Abstract

Agricultural production is limited by a wide range of abiotic (e.g. drought, water-logging) and biotic (pests, diseases and weeds) stresses. The impact of these stresses can be minimized by appropriate management actions such as irrigation or chemical pesticide application. However further optimization requires the ability to diagnose and quantify the different stresses at an early stage. Particularly valuable information of plant stress responses is provided by (a) thermal imaging which primarily detects changes in transpiration rate and (b) fluorescence sensing which may indicate functioning of photosynthesis and other physiological processes. These can be supplemented by conventional video imagery for study of growth. An efficient early warning system would need to discriminate between different stressors. Given the wide range of sensors, and the association of specific plant physiological responses with changes at particular wavelengths, this goal seems within reach. This is based on the organization of the individual sensor results in a matrix that identifies specific signatures for multiple types of biotic and abiotic stress. In this paper we first review the diagnostic effectiveness of different individual imaging techniques, and then extend this to the multi-sensor stress-identification approach.

1 Introduction

In the 1930s, the term 'stress' was introduced as a human health syndrome by the Canadian medical researcher and endocrinologist of Hungarian origin Hans (János) Selye (1907-1982) [1]. Plant stress is defined as "a significant deviation from the conditions optimal for life" [2]. This definition implies that the occurrence of stress depends on the conditions to which a plant has acclimated. One can distinguish between abiotic (radiation, temperature, water, gases, minerals, mechanical effects) and biotic (induced by micro-organisms, animals, plants, anthropogenic factors) stresses.

In order to properly interpret the causes and effects of the different types of stress, it is usual to study single stresses under controlled conditions. Nevertheless such studies are of only partial relevance to natural conditions because plants are normally exposed to a multitude of interacting concurrent influences. Primary stress responses may be modified both by the acclimation and adaptation of the plants to the previous environmental factors, and by interactions with other organisms. As a further complicating factor the effect or impact of these stresses can vary with the developmental stage of the plant.

Stress does not necessarily need to be lethal. Mild stress conditions can lead to an increased resistance, which will help the plant to react to and overcome a subsequent stress (acquired stress resistance). This positive stress has also been termed 'eustress'. A strong stress may immediately lead to acute damage or later on - when there is not enough resistance - to chronic damage. A damaging stress is also called '-distress' [3].

The importance of biotic and abiotic stresses on plant yield and their impact on agricultural production has been widely recognized. Therefore this subject has received ample attention in the last 20 years, as evidenced by multiple reviews and books with a wide range

1
2
3 of ecophysiological topics [2-13] and others with focus on photosynthesis [14, 15],
4
5 phytochemistry [16, 17] and air pollution [18].
6
7

8 This fact, together with the increasing awareness that stresses associated with global
9
10 anthropogenic factors ('greenhouse effect', 'ozone hole') caused by industrialization may have
11
12 substantial ecological and economic impacts, has led to the emergence of a large body of
13
14 literature on detection of plant stresses and plant responses.
15
16

17 With the increasing pressure on available arable land and water resources, plant stress
18
19 alleviation and avoidance will increase in importance in the near future. There is therefore an
20
21 urgent need to improve techniques for the sensitive early detection, monitoring and diagnosis
22
23 of stress to allow effective management responses. It is essential that the detection methods
24
25 are rapid, non-destructive and low cost. The detection of stress-induced changes of
26
27 physiological parameters is a focus of much recent and current basic and applied plant
28
29 physiological research and a range of instruments have been developed in the past 20 years
30
31 that aim to detect stress effects on plants in a non-contact way. The search for optimal
32
33 imaging-derived stress detection parameters is still ongoing, while the advent of multi-sensor
34
35 detection of a combination of parameters could effectively lead to the identification and
36
37 subsequent remediation of emerging stresses. These aims are an integral part of precision
38
39 agriculture, which strives to limit the inputs of nutrients, pesticides and herbicides by
40
41 matching them to the actual crop needs, which would avoid unnecessary expenditures and
42
43 detrimental impact on the environment and ultimately human health.
44
45
46
47
48
49

50 This review is based on an evaluation of stress detection by a range of imaging techniques
51
52 including thermography and different types of fluorescence imaging that was undertaken in
53
54 the frame of the EU-Research Training Network "STRESSIMAGING" but is extended to
55
56 include a wide range of available information on stress-imaging at the leaf and plant level.
57
58 Although we concentrate here on measurements applicable at the leaf- or plant-level the
59
60

1
2
3 results here should provide a sound basis for interpretation of measurements at the canopy or
4 field scale and for application at larger scales and in precision agriculture approaches. It is
5 worth noting, however, that extension to the canopy or remote-sensing scales may provide yet
6 further opportunities for incorporation of additional information useful for stress diagnosis.
7
8
9
10
11

12 The non-contact detection of stress is largely based on optical measurements of plant
13 temperature (by thermal imaging) and fluorescence emission (for recent reviews: [19, 20]).
14 The latter two signals can be subdivided in spectral ranges by applying multi- or hyper-
15 spectral imaging. Thermography and chlorophyll fluorescence imaging are central in this
16 review since they provide information on two key physiological parameters: transpiration and
17 photosynthesis. In certain circumstances these may be supplemented by conventional digital
18 imagery that allows, for example, measurement of growth. The most useful diagnostic
19 information is obtained when several measured parameters, highlighting a wide range of plant
20 physiological responses, are combined: for example leaf temperature with spectral
21 fluorescence detected at particular wavelength bands. In the following sections, the results
22 obtained with the different imaging techniques will be described first. Thereafter multi-sensor
23 stress imaging will be illustrated, and the stress factors and their induced responses will be
24 summarized in a tabular form: the stress catalogue.

2 Thermography

Canopy or leaf temperature, as measured using thermography (thermal infrared sensing or imaging), provides a powerful monitoring tool for a broad range of plant stresses that affect any aspect of plant water relations. The basis underlying most uses of leaf temperature as a stress detection tool is that leaf temperature is strongly affected by transpiration, which itself is primarily regulated by stomatal conductance, with leaf temperature increasing as transpiration rate decreases [21]. Leaf temperature is a particularly sensitive indicator of changes in stomatal conductance because latent heat loss is a large component of the overall leaf energy balance that determines leaf temperature [22]. **Current thermal camera models commonly have a temperature resolution of 0.1°C which is adequate to reveal transpirational changes or heterogeneity at the leaf surface. Spatial resolution however is rather limited in comparison with the currently available cameras for the visual spectrum, but proved to be sufficient for leaf to plant level monitoring, and can be compensated for by automation approaches in which multiple images are captured.**

At a canopy scale where image pixels may include both leaf and soil, observed temperatures can also change as a result of varying vegetative ground cover, with increasing proportions of soil (as the canopy becomes sparser or as leaves wilt) tending to lead to higher temperatures. An approach to correct the observed average temperatures to better reflect leaf temperatures only has been proposed by [23], while for higher resolution data the image analysis approaches described in [24] can be useful.

The development of methods for stress diagnosis or quantification based on leaf temperature observations under field conditions is complicated by the fact that environmental variables, including air temperature, net radiation absorbed (which is a function of leaf angle), boundary layer resistance (a function of leaf size and wind speed) and air vapor pressure

1
2
3 deficit, all affect leaf temperature. Therefore in the simplest applications, thermal sensing is
4
5 commonly used in a relative mode, with comparisons between known healthy and unknown
6
7 sample plants/crops. The “stress index” approach [25] aimed to normalize results for the
8
9 environmental variation. Further improvements in normalization have been made by the use
10
11 of artificial or theoretical wet and dry references, leading to better “stress indices” [26, 27].
12
13 Where all the relevant environmental variables are known, recent work in the
14
15 STRESSIMAGING project has shown that it is possible to obtain quantitative estimates of
16
17 absolute leaf stomatal conductance from thermal images if appropriate reference temperature
18
19 information is available, or by using energy-balance calculations based on appropriate
20
21 meteorological data [27]. Notwithstanding the adoption of “stress indices”, the association of
22
23 leaf temperature rise with the degree of stress is generally *qualitative* rather than *quantitative*,
24
25 partly because conductance itself is only an indirect indicator of the underlying stress (with
26
27 different responses in different species/cultivars) and partly because the relationship between
28
29 the stress indices and stomatal conductance is also dependent on environmental variables.
30
31
32
33
34
35
36
37
38

39 **Abiotic stress detection**

40
41 As already indicated, many stresses, including especially water deficits, lead to stomatal
42
43 closure. Therefore all such stresses can, in principle, be detected and quantified by thermal
44
45 sensing of stomatal closure, albeit in relative mode [28, 29]. In many cases an observed leaf
46
47 temperature increase can be related to water stress, even though a water deficit may not have
48
49 been the original primary stress (see below). This multiple causation also highlights the
50
51 challenge of identifying particular stress classes.
52
53

54
55 Because drought causes stomatal closure and leaf temperature rise, thermal sensing has
56
57 been of particular interest for many years as a tool for scheduling irrigation [25, 30]. A
58
59 fundamental difficulty in the use of stomatal conductance (and hence of leaf temperature) as a
60

1
2
3 proxy indicator of the causal stress is that the relationship between stomatal conductance and
4
5 leaf water status varies between species. Some plant species minimize the depression of leaf
6
7 water potential as the water supply decreases by stomatal closure, for these so-called
8
9 “isohydric” plants [31] stomatal closure (and hence leaf temperature) is a very good indicator
10
11 of water supply. On the other hand, so called “anisohydric” species do not close their stomata
12
13 until the water deficit is severe; in such cases stomatal closure is not a sensitive indicator of
14
15 water deficit stress (see [32]). Sunflower, most crop plants (e.g. wheat, barley and soybean)
16
17 and the grapevine cultivar ‘Shiraz’ are commonly classified as anisohydric, while maize and
18
19 many temperate trees, together with the grapevine cultivar ‘Grenache’ are typically
20
21 characterized as isohydric [31, 33]. The latter are, given their tight stomatal control, suitable
22
23 for thermal sensing for irrigation control [34].
24
25
26
27
28

29 Thermal sensing can also be used to study the spatial and temporal dynamics of plant
30
31 freezing, due to the local heat generation as tissue water freezes [35]. In addition, the rates of
32
33 water loss from leaves can change in response to atmospheric pollution (e.g. [36]), nutritional
34
35 status [37] and salinity [38]. Other abiotic stresses, such as the uptake of herbicides can also
36
37 be detected by thermal imaging. For example, methylurea herbicide uptake induces a
38
39 temperature increase emerging from the main veins and spreading to finally affect the whole
40
41 leaf [39]. Although this effect was visualized with more contrast by using parallel chlorophyll
42
43 fluorescence (Chl-F) imaging (see below), the clear spatial and temporal pattern of the
44
45 development of the thermal effect adds to the information available from the thermal signal
46
47 and helps to distinguish this from other stresses.
48
49
50
51
52
53
54

55 **Biotic stress detection**

56
57 Leaf temperature has been used as an indicator of several biotic stresses [21, 40-43].
58
59 Local, rapidly expanding increases in leaf temperature develop at tobacco mosaic virus
60

1
2
3 (TMV) infection sites in resistant tobacco, before visual symptoms can be discerned [44].
4
5 This symptom is synchronous with an increase in Chl-F and an increase in UV-excited
6
7 fluorescence (see below). As underlying mechanism, a coincident accumulation of the
8
9 phenolic compound salicylic acid (SA) was revealed which reduced transpiration by its
10
11 known stomatal closing activity. Phenolic compounds typically accumulate during resistance
12
13 responses of plants to pathogens, and multiple reports indicate a reduction in stomatal
14
15 conductance or aperture, pointing at a possibly general mechanism of symptom manifestation.
16
17
18 Apart from phenolics, other classes of chemicals interfere with stomatal control; these include
19
20 various pathogen toxins [45] such as the fungal toxins which cause (internal) tissue
21
22 degradation, leading to local leaf temperature decreases at early stages of *Cercospora*
23
24 infection in sugar beet [46, 47]. Concomitantly Chl-F was shown to increase (see below). An
25
26 increase of the thermal signal was observed, both at early stages of infection with the
27
28 oomycete *Pseudoperonospora cubensis* causing downy mildew in cucumber [48] and in the
29
30 case of the fungus *Phyllosticta* acting on two tree species [49].
31
32
33
34
35

36 Plant surface degradation and leaf cell death is commonly a consequence of certain
37
38 specific or multiple biotic aggressions. Such damage frequently decreases leaf temperature
39
40 locally due to evaporation of leaf water from the damaged tissue. Examples where
41
42 temperature decreases occur include the late stages of TMV infection and upon spontaneous,
43
44 disease-like lesion formation in *Arabidopsis* and tobacco [42, 44]. Similarly, damage by
45
46 mechanical leaf wounding can lead to an immediate temperature increase, followed by a
47
48 localized decrease due to water loss from damaged cells, that progressively disappears again
49
50 upon wound healing [49, 50]. In case of arthropod-induced gall formation a temperature
51
52 decrease has also been described [49].
53
54
55
56

57 As well as being of value for the topical diagnosis and monitoring of local (leaf)
58
59 infections, thermal imaging can also provide information relating to root diseases and rots
60

1
2
3 caused by fungi or oomycetes and for vascular wilts induced by the proliferation of bacteria or
4
5 fungi. This is because these all impact on water uptake and transport, and ultimately result in
6
7 a decrease in transpiration (reviewed in [21]). Toxic compounds absorbed by the root system
8
9 of plants will also gradually affect leaf transpiration [39].
10
11

12 13 14 15 **Diagnostic capability**

16
17 From the above it follows that (especially) single-time point leaf temperature
18
19 measurements by themselves are not usually diagnostic, and normally require some ancillary
20
21 information to determine the precise cause of any observed temperature change. As is
22
23 apparent from the detailed symptoms, especially of the various biotic stresses outlined above,
24
25 additional diagnostic information can be obtained from the temporal and spatial dynamics of
26
27 the temperature changes. In general leaf level-stresses, such as caused by leaf infections, tend
28
29 to induce a (persistent) heterogeneous response pattern, whereas root level stresses evolve
30
31 towards a more homogeneous leaf-level response. The spatial and temporal pattern of the
32
33 stress response can most likely provide a first approach to further discriminate different
34
35 stressors. Dedicated image processing algorithms will enable detection and discrimination of
36
37 (the kinetics of) different patterns.
38
39
40
41
42

43 **3 Fluorescence**

44
45
46
47
48 Leaves emit fluorescence upon absorption of radiation ranging from the UV to the visible;
49
50 however this dissipation typically accounts for only a few percent of the actual energy uptake.
51
52
53 Fluorescence always has a longer wavelength (i.e. lower energy per quantum) than the
54
55 absorbed light (“Stokes-shift”).
56

57
58 **Reliable detection of fluorescence emission requires a homogeneous illumination of the**
59
60 **monitored leaf area(s), implying a dedicated illumination system. As mentioned for**

1
2
3 **thermography, in the case of field measurements, confounding influences from the**
4 **environment (weather conditions, time of day) limit the detectability of stress factors.**
5

6
7
8 Several compounds within leaves fluoresce, and one can distinguish between the most
9
10 important emissions including blue-green fluorescence emitted by cell wall bound ferulic acid
11
12 [51, 52] and red-far red fluorescence emitted by chlorophyll (Chl) *a* in photosystem II [53].
13

14
15 The intensity of fluorescence generally depends on (a) the concentration of the fluorophores,
16
17 (b) the temperature of the leaf, (c) the penetration of the excitation light into the leaf and (d)
18
19 the fluorescence emission from different depths of the leaf. Chlorophyll fluorescence (Chl-F)
20
21 is a particularly powerful probe for investigating activity and integrity of the photosynthetic
22
23 system. The intensity of this Chl-F varies as a function of the various alternative pathways
24
25 which compete with fluorescence for de-excitation of radiant energy absorbed by the Chl
26
27 antenna pigments. These include (e) use of energy to drive photosynthetic electron transport
28
29 (photochemical quenching), and (f) non-radiative de-excitation resulting in heat loss (**non-**
30
31 **photochemical quenching – Nfq**). The magnitude of fluorescence is quenched from its
32
33 maximum (F_m - which occurs when the primary electron acceptor is fully reduced) both by
34
35 increasing photosynthetic electron transport and by non-photochemical quenching (including
36
37 photoinhibition) dependent on pH and xanthophyll de-epoxidation in the thylakoids.
38
39 Parameters such as the efficiency of photosystem II (PS II) and rates of electron transport can
40
41 be readily obtained from F_m together with the minimal fluorescence (F_o) and the steady state
42
43 fluorescence (F_s) and the variable fluorescence ($F_v = F_m - F_o$) using the formulae outlined
44
45 earlier [54, 58].
46
47
48
49
50
51

52
53 Fluorescence images have been used as a tool to detect stress susceptibility in different plants,
54
55 comparing genotypes or mutants [59, 61]. Further reviews on biotic and abiotic stress effects
56
57 as monitored by fluorescence imaging have been presented earlier [61, 70]. Chl-F therefore
58
59 primarily assesses effects on photosynthetic function while UV-fluorescence primarily
60

1
2
3 assesses changes in chemical composition; either of these may be modified by abiotic and
4
5 biotic stresses [71].
6

7 **Abiotic stress detection**

8
9
10 Many environmental stresses affect leaf composition and photosynthesis and can therefore be
11
12 monitored using fluorescence imaging; among the most important are drought and mineral
13
14 nutrition. In addition high light becomes particularly damaging to the photosynthetic
15
16 apparatus when photosynthesis is already inhibited (e.g. as a result of low temperatures or
17
18 drought-induced stomatal closure). The excess light leads to photoinhibitory damage to the
19
20 photosystems – a process that can be readily detected as a decrease in Chl-F [65, 72, 73] and
21
22 as a reduction in maximum quantum yield of PS II (F_v/F_m which was introduced by [54]).
23
24 Importantly, plants under stress display an enhanced sensitivity to photoinhibition. As an
25
26 example, the characteristics of photoinhibition and recovery in relation to cold exposure and
27
28 acclimation have been derived from the differences in maximum quantum yield of PS II
29
30 F_v/F_m , detected from images of Chl-F [74].
31
32
33
34
35

36 Plants have evolved countermeasures to avoid light-induced damage. Increased sun
37
38 exposure of leaves leads to a lower intensity of UV-excited Chl-F [20, 75-77], since UV-
39
40 absorbing substances accumulated in the epidermis shield the Chl-containing mesophyll, and
41
42 thus reduce fluorescence excitation by UV. UV-B treatment was shown to lead to an
43
44 increased blue-green fluorescence [78]. The effect of excess light together with the formation
45
46 of reactive oxygen species could be monitored by a decrease of photosynthesis via Chl-F
47
48 images [79-82].
49
50
51
52

53 The most prevalent abiotic stress under natural conditions is water shortage. Although
54
55 drought can affect photosynthetic rate, this is initially at least, primarily through stomatal
56
57 closure with rather little effect on the activity of the photosystems as measured by F_v/F_m (e.g.
58
59 [83]). Nevertheless drought stress can lead to an increase in blue-green fluorescence, a
60

1
2
3 decrease of Chl-F [75, 84-86] and a decrease of variable Chl-F [87-89]. A particularly useful
4
5 measure of stress is the photochemical yield parameter, which is expressed as $(1 - F_s)/F_m$
6
7 [56]. A decrease in Chl-F and its derived parameters for photochemical quenching, and an
8
9 increase in non-photochemical quenching have been demonstrated in leaves of roses
10
11 undergoing progressive water stress [90].
12
13

14
15 In addition to sufficient water supply, nutrients should be available in a balanced way to
16
17 sustain optimal plant growth. Nitrogen deficiency can be recognized by a higher blue-green
18
19 fluorescence and higher Chl-F at 690 nm [91-93]. Blue-green fluorescence increases because
20
21 of changes in secondary metabolism induced by biotic or abiotic stress [94]; Chl-F at 690 nm
22
23 increases due to a lower Chl content of the leaves, which results in less re-absorption of Chl-F
24
25 (for a review see [95]). Low temperatures and gaseous pollutants can also affect
26
27 photosynthesis and Chl-F emission (e.g. [96, 97]). In addition, inhibition of photosynthesis by
28
29 heavy metal uptake was demonstrated by fluorescence imaging [98]. A decrease of Chl-F as
30
31 detected by photography was taken as an indicator of chilling [59], and upon ozone-induced
32
33 damage of *Brassica* plants and beech trees the maximum quantum yield of PS II F_v/F_m was
34
35 significantly reduced [99, 100]. This was also observed at the cellular level at the very early
36
37 stages of ozone stress [101], and more generally, ozone-damage was detected by an increase
38
39 in the Chl-F [102]. Mechanical damage to plant foliage can be caused by both biotic (e.g.
40
41 insect damage) and abiotic factors (e.g. hail damage), but is commonly caused by wind-
42
43 induced movements leading to tearing damage of leaves. An artificially wounded leaf site first
44
45 displays an increase in fluorescence emission, followed by a decrease to zero fluorescence in
46
47 the regions where the cells were irreversibly damaged and subsequently died [103]. Cells
48
49 proximal to a wound are characterized by a rapid induction of quantum efficiency of PS II
50
51 upon actinic illumination after dark adaptation in *Arabidopsis* plants, revealing the power of
52
53 fluorescence imaging to monitor changes in fluorescence induction kinetics [104].
54
55
56
57
58

9
10
11 [39, 61, 105-108]. To assess herbicide efficiency, the effects of multiple compounds can be
12
13 tracked in screening approaches [109].

14 15 **Biotic stress detection**

16
17 Again, the use of fluorescence for detection of biotic stresses, including both arthropod
18
19 and microbial attacks primarily depends on their effects on photosynthesis, Arthropod
20
21 wounding of leaves, mainly by chewing can lead to reductions in quantum efficiency of PS II
22
23 ([110]; Aldea et al. 2006). The leaf areas around the holes created by caterpillars are
24
25 characterized by a lower PS II activity, as visualized by Chl-F images [111]. Even footsteps of
26
27 herbivore insects can be detected by an increased Chl-F [112]. In other cases, leaves affected
28
29 by mite attack or by the tobacco whitefly can be recognized by the increase of blue
30
31 fluorescence in a characteristic pattern related to the arthropod feeding behavior [65]. The
32
33 response of the plant to localized wounding was monitored by Chl-F imaging as a decrease of
34
35 the plant's photosynthetic activity [79, 80, 82]. Infection of sugar beet plants with root
36
37 nematodes also induced an increase in Chl-F emission [113]. Any factor interfering with root
38
39 water or nutrient uptake can thus potentially be revealed at an early stage by monitoring at
40
41
42
43
44
45
46 leaf level.

47
48 Damage caused by micro-organisms is the second but equally important source of biotic
49
50 plant yield losses. Effects of viruses, bacteria, fungi and oomycetes on plant leaf physiology
51
52 have been visualized with Chl-F imaging. For example, the infection with a virulent strain of
53
54 the bacterium *Pseudomonas syringae* could be monitored by a decrease in the maximum
55
56 quantum yield for PS II F_v / F_m [114-116]. The infection of *Arabidopsis* plants with
57
58
59
60 *Pseudomonas syringae* was monitored by Chl-F and the different infection phases by

1
2
3 analyzing the most contrasting images [117]. **This research highlighted the possibility of**
4 **assessing the relative merit of a wide range of chlorophyll fluorescence parameters**
5 **(including NFQ and Maximum yield of PSII) generated by an elaborate measuring**
6 **protocol. Indications were found that certain parameters could excel in signaling the**
7 **onset of the early stages of stress buildup upon bacterial infection. However, spatial**
8 **variability inherent to measuring conditions and plant material characteristics**
9 **(including illumination heterogeneity linked to heterogeneity in leaf morphology)**
10 **reduced the discriminating power and prevented the derivation of a reliable signature or**
11 **classifier. Thus, it is premature to select a particular fluorescence parameter as a**
12 **signature for a given class of stressors; in-depth research will be needed.**

60

Virus infection can be followed by means of fluorescence imaging (e.g. infection of Chinese cabbage with turnip yellow mosaic virus: [118]). During the early stages of TMV infection of resistant tobacco (*Nicotiana tabacum*) plants, an increase in Chl-F and blue-green fluorescence could be observed along with the rise of the thermal signal [44, 119]. Thereafter, the blue-green fluorescence remained at a high level, but as cell death progressed, leaf temperature decreased sharply at the infected loci, as did the Chl-F. Photosynthetic damage induced by mosaic viruses in susceptible plants was also detected by a variation in variable Chl-F [120-123]. Systemic infection of pepper mild mottle virus (PMMoV) in tobacco (*Nicotiana benthamiana*) plants could be revealed by Chl-F imaging, as a dynamic increase emanating from the main veins [43].

Fungi are generally considered more damaging to crop yields than viral infections, due to their rapid spread and propagation. An early increase of Chl-F was observed upon infection of sugar beet plants with the fungus *Cercospora* [46, 47]. The decrease of the photosynthetic electron transport upon infection with fungi was demonstrated by Chl-F images representing the photochemical yield parameter $(1 - F_s) / F_m$ (bean plants infected with *Colletotrichum*

1
2
3 *lindemuthianum*: [124]), the maximum quantum yield of PS II F_v / F_m (tomato leaves infected
4
5 with *Botrytis cinerea*: [125] or barley leaves infected with *Blumeria graminis*: [126]) or $(F'_m -$
6
7 $F') / F'_m$ (measurements obtained during full-spectrum photosynthetic illumination in tobacco
8
9 leaves infected with *Phytophthora nicotianae*: [127]). An increase in blue-green fluorescence
10
11 has been reported in images of grapevine infected with powdery mildew (*Uncinula necator*,
12
13 [128]). Many fungi exert their damaging effects through the secretion of toxins. The action of
14
15 these fungal phytotoxins could be visualized by fluorescence imaging [129]. Destruxin (a
16
17 phytotoxin of the fungus *Alternaria brassica*, which causes significant damage to *Brassica*
18
19 crops) in a concentration as low as 0.05 mg l^{-1} induced an increase of the imaged Chl-F ratio
20
21 F_0 / F_m [130]. As a further example, the efficiency of PS II was decreased upon infection of
22
23 oat leaves with crown rust *Puccinia coronata* [131]. Various phases of infection could be
24
25 followed by imaging of Chl-F during infection of bean leaves with bean rust (*Uromyces*
26
27 *appendiculatus*) [132].

28
29
30
31
32
33
34 In an agricultural context, some plants are considered pests since they compete with the
35
36 cultivated crops. Chl-F imaging can be advantageously used to visualize the speed of
37
38 herbicide uptake and to quantify its effects. The penetration of the herbicide diuron, which
39
40 inhibits PS II activity, can be followed in a time-lapse sequence of fluorescence images,
41
42 showing the increase of Chl-F in the affected leaf tissue [106].
43
44
45
46

47 **Diagnostic capability**

48
49 As pointed out above for thermal imaging, the physiological processes (especially
50
51 photosynthesis) detected by fluorescence are potentially affected by a wide range of biotic and
52
53 abiotic stresses. An explorative approach in which multiple chlorophyll fluorescence imaging
54
55 derived parameters are quantified and plotted according to a spider diagram provide a visual
56
57 signature of the stress impact and have the potential for automated recognition [115, 117]. For
58
59 comparative purposes different stressors have to be measured according to the same
60

1
2
3 measuring protocol and under similar conditions to be able to draw conclusions and to expand
4
5 on the preliminary stress class classification of Table1. In addition effective methods for
6
7 distinguishing between different causes of the symptoms detected again depend on both the
8
9 utilization of the temporal and spatial characteristics of the response and the use of
10
11 complementary signals (such as thermal imagery, blue-green fluorescence and reflectance
12
13 indices) that respond to different physiological processes. **A combination of temporal**
14
15 **measurements and multiple imaging techniques likely will allow to derive time-**
16
17 **dependent signatures typical for a particular stress factor, and provide enough**
18
19 **redundancy to overcome the confounding effects of measuring conditions.**

4 Future development: Multi-sensor monitoring

With the ongoing technical development, imaging is more and more replacing the usual point measurement devices. Imaging allows measuring multiple samples (plants, leaves or leaf regions) simultaneously with a high two-dimensional resolution, and thus provides both the statistical distribution of the signal and information on the spatial variation. The use of imaging lends itself to a multi-sensor approach where images are obtained using different sensors (thermal and fluorescence) and overlaid to obtain a wide range of information for each area of the object. This maximizes the opportunities for discriminating stresses. A promising technique in this respect seems also the 'combinatorial imaging' by searching the most contrasting images taken with different protocols, **as illustrated for chlorophyll fluorescence parameters** [117] , and the analysis of time sequence images [133]. **The latter is advantageously combined with the derivation of parameters describing image statistical information, for example maximum temperature difference (MTD) as a measure of heterogeneity in thermal images [48]. A similar approach can be applied to chlorophyll fluorescence (parameter) images. Developing strategies of signature definition and recognition based on dedicated models and training datasets is gaining importance as an approach for stress factor discrimination [115], [19 and references therein].**

When considering field or greenhouse measurements, adequate monitoring of environmental data is of prime importance to ascertain comparability of the obtained data to earlier or future results. The same pertains to closed environment measurements when considering integration of results obtained by different research groups on monitoring multiple plant-stressor combinations into a global overview that aims at a first-line identification of stressor classes.

Thermal imaging

Thermography detects infrared radiation within the 3 to 14 micrometer range, the exact wavelength sensitivity depending on the chosen model, and can readily reveal temperature distributions at plant canopy to leaf level, without the need for any illumination. Many current models have a sensitivity of 0.1 °C which is adequate for leaf temperature heterogeneity visualization. Thermal cameras are increasingly popular with industrial, maintenance and safety monitoring, which tends to further lower their price **and increases the availability of higher resolution detectors.**

Fluorescence imaging

A fluorescence imaging system includes an excitation light source(s), a detector equipped to measure only at specific wavebands (usually achieved by inserting filter(s) in front of the camera), and a computer for controlling the measurement, the data acquisition and the data analysis (see e.g. [66]). **The excitation light distribution over the target surface needs to be as homogeneous as possible to avoid masking the heterogeneity of the photosynthetic processes underlying the chlorophyll fluorescence emission.**

The spectral range of the excitation light source determines the fluorescence that can be measured. When measuring Chl-F blue or short wavelength red excitation is used most frequently, because Chls absorb in these regions with the highest quantum efficiency. With UV radiation both blue-green fluorescence and Chl-F can be detected. However, when using UV excitation the intensity of Chl-F strongly depends on the presence of UV absorbing substances in the epidermis which cause UV shielding of the Chl in the mesophyll tissue below.

The light sources are usually operated in pulsed mode in order to eliminate ambient and reflected background light. As light sources either light emitting diodes (LEDs) or lamps

1
2
3 (Xenon or halogen) fitted with band-pass filters are used. The fluorescence images are
4
5 detected by monochrome charged coupled device (CCD) cameras combined with different
6
7 band-pass filters (e.g. a high-pass red filter blocking all light with wavelength smaller than
8
9 650 nm for Chl-F detection) and synchronized with the excitation light pulses. Cooled CCDs
10
11 are used for the determination of particularly low fluorescence signals (e.g. F_0) [67]. CCDs
12
13 with an image intensifier unit allow shorter integration time, and photon counting for
14
15 measuring extremely short and low signals, respectively.
16
17
18

19
20 When using imaging to monitor stress responses, it is beneficial to compare several
21
22 repeats and treatments or cultivars with differing resistance levels within a single experiment.
23
24 Either high-resolution sensors or automation can accommodate screening approaches. The
25
26 latter setup can be realized by robotized systems that move the sensor, or alternatively the
27
28 plants.
29
30

31
32 Manual analysis of many images is generally time consuming, and especially with thermal
33
34 images it is often difficult to separate leaf area from background. To solve these problems, a
35
36 semi-automated method for image analysis was developed [24]. In this method, information
37
38 from images of different type is combined to identify the area of interest. First, two different
39
40 images (e.g. thermal and visible or thermal and fluorescence) representing the same area are
41
42 overlaid using pre-selected reference (or “ground control”) points. Second, the leaf area is
43
44 separated from background using for example supervised classification for the visible image
45
46 or pixel intensity thresholding in the fluorescence image. Finally, the identified leaf area is
47
48 used to extract leaf-specific information from the other image, for example to calculate the
49
50 temperature statistics of leaves in the thermal image. In cases where the positions of the
51
52 cameras (thermal, fluorescence) are fixed in relation to each other [46], the method can be
53
54 fully automated and allows rapid analysis of large number of images. In addition, specific
55
56
57
58
59
60

1
2
3 masks can be obtained for discriminating shadow versus sunlit leaves under field conditions
4
5 [134].
6
7

8 As described above, although the individual imaging techniques are able to reveal
9
10 symptoms at early stages for a wide range of stresses effective discrimination between causal
11
12 stresses is improved by the use of multiple sensors (such as thermography and chlorophyll
13
14 fluorescence imaging) that monitor different physiological processes. For example both water
15
16 stress and nitrogen deficiency can reduce the Chl concentration (which is revealed by changes
17
18 in Chl-F Imaging), but water stress typically has a more pronounced and swift effect on
19
20 stomatal closure (detected by thermography), given the fact that only water stress leads to leaf
21
22 wilting. Water stress will also inhibit photosynthesis by stomatal limitation of CO₂ uptake,
23
24 which will affect Chl-F emission. As a consequence the kinetics of Chl-F emission will likely
25
26 differ between water stress and nitrogen deficiency.
27
28
29
30
31
32
33

34 **Examples for multi-sensor imaging**

35
36 Dynamics of stomatal patchiness, induced by changes in environmental factors, were
37
38 visualized simultaneously by thermal and chlorophyll fluorescence imaging. [135]. Both
39
40 techniques provide spatial information for the interpretation of heterogeneity of stomatal and
41
42 possibly linked photosynthetic responses, as well as of excess light energy dissipation
43
44 mechanisms [136].
45
46
47

48 Both a viral (TMV) and a fungal (*Cercospora*) infection lead to the enhancement of Chl-F
49
50 emission, followed by a subsequent decrease. The thermal picture shows a marked contrast in
51
52 response, revealing a temperature increase after viral ingress in tobacco, versus a strong local
53
54 cooling for the fungal infection in sugar beet (see Fig. 1). Fungal *Botrytis cinerea* infection in
55
56 common bean resulted in a similar pattern for thermal and chlorophyll fluorescence as
57
58 compared to the viral infection example mentioned above [103]. However, UV-excited
59
60

1
2
3 fluorescence would likely be able to discern these two plant-pathogen interactions, based on
4
5 the specificity of accumulating fluorescing compounds upon TMV-infection [119]. The 3
6
7
8 examples from Figure 1 illustrate that both thermography and Chl-F imaging reveal the
9
10 infection at an early stage, with Chl-F imaging providing a higher spatial resolution, while
11
12 thermography visualizes a slightly more extended affected region.
13
14

15 The quantification of stress-induced tissue damage can be dramatically enhanced by
16
17 choosing a different imaging sensor or waveband. In general, Chl-F provides excellent
18
19 contrast in comparison with visual images. Under certain circumstances, however, green
20
21 fluorescence imaging after UV-excitation proves superior in revealing damage due to its
22
23 ability to detect specific highly fluorescing compounds induced by a particular stress. In
24
25 Figure 2, spontaneous cell death is apparent in the visual image of Arabidopsis *lsd* mutants,
26
27 but thresholding the symptoms from the green fluorescence resolves the symptoms better
28
29 from the unaffected leaf areas, whereas the chlorophyll fluorescence image displays very little
30
31 contrast and suffers from signal emission from the background owing to algal growth on the
32
33 substrate. The affected area calculated per *lsd* plant, by taking the ratio of the 2 thresholded
34
35 images (green fluorescence over green channel of the visual reflectance image), is 11 and
36
37 12%, respectively.
38
39
40
41
42

43 An optimal sensor-combination for discriminating a set of stresses can be chosen on the
44
45 basis of a thorough understanding of the various physiological causes and effects of each
46
47 stress. Key responses are summarized in Table 1 which represents the basis for a stress-
48
49 catalogue.

56
57
58
59
60

5 Conclusion

The multi-sensor imaging equipment can be used as a first early-warning system to pick up signals of plants in stress. As a consequence of its mobility that allows a wide range of action, especially in a horticultural or agricultural setting, an imaging sensor will detect emerging stresses, and at the same time allow targeted sampling for further diagnosis. With the aid of a stress catalogue, based on previously established stress responses under controlled or standard conditions (Table 1), a first coarse identification of the stress class will be facilitated. **The stress catalogue will however need to be linked to a performant knowledge model or expert system that makes optimal usage of the sensor fusion approach, to derive the specific signatures needed for a sufficient level of discrimination.** As a next step, the stressor can be identified by using tissue analysis (nutrient deficiencies) or diagnostic tests (pathogens). Therefore the multi-sensor approach could lead to a timely, localized and specific treatment, benefiting both culture economics and the environment and will become a valuable tool for the near future.

Figure 1. Comparison of presymptomatic symptoms of 3 plant pathogen interactions. Each column displays from top to bottom visual color image, thermal image and chlorophyll fluorescence image at respectively low and high excitation intensity.

1
2
3 Left column: 54 hours after infection, the TMV-tobacco (*Nicotiana tabacum*) interaction
4 results in a local temperature increase of maximum 0.5°C above the non-affected area of the
5 leaf (corresponding with a 2 fold increase in pixel intensity) (second row). The increase
6 extends beyond the visually affected area (image first row). The area of chlorophyll
7 fluorescence decrease is also more extended than the visual damage, and expanding further
8 outward is a halo of increased fluorescence (third row, halo presents an 1.5 fold increase in
9 pixel intensity compared to unaffected tissue). Chlorophyll fluorescence under high intensity
10 illumination only show the extent of tissue death (fourth row) (see also [46]).
11
12

13
14
15 Middle column: *Cercospora beticola* infection of sugar beet (*Beta vulgaris*) at 7days after
16 infection shows a local decrease in leaf temperature of maximum 1°C (second row), while the
17 visual effect is limited to a pin-point lesion (first row), which can also be seen as a small spot
18 of lower chlorophyll fluorescence (third row). An increase in chlorophyll fluorescence is
19 visible around this spot, and is more clearly visible at higher intensity illumination (fourth
20 row); chlorophyll fluorescence intensity increases at least 3 fold compared with the unaffected
21 leaf area (see also [46]).
22
23

24
25
26 Right column: *Botrytis cinerea* infection of common bean (*Phaseolus vulgaris*) 21 h after
27 infection. An increase in local, leaf temperature is apparent (second row, maximum increase
28 of 0.3°C), while a few co-located spots of increased chlorophyll fluorescence are detectable
29 (third row, intensity increase 2 fold over unaffected tissue). As a reference a wounding spot is
30 included on the other side of the main leaf vein, and visible as a cold spot in the thermal
31 picture (second row). The visible damage (first row) corresponds to the black spots in the Chl-
32 F image captured at high light-intensity (fourth row) (see also [103]).

Figure 2. *Arabidopsis* plants as imaged with a multispectral fluorescence imaging system. In each panel, upper left and lower right position feature a spontaneous cell death mutant *Isd* (lesions simulating disease resistance, [42]; the other 2 plants are the Col-0 wild type from which this mutant was derived. Upper left: color reflectance image, middle panel: green fluorescence emission (550nm), right panel: chlorophyll fluorescence emission (690nm). The lower panels show thresholding of respectively color video and green fluorescence image, the latter indicating the leaf area affected by cell death. Thresholding of the chlorophyll fluorescence image includes part of the growing medium background and displays little or no contrast between affected and unaffected leaf areas, as is already evident from the depicted original fluorescence image. The lower right panel shows a schematic robotized system applicable for multi-sensor imaging.

Table 1. Summary of stress effects and their detection by thermography and fluorescence imaging.

	<i>Thermography</i>		<i>Fluorescence</i>	
<i>Abiotic stress</i>				
Water stress	Temperature rise (primary response in 'isohydric plants)	[26, 30]	Increase in blue-green-F, decrease of Chl-F, decrease of variable Chl-F, increase of non-photochemical quenching	[75, 84-90, 137]
Sun exposure			Decrease of UV-excited Chl-F, increase of blue-green fluorescence, detection of reactive oxygen species via fluorescence dyes	[75, 76, 78, 138]
Photoinhibition			Decrease of Chl -F, decrease of variable fluorescence, detection of reactive oxygen species via fluorescence dyes	[65, 73, 74, 138, 139]
Photooxidation			Decrease of photosynthetic electron transport detected by Chl-F, detection of reactive oxygen species via fluorescent dyes	[79-81]
Heavy metal uptake			Decrease of photosynthetic electron transport detected by Chl-F	[98]
Salinity stress	Rise (not consistent)	[40]		
Freezing	Rise (freezing exotherm)	[35]		
Chilling			Decrease of variable Chl-F	[139]
Nitrogen deficiency	Tendency to rise (may relate to the reduced leaf area effect)	[40]	Higher blue-green-F and higher Chl-F at 690 nm	[91, 93]
Gaseous pollutants (NO ₂ , SO ₂ , O ₃)	Rise (result of stomatal closure with often increased stomatal heterogeneity)	[36, 96, 97]	Chl-F increase	[99, 102]
Wounding	Temperature decrease due to water loss	[50, 140]	Decrease of photosynthetic electron transport detected by Chl-F, rapid induction of quantum efficiency of photosystem II	[79, 80, 82, 104]
Herbicides	Temperature increase	[39]	Diuron or linuron: increase of Chl-F	[39, 61, 102, 105-108]
<i>Biotic stress</i>				
Insect attack			Increase of blue-F, change of photosynthetic parameters	[65, 110, 111]

			derived from Chl-F images	
Vascular wilt diseases and root rots	Raise temperatures as lead to water deficits and stomatal closure	[40]		
Fungal foliar infection	Temperature decrease	[46, 48]	Increase of Chl-F decrease of variable Chl-F, increase of blue-green-F	[132]; [131]; [124]; [130]; [125];[46];[127];[126];[128]
Viral infection	TMV: Initial temperature rise, followed by decrease upon cell death	[44]	Variation in Chl-F parameters related to photosynthesis, increase of Chl-F and blue-green-F	[43, 118, 121-123]
Bacterial infection	<i>Erwinia</i> : Presymptomatic temperature decrease	[141]	decrease of variable fluorescence	[114-117]

Comparison of presymptomatic symptoms of 3 plant pathogen interactions. Each column displays from top to bottom visual colour image, thermal image and chlorophyll fluorescence image at respectively low and high excitation intensity.

Left column: 54 hours after infection, the TMV-tobacco (*Nicotiana tabacum*) interaction results in a local temperature increase (second row), beyond the visually affected area (image first row). The area of chlorophyll fluorescence decrease is also more extended than the visual damage, and expanding further outward is a halo of increased fluorescence (third row). Chlorophyll fluorescence under high intensity illumination only show the extent of tissue death (fourth row) (see also [46]). Middle column: *Cercospora beticola* infection of sugar beet (*Beta vulgaris*) at 7 days after infection shows a local decrease in leaf temperature (second row), while the visual effect is limited to a pin-point lesion (first row), which can also be seen as a small spot of lower chlorophyll fluorescence (third row). An increase in chlorophyll fluorescence is visible around this spot, and is more clearly visible at higher intensity illumination (fourth row) (see also [46]).

1
2
3 Right column: *Botrytis cinerea* infection of common bean (*Phaseolus vulgaris*) 21 h after infection.

4 An increase in local, leaf temperature is apparent (second row), while a few co-located spots of
5 increased chlorophyll fluorescence are detectable (third row). As a reference a wounding spot is
6 included on the other side of the main leaf vein, and visible as a cold spot in the thermal picture
7 (second row). The visible damage (first row) corresponds to the black spots in the Chl-F image
8 captured at high light-intensity (fourth row) (see also [102]).

For Peer Review

Arabidopsis plants as imaged with a multispectral fluorescence imaging system. In each panel, upper left and lower right position feature a spontaneous cell death mutant lsd (lesions simulating disease resistance, [42]; the other 2 plants are the Col-0 wild type from which this mutant was derived. Upper left: color reflectance image, middle panel: green fluorescence emission (550nm), right panel: chlorophyll fluorescence emission (690nm). The lower panels show thresholding of respectively color video and green fluorescence image, the latter indicating the leaf area affected by cell death. Thresholding of the chlorophyll fluorescence image includes part of the growing medium background and displays little or no contrast between affected and unaffected leaf areas, as is already evident from the depicted original fluorescence image. The lower right panel shows a

schematic robotized system applicable for multi-sensor imaging.
