using UPPAAL or on the T-TPN using reachability analysis leads to create an observer or modify the model. For instance, to use UPPAAL we have to add an additional clock that starts when a train change its state to $\text{close}_i$. By using KRONOS, there is no
need to modify or create an observer. Given the TA and a TCTL formula, KRONOS can perform model-checking using classical TCTL forward or backward algorithms.

6.2 Mixing Timed Automata and Time Petri Nets

The method proposed in this paper provides a common framework for using and analyzing reactive systems modeled with Timed Automata or Time Petri Nets.

Many systems are modeled using T-TPN (FIP, CAN), nevertheless some problems (time controller synthesis for instance) benefit of larger studies and efficient tools. Then, it may be necessary to have a mixed representation of the system.

We give here some examples of mixing Timed Automata and Time Petri Nets:

Test Case Given a reactive system expressed with a T-TPN, different scenarios may be studied by synchronizing it with a Test Automaton. This Test Automaton represents the sequence of transitions to be fired and the synchronization is made over the firing of transitions.

Controller Given a reactive system expressed with a T-TPN, a controller may be modeled using TA to constraint the execution of the system.
7 Conclusions

In this paper, we proposed an efficient method to compute the state space of a bounded T-TPN. The proposed algorithm performs a forward computation of the state space and we proved it is exact with respect to reachability even for bounded T-TPN with $\infty$ as latest firing time. We proposed a labeling algorithm of the produced graph to build a Timed Automaton that we proved to be timed bisimilar to the original T-TPN. Some examples were given to show that our tool performs better than two other methods used to compute the state space of a T-TPN: the State Class Timed Automaton (Gpn) and the State Class Graph (Tina). Though the number of clocks of our TA is greater than the one of the State Class Timed Automaton, our construction is faster and syntactical clocks reduction algorithms may be successfully applied to reduce it.

Consequently, our method allows the use of Timed Automaton tools to model-check T-TPN. In particular, the Timed Marking Automaton makes TCTL model-checking feasible for bounded T-TPN, which, to our knowledge has not been done before.

We are currently involved in two different research areas. First, we think possible to use efficient data structures (BDD-like structure) to improve our implementation and we are studying Partial Order methods to reduce time and space requirements. Finally, it would be useful to develop a full model-checker for T-TPN without having to build the Timed Automaton. Then, a further step in the analysis of real-time reactive systems will be to provide methods for the time controller synthesis problem for T-TPN.
