Abstract

Model biopolymers are powerful tools to guide the interpretation of physical properties in complex systems. (Pro-Pro-Gly)$_{10}$, (PPG)$_{10}$, is a collagen model peptide, whose structure is known at high resolution. Herein, Raman microscopy data of (PPG)$_{10}$ powders and single crystals are reported. The spectra interpretation leads to an accurate assignment of three well-resolved amide bands corresponding to the three peptide bonds (PP, PG and GP) present in the (PPG)$_{10}$ structure. These data together with the availability of torsional angles $\phi$ and $\psi$ derived from the high-resolution crystal structure, provide the opportunity to test the validity of theoretical equations for the calculation of non canonical amide III bands and represent a reference for theoretical calculations of vibrational spectra and for polyproline II detection in complex proteins. Spectroscopic data do not support the indication of two distinct and equally populated up and down conformations of the pyrrolidin rings observed in the (PPG)$_{10}$ crystal structure.

Keywords: Raman crystallography, collagen, amide bands, proline puckering.
Introduction

Collagen, the most abundant protein in animals, readily forms fibers, which yield mechanical support to skin, tendons and bones. In the last decade, a variety of collagen model polypeptides have been synthesized and characterized, and they have shed light on peculiar features related to collagen structure and stability.

Two of these collagen models, (Pro-Pro-Gly)$_{10}$, referred to as (PPG)$_{10}$, and (Pro-Hyp-Gly)$_{10}$ (POG) adopt a structural motif typical of a triple helix. (PPG)$_{10}$ is well characterized both from a structural [1] and a thermodynamic [2] point of view. Particularly, the melting temperature associated to the trimer disassembly is around 40 °C [2]. The low-resolution picture of (PPG)$_{10}$ shows a cylinder with length and diameter of 8.6 and 1.5 nm, respectively. The high resolution (1.3 Å) crystallographic structure of (PPG)$_{10}$ (Protein Data Bank code 1K6F) revealed accurate $\phi$ and $\psi$ angles, and an alignment between chains driven by the charged extremity (N and C terminals) [1]. Based on high resolution structural information of (PPG)$_{10}$ [1], generalized as (X-Y-G)$_{10}$, a new hypothesis was proposed for the extra stabilization induced by Hyp in Y [3]. This hypothesis is based on intrinsic conformational propensities of pyrrolidine rings within the triple helix of (X-Y-Gly)$_{10}$. According to this hypothesis, proline rings in the X position take down puckering and those in the Y position take up puckering. Here, up and down puckering correspond to the negative and positive values of $\chi_1$ dihedral angles, respectively. This strict dependence of proline puckering on its position in the triplet was first observed at 100 K inside the (PPG)$_{10}$ crystals for the inner proline residues [1], though the equivalent structure for (PPG)$_{9}$ revealed that five proline residues at the Y position are in a down puckering conformation [4]. Furthermore, NMR study of (POG)$_{10}$ in an aqueous solution showed that proline residues at the X
position have a *down* puckering conformation [5]. Successively, proline ring puckering of (Pro-Hyp-Gly)$_{10}$ was re-examined using X-ray diffraction data collected at high resolution (1.26 Å) in order to obtain reliable information both at 100 K and room temperature [6]. At 100 K, all the seven Hyp residues in the asymmetric unit at the Y position show *up* puckering, while proline rings at the X position take three *up* and four *down* puckering. Differently, at room temperature, X position has one *up* and six *down* puckering in (Pro-Hyp-Gly)$_{11}$. The crystal structure of (GOO)$_9$ shows even *up* puckering of the proline ring in the X position [7].

Raman spectroscopy has been extensively used on protein systems in order to investigate secondary structure features [8], ligand binding [9], Se-Met incorporation [10], disulfide-bridge formation and conformation [11]. Raman microscopy is a valuable tool in assisting biocrystallographers [12, 13], and it is now available on synchrotron beamlines [14]. Many Raman studies have been conducted to detect polyproline II conformation in oligo- [15, 16], poly-peptides and proteins [17]. Raman optical activity [18] and UV-Raman resonance spectroscopy [19] are also valuable tools to extract secondary structural details. *Ab initio* studies [20] and semi-empirical relationships [21, 22] of amide I and III bands (IR inactive) with torsional angles $\phi$ and $\psi$ are also available. The availability of polypeptides such as (PPG)$_{10}$ with a repetitive primary structure [only three types of peptide bonds (PP, PG and GP)], and a unique polyproline II secondary structure in a pure triple-helix quaternary structure provides the opportunity to define a relationship between vibrational properties and high-resolution structural details.

**Materials and Methods**

**Materials.** (PPG)$_{10}$ powders were purchased from Peninsula Laboratories. The other chemicals used in this work were purchased from Sigma Chemical Co.
**Results and discussion**

A Raman microscopy study was conducted on (PPG)\textsubscript{10} powders and single crystals. (PPG)\textsubscript{10} crystals grown for this Raman studies are isomorphous with those used for the structural determination \[1\]. Spectra at low (400-1200 cm\textsuperscript{-1}) and high (1200-1700 cm\textsuperscript{-1}) frequency are reported in Figure 1 A and B. The Raman spectrum of a polypeptide is usually subdivided into three main regions of interest: 1) the range between 870–1150 cm\textsuperscript{-1} associated with the vibrations...
of the backbone Cα-C and Cα-N; 2) the range between 1230–1350 cm\(^{-1}\) containing the amide III region vibrations associated with normal modes of various combinations of the Cα-H and N-H deformations together with the Cα-C and Cα-N stretches \[24\]; 3) the range between 1630–1700 cm\(^{-1}\) associated with C=O stretching modes, defined amide I region \[25\].

In our case, the assignment of the primary structure features of Raman bands is very straightforward, since only Pro side-chains are present. For (PPG)\(_{10}\) crystals, signals corresponding to the mother liquor (containing PEG 400 10 %, sodium acetate 100 mM pH 5.3) are observed and are marked by a star in the Raman spectra. For (PPG)\(_{10}\) powders, no background peak is expected.

Frequencies corresponding to the major bands and their tentative assignments, proposed in agreement with previous studies \[26\], are reported in Table 1. The CH regions, reported in the supplementary material (Figure S1), is similar to the proline spectrum \[27\].

Since crystals are isomorphous to those used for structural determination \[1\], the Raman crystallography study of (PPG)\(_{10}\) provides the opportunity to define a relationship between vibrational properties and high-resolution structural details regarding both the \(\phi\) and \(\psi\) torsional angles and the proline puckering.

Amide bands

Raman amide I \[28\] and amide III \[22\] frequencies correlate with Ramachandran torsion angles and hydrogen bonds. Therefore, these bands reveal secondary structure features and hydration level. The peculiar absence of intra/inter chain H-bond in the (PPG)\(_{10}\) structure implies a relevant effect of the hydration pattern to define the super-assembly \[1, 6\]. The position of three amide I bands in (PPG)\(_{10}\) crystals (1629, 1645 and 1669 cm\(^{-1}\)) is in good agreement with previous FT-IR absorption spectra of (PPG)\(_{10}\) solution \[29\]. This finding provides strong evidence of similar
hydration and Ramanchandran angles between (PPG)_{10} solutions and crystals, thus suggesting that crystal packing effects are not detectable for this (PPG)_{10} Raman study. In the FT-IR study [29], the central peak has the highest absorbance, followed by the shoulders 1629 and 1667 cm\(^{-1}\), whereas in this Raman study the 1629 cm\(^{-1}\) peak has highest intensity, followed by the peaks 1645 and 1669 cm\(^{-1}\). These three bands correspond to three non-equivalent amide C=O groups in each of the Pro-Pro-Gly units. According to a previous study [29], the main peak at 1629 cm\(^{-1}\) comes mainly from the carbonyl of Pro in X position (with a small contribution of the glycy1 group). The high frequency peak is mainly due to the carbonyl of Pro in Y position, whereas the central peak comes from the glycy1 carbonyl, with a minor contribution of X and Y Pro carbonyls.

The amide I bands of (PPG)\(_{10}\) crystals and powders are significantly different, not only for the intensity distribution of the crystal spectrum (depending on the orientation of the polarization of the exciting laser beam with respect to the main axes of the Raman tensor in the respective unit cell [30]), but also for the frequency of the Raman peaks. Analogously to (PPG)\(_{10}\) crystals, spectra of (PPG)\(_{10}\) powders are characterized by three distinct well-resolved amide I bands (1638, 1655, 1690 cm\(^{-1}\)), suggesting only one conformation (\(\phi\) and \(\psi\) pair) for each residue of the repeating triplet. The three amide I bands, and especially the well resolved band at 1690 cm\(^{-1}\), do not match the frequencies reported by FT-IR solution studies for the unfolded (PPG)\(_{10}\) (maximum at 1633 and a shoulder at 1665 cm\(^{-1}\)) or for the unfolded polyproline (one band at 1621 cm\(^{-1}\)) [29]. Therefore, the differences between amide I regions of (PPG)\(_{10}\) powders and crystals might be attributed to a different hydration state, due to the liophylization process used to prepare commercial powder.

The 1200-1350 cm\(^{-1}\) region of (PPG)\(_{10}\), generalized as (X-Y-G)\(_{10}\), is here reported for the first time. The analysis of the 1200 and 1350 cm\(^{-1}\) region is problematic for Pro residues. Indeed,
prolines do not exhibit a canonical amide III vibration owing to the absence of a NH bond. Nevertheless, in this region two major bands can be distinguished, both for (PPG)_10 crystals and powders. For powders, two prominent bands are observed (1249 and 1269 cm\(^{-1}\)). Furthermore, a very minor higher frequency band has been observed at ca. 1302 cm\(^{-1}\). For (PPG)_10 single crystals, two prominent shorter frequencies at ca. 1249 and 1274 cm\(^{-1}\) and a very minor higher frequency (ca. 1320 cm\(^{-1}\)) are observed.

The analysis of these three bands in the amide III (Table 1) has been tentatively carried out by a correlation between predicting equations derived for canonical amide III bands [21, 22] and the structural information of (PPG)_10 average \(\psi\) angles previously reported [1]. In fact, though the \(\phi\) angles vary as well along the helix [1], the \(\phi\) angular dependence of amide III frequency is supposed to be small [22]. In general, predictive equations [21, 22] capture the physics of the frequency dependence in that they calculate the \(\psi\) angular dependence of the coupling of the Amide III vibration with \(\text{C}^\alpha\text{H}\) bending. If the 1200-1320 cm\(^{-1}\) region has a significant contribution of the non-canonical amide III bands expected for Pro residues, besides the \(\text{CH}_2\) rocking-wagging bands, the comparison between experimental bands in the amide III region and predicted amide III frequencies is good for the Asher’s equation [21] (see Table 2), but not for others [22]. Despite the hydration, accurately described in the structural studies [1, 6], is not included explicitly into the successful semi-empirical equation [21], the agreement between experimental and theoretical frequencies in the amide III region of (PPG)_10 is quite good. Within this assignment, the strong putative amide III bands correspond to the two proline residues in X and Y position, whereas the very minor amide III bands correspond to the Gly amide bonds.

*Proline puckering*
Regarding the proline puckering in collagen-model peptides, multiple structural observations have been reported, as summarized in the Introduction. Raman crystallography might shed light on this issue, since the preferential alternate \textit{up} and \textit{down} puckering of the proline ring observed in (PPG)\textsubscript{10} crystal structure \cite{1} is expected to have a vibrational spectroscopy counterpart. Indeed, Raman bands are sensitive to the Pro ring puckering \cite{26}. In particular, on the bases of DFT calculations performed on the two isomers (puckering \textit{up} and \textit{down}) of proline zwitterion, several vibrational modes are expected at different frequency, producing band broadening or even two well-resolved bands \cite{26}. Though the two equally intense bands at 564 and 543 cm\textsuperscript{-1} in Figure 1B might remind a doublet (568 and 546 cm\textsuperscript{-1}) for ring bending II (mode 7 in ref \cite{26}) of the two \textit{up} and \textit{down} isomers reported by Kapitan et al for Pro zwitterion, \cite{26} the inspection of (PPG)\textsubscript{10} crystal Raman spectra does not indicate other predicted doublets. This observation can be explained with a higher abundance of \textit{down} Pro conformation in (PPG)\textsubscript{10} crystals \cite{1, 4, 6} or with a failure in extending DFT calculations on Pro zwitterion and Polyproline \cite{26} to (PPG)\textsubscript{10}. In the last case, further computational analyses are required to definitively assign the bands corresponding to the two \textit{up} and \textit{down} isomers of proline rings in (PPG)\textsubscript{10}. Ultimately, this work does not support the indication of two distinct and equally populated up and down conformations of the pyrrolidin rings observed in the (PPG)\textsubscript{10} crystal structure.

Altogether these data suggest that Raman microscopy of single crystals is a valuable tool to study ring conformation and amide bands, detectable in solution only via UV Resonance Raman (UV-RR) spectra. Possible disadvantages of Raman crystallography versus UV-RR can be a) the presence of mother liquor and b) the risk of structural perturbation induced by packing contacts. On the other hand, advantages are a) a tight comparison between microscopic spectra and crystal
structure, when compared under the same environmental conditions (e.g. temperature and cryoprotectant) and b) that UV-RR solution spectra register a distribution of aggregation states and of accessible torsional angles, possibly wider in solution than in the crystal phase.
