Abstract

The self assembly in aqueous solution of a modified amyloid beta peptide fragment is studied. We focus on sequence Aβ(16-20), KLVFF, extended by two alanines at the N terminus to give AAKLVFF. Self-assembly into twisted ribbon fibrils is observed, as confirmed by transmission electron microscopy (TEM). Dynamic light scattering reveals the semi-flexible nature of the AAKLVFF fibrils, while polarized optical microscopy shows that the peptide fibrils crystallize after an aqueous solution of AAKLVFF is matured over 5 days.

The secondary structure of the fibrils is studied by FTIR, circular dichroism and x-ray diffraction (XRD), which provide evidence for β-sheet structure in the fibril. From high resolution TEM it is concluded that the average width of an AAKLVFF fibril is (63±18) nm, indicating that these fibrils comprise beta-sheets with multiple repeats of the unit cell, determined by XRD to have have b and c dimensions 1.9 and 4.8 nm with an a axis 0.96nm, corresponding to twice the peptide backbone spacing in the antiparallel β-sheet.
1. Introduction

The formation of fibrils by peptides or proteins under appropriate solution conditions is relevant to amyloid diseases such as Alzheimer's [1]. Understanding the process of peptide fibrillisation in terms of peptide structure and intermolecular interactions is therefore of great interest. Fibrils are commonly based on hydrogen-bonded $\beta$-sheet, and the precise details of $\beta$-strand packing will depend on non-covalent forces including aromatic $\pi - \pi^*$ stacking interactions, hydrophobic interactions and electrostatic interactions.

We have recently been investigating the self-assembly of peptides based on a core sequence of the amyloid $\beta$ peptide. The amyloid $\beta$ peptide is important in Alzheimer's, a so-called amyloid disease and is cleaved in vivo from a larger precursor protein to form fragments with predominantly 40 or 42 residues [1-3]. We have focussed on sequence KLVFF, corresponding to $\text{A}_\beta$(16-20). This core sequence of the amyloid $\beta$ peptide is believed to be critical in aggregation of $\text{A}_\beta$ into fibrils, as reviewed elsewhere [1]. We have examined its self-assembly in aqueous solution [4]. due to controversy as to whether it forms $\beta$-sheet fibrils or not. We find clear evidence from in situ cryo-TEM (transmission electron microscopy) and small-angle x-ray scattering experiments that it does fibrillise and FTIR spectroscopy and fibre x-ray diffraction confirm $\beta$-sheet structure (we discuss in detail the effects of drying during sample preparation) [4]. This sample also forms hydrogels in more concentrated solution [4].

We have prepared variants of KLVFF extended at the N-terminus with additional hydrophobic residues with the aim to investigate the role of hydrophobic and aromatic interactions on peptide self-assembly. In particular, we have examined the fibrillisation of FFKLVFF in methanol (the peptide is too hydrophobic to dissolve in water) and found evidence for $\beta$-sheet self-assembly [5]. We propose that this is
driven in large part by aromatic interactions between F residues, as confirmed by UV (ultraviolet) and CD (circular dichroism) spectroscopy.

A sample with non-aromatic residues at one terminus, AAKLVFF, was also prepared [6]. This has solubility in both aqueous and non-aqueous solvents. The self assembly of AAKLVFF in methanol is reported elsewhere [6]. We show that when dissolved in methanol, AAKLVFF self-assembles into nanotubes, which can form a nematic phase at sufficiently high concentration [6]. The present paper presents a comprehensive study on the self-assembly of AAKLVFF in aqueous solution. Our studies reveal that the peptide self assembles into very well ordered fibrils in water. The structure of the AAKLVFF fibrils was studied by transmission electron microscopy (TEM) and dynamic light scattering (DLS). Polarized optical microscopy (POM) was used to quantify the ageing behaviour of the fibrils. The secondary structure of the peptide fibres was studied by Fourier transform infrared (FT-IR), circular dichroism (CD) and X-ray diffraction (XRD).

2. Experimental Section

Materials. AAKLVFF was custom synthesized by C.S. Bio Company (USA) and was used as received, without further purification. Scheme 1 shows the chemical structure of AAKLVFF. Solutions were made using amounts of peptide and Millipore filtered water. The solutions were mixed using a magnetic stirrer for 1 hour and left to rest for the following two hours. Experiments were performed within 12 hrs of sample preparation, with the exception of the POM experiment, which was performed after 5 days of sample preparation (to allow for the ageing of the solution).

TEM. Experiments were performed using a Philips CM20 transmission electron microscope operated at 80kV while HR-TEM was done using a JEOL microscope operated at 100 kV. Droplets of the peptide solution (1 wt % AAKLVFF) was placed
on Cu grids coated with a carbon film (Agar Scientific, UK), stained with uranyl acetate (1 wt %) (Agar Scientific, UK) and dried.

**DLS.** Experiments were performed using an ALV CGS-3 system with 5003 multi-digital correlator. The light source was a 20 mW He-Ne laser, linearly polarized, with $\lambda = 633$ nm. Scattering angles in the range $50 \leq \theta \leq 150^\circ$ were used for all the experiments. Samples containing 0.5 and 1 wt % AAKLVFF were filtered through 0.20-$\mu$m Anotop filters from Whatman into standard 0.5 cm diameter cylindrical glass cells.

DLS experiments measured the intensity correlation function:

$$g^{(2)}(q,t) = \frac{\langle I(q,0)I(q,t) \rangle_T}{\langle I(q,0) \rangle_T^2}$$  \hspace{1cm} (1)

where $q = \frac{4\pi\sin(\theta/2)}{\lambda}$ is the scattering vector ($\lambda$= vacuum wavelength of the radiation and $n$= refractive index of the medium) and $I(q,t)$ is the intensity scattered by the sample at time $t$ in the course of an experiment of duration $\tau$.

The measured intensity correlation function is related to the field correlation function, $g^{(1)}(q,t)$, by the Siegert relationship:[7]

$$g^{(2)}(q,t) = 1 + A[g^{(1)}(q,t)]^2$$  \hspace{1cm} (2)

where $A$ is an experimental constant proportional to the ratio between the coherence area and the detector area, which takes the value 0.5 for our experimental setup.

**POM.** Images were obtained with an Olympus BX41 polarized microscope by placing the sample between crossed polarizers. Samples were placed between a glass slide and a coverslip before capturing the images with a Canon G2 digital camera.

**Circular Dichroism.** The circular dichroism (CD) spectra were recorded on a Chirascan spectropolarimeter (Applied Photophysics, UK). The peptide solution (1 wt % AAKLVFF) was loaded into a 1 mm or 0.1 mm quartz cells. CD experiments were also performed on a dried film from a 0.5 wt % AAKLVFF solution, obtained by drying a few drops of the solution on a cover slip. Spectra were obtained from 200 to 260
nm with a 0.5 nm step and 2 second collection time per step at 20 °C, taking five averages. The absorbance $A$ was monitored and the CD data is presented for $A < 2$ at any measured point.

**FT-IR.** Spectra were recorded using a Nexus-FTIR spectrometer equipped with a DTGS detector and a multiple reflection ATR system. Transmission FT-IR measurements were performed using a CaF$_2$ plate, while grazing angle FT-IR experiments were done using a ZnSe plate. For both transmission and grazing angle configurations, small aliquots of a 1 wt % AAKLVFF solution was deposited on the corresponding plate and allowed to dry, providing a solid film of dry peptide. Spectra were scanned 64 times and 128 times for transmission and grazing angle geometries respectively, over the range of 4000-400 cm$^{-1}$.

**XRD.** X-ray diffraction was performed on stalks prepared by drying filaments of the peptide. An aqueous solution of the peptide (1 wt %) was suspended in between the ends of wax-coated capillaries and dried. The stalks were mounted (vertically) onto the four axis goniometer of a RAXIS IV++ x-ray diffractometer (Rigaku) equipped with a rotating anode generator. The XRD data was collected using a Saturn 992 CCD camera.

### 3. Results and Discussion

The self-assembled morphology of AAKLVFF in water was studied by TEM and HR-TEM and DLS. The time evolution of fibrillar aggregates was studied by POM. In a second stage, the secondary structure of AAKLVFF fibrils was assessed using CD, FTIR and XRD. The presentation of our results starts with the discussion of the results concerning the fibrillar structure, followed by the spectroscopy results on the study of the secondary structure.
**Self-organisation of AAKLVFF**

Solutions containing 1 wt % AAKLVFF were studied by TEM and HR-TEM. Figures 1 a-b show TEM images for a dried film. It was observed that AAKLVFF fibrils were well defined; with a high polydispersity in length. The TEM image in Figure 1a reveals that the fibrils are twisted. A detail of this twisting is shown in Figure 1b which presents an image obtained via HR-TEM. According to the images in Figures 1a-b, each fibre is appears to comprise three (21±6) nm wide protofilaments. The average thickness of fibrils is (63±18) nm while the pitch of the helically twisted fibrils is very polydisperse, being approximately (770 ± 370) nm. TEM and HR TEM did not provide a definite value for the fibril length. However, it was possible to determine that 1 wt % AAKLVFF solutions might contain fibrils longer than 5000 nm.

DLS experiments were undertaken in order to evaluate the flexibility of AAKLVFF fibrils in solution. Figure 2 shows the intensity correlation functions measured at 90° for 1 and 0.5 wt % AAKLVFF. DLS experiments were initially done on 1 wt % AAKLVFF samples, but these samples gave evidence not only of fibril formation but also of the onset of gelation. Indeed, the broad peak measured in the intensity correlation function for longer diffusion times indicates non-ergodic dynamics (Figure 2). In order to inhibit gelation effects, the sample was diluted to 0.5 wt % AAKLVFF, which resulted in the suppression of the ‘gelation’ peak, as can be observed in Figure 2.

DLS has already been used to study the formation of amyloid fibres from many peptides and fibrils, such as β-lactoglobulin [8-10]. The field correlation function corresponding to a solution of protein fibres with several tens of nanometers in length presents a single exponential behaviour, corresponding to a single relaxation mode with a well-defined hydrodynamic radius. We found that it was necessary to account for a distribution of relaxation times in analysing DLS data from AAKLVFF. A
stretched exponential function to model \( g^{(1)}(q,t) \) allows for a spectrum of relaxation times resulting from the internal modes of the fibres:

\[
g^{(1)}(q,t) = A_0 + A_i \exp\left(-\frac{t}{\tau_\beta}\right)^\beta
\]

where \( \tau_\beta \) is a characteristic decay time of the system, \( A_i \) are the relative scattering amplitudes of the system (\( \sum_i A_i = 1 \)) and the exponent \( \beta (0 \leq \beta \leq 1) \) is a measure of the width of the corresponding distribution of relaxation times, the smaller the value of \( \beta \), the broader is the distribution. The mean characteristic time, \( \overline{\tau_\beta} \), of the stretched exponential mode is given by \( \overline{\tau_\beta} = (\tau_\beta / \beta) \Gamma(1/\beta) \) where \( \Gamma(1/\beta) \) is the gamma function. The corresponding decay time is \( \overline{\Gamma_\beta} = 1/\overline{\tau_\beta} \). An alternative procedure to describe a distribution of decay times is the method of cumulants, as used for example by Murphy and coworkers to analyse DLS data from amyloid \( \beta \) (A\( \beta \)) peptide fragments [2,11,12]. Here, we have used the alternative, Eq.3.

DLS curves measured in the interval \( 50 \leq \theta \leq 150^\circ \) were used to calculate the corresponding \( g^{(1)}(q,t) \) (Equation 2). The resulting field correlation function was then fitted to Equation 3. The parameter \( \beta \) was fixed to 0.75 for all the fittings which is the value expected for a system of semiflexible polymers (\( \beta = 3/4 \)) [13]. Figure 3a shows a representative example for \( g^{(1)}(q,t) \) calculated for \( \theta =70^\circ \) and fitted using Equation 3, while Figure 3b shows the dependence of \( \overline{\Gamma_\beta} \) with \( q^2 \) obtained from the fitting of the correlation functions using Equation 3.

The straight line for the \( q^2 \) dependence of \( \overline{\Gamma_\beta} \) in Figure 3b does not pass through the origin, suggesting that \( \overline{\Gamma_\beta} \) should be associated to an internal mode of the AAKLVFF fibrils.
If a system presents diffusive dynamics, the decay rate approaches zero close to $q = 0$. The diffusion coefficient $D$ can then be calculated from the gradient of the plot of $\Gamma$ vs. $q^2$ according to the expression:

$$\Gamma = Dq^2$$  \hspace{1cm} (4)

But, since the straight line for the $q^2$ dependence of $\Gamma$ in Figure 3b does not pass through the origin, i.e. Equation 4 had to be modified to include an additional constant offset. However, it is possible to base the analysis of the dynamics defining $D_f$ as the gradient of the line excluding the constant offset, which will be understood as an “effective diffusion coefficient”. In this way, it is possible to calculate from the slope in Figure 3a a value $D_f = 3.6 \times 10^{-14}$ m$^2$ s$^{-1}$.

Since the diffusion coefficient and the hydrodynamic radius are reciprocally related by the Stokes-Einstein equation, and this $D_f$ value is smaller than $D = 3.8 \times 10^{-13}$ m$^2$ s$^{-1}$ reported for AAKLVFF nanotubes in methanol [6], the AAKLVFF fibrils in water occupy a larger volume than the nanotubes in methanol.

The ageing of AAKLVFF fibrils was investigated by microscopy. A small volume (1 ml) of 1 wt % AAKLVFF solution was matured for 5 days in a glass vial. The naked eye observation of the matured sample denoted a well defined two-phase separation, consisting of a solid white precipitate of peptide on the bottom of the vial and a top layer of water. This result shows that the white precipitate of peptide is heavier than water and probably consists of AAKLVFF crystals. The crystallization of peptides upon incubation in an aqueous phase has already been noted, for example for KFFEAAAKKFFE which crystallized after incubation of the peptide for several days in a phosphate buffer saline (PBS) aqueous solution.[14] Needle-shape crystals were observed, with lengths in the order of micrometers and diameters in the range ~(12-240) nm [14].

The partially hydrated AAKLVFF precipitate of the 1 wt % peptide matured sample was studied by POM. Figure 4a shows a POM image obtained for the
precipitate placed between a glass slide and a coverslip, at time \( t = 0 \) s. Figure 4b shows a photograph of the same area taken at \( t = 4 \) s, after the spontaneous process of drying the partially hydrated precipitate under the coverslip has started. A qualitative evaluation of the results in Figure 4 reveals that the incubation of AAKLVFF in water gives rise to needle-shape crystals with an average length of \((41.2 \pm 9.4) \mu m\) and an average width of \((2.4 \pm 0.8) \mu m\). These are much larger than the dimensions of the fibrous crystals observed for KFFEAAKKFFE, suggesting a higher crystallization propensity in AAKLVFF. It is probable that the change in configuration between Figure 4a and Figure 4b results from further crystallization upon drying.

**Secondary Structure of AAKLVFF fibrils**

The secondary structure of the AAKLVFF fibres observed in a 1 wt % peptide solution, was studied for dried films, using FT-IR in transmission and grazing incidence modes. The FT-IR spectra in transmission and grazing incidence mode obtained in the wave-numbers range \((1350-1975) \text{ cm}^{-1}\) and \((2500-3825) \text{ cm}^{-1}\) are shown in Figure 5a and Figure 5b respectively. The direct comparison of transmission and grazing incidence FT-IR results has already been used by Hartgerink and co-workers [15] as a strategy to determine the orientation of the \(\beta\)-sheets with respect to the main axis of the fibril, in \(\beta\)-sheet nanofibers of peptide-amphiphiles.

The orientation of the sample surface is perpendicular to the incident IR beam for the transmission FT-IR experiments, while for grazing incidence FT-IR experiments the beam is almost parallel to the surface of the sample. As already pointed out by Hartgerink and co-workers [15] peptide fibrils with a large length to diameter radius will lie flat when deposited as a dry film onto a solid surface. This hypothesis applies to AAKLVFF fibrils, which present a large length to diameter
radius (according to TEM length/radius > 5000 nm/30 nm). Therefore, a change in the angle between the IR beam and the sample surface is equivalent to a change in the angle between the IR beam and the amide bond.

Figure 5 shows that both the grazing incidence and transmission FT-IR data present absorbance peaks at similar wavenumbers but with different intensity.

FT-IR spectra in the amide I band are sensitive to secondary structure (Figure 5a). The peaks at 1693 and 1628 cm\(^{-1}\), in the amide I band, are associated with a \(\beta\)-sheet structure [16,17]. In particular, the strong amide I band at 1628 cm\(^{-1}\) in combination with the weaker amide I band at 1693 cm\(^{-1}\) obtained for the transmission FT-IR, suggests an antiparallel \(\beta\)-sheet conformation of the peptide chains [16-18].

The peak at 1453 cm\(^{-1}\) is associated with the amide II band,[17, 19] while the peak at 1533 cm\(^{-1}\) is associated with the N-H in-plane bending or C-N stretching modes.[20]

Additional FT-IR peaks were located in the amide A band at 3278 cm\(^{-1}\) and amide B band at 3083 cm\(^{-1}\) (Figure 5b). An absorption peak at 3030 cm\(^{-1}\) was due to the stretching vibration from the benzene rings. A peak at 2959 cm\(^{-1}\) was due to the CH\(_3\) vibration. A peak at 2930 cm\(^{-1}\) was assigned to the CH\(_2\) asymmetric stretching bands while a peak at 2869 cm\(^{-1}\) was due to the CH\(_3\) symmetric stretching bands.

Figure 5a provides evidence of \(\beta\)-sheet structure in the AAKLVFF fibrils. The results in Figure 5a show that the amide I band is attenuated and the amide II band is enhanced in the grazing incidence experiment. Hartgerink and co-workers [15] show that this occurs when the IR laser beam is oriented parallel to the C=O bonds. These are oriented along the fibril axis. This alone does not enable twisted fibrils to be differentiated from untwisted ones, however the TEM clearly shows the twisted structure.

In a previous work we showed that AAKLVFF self assembles in methanol into nanotubes. It was suggested that the walls of the nanotubes arise from the helical
The wrapping of AAKLVFF β-sheets [6]. The fibril model for AAKLVFF in water (represented by β-strands twisted around a common axis) is consistent with that previously proposed by us for the structure of AAKLVFF nanotubes in methanol [6], but here the β-sheets do not close into nanotubes, possibly due to unfavourable interactions between ribbon edges. Both models for the AAKLVFF nanotube or fibril follow the geometrical relationships for winding of a tape into a helical ribbon developed by Chung et al. [21]. The tendency for the β-sheets to twist into ribbons [22] results from the interfacial curvature with its origin in the packing of side chains with different effective volumes (eg. aromatic vs. non-aromatic residues). 

SAXS shows AAKLVFF nanotubes in methanol have a diameter of (72±8) nm [6], which is similar to the (63±18) nm diameter measured in this work using HR-TEM for the AAKLVFF fibrils in water (when dried TEM suggested that the AAKLVFF nanotubes unwrap to give 130 nm wide sheets). This suggests that the nanotubes are “fully wrapped” ribbons, as suggested in our original work. The formation of closed nanotubes may result from changes in solution permittivity in methanol compared to water. This may modulate the electrostatic interactions between ribbon edges resulting from the charged peptide termini and lysine residue, that may lead to closed nanotube formation. It may be noted that the β-sheet width may also differ in methanol compared to water due to different H-bond strengths.

CD experiments were undertaken on a 1 wt % AAKLVFF solution and on a dried film obtained from a 1 wt % AAKLVFF solution, to provide additional information on the secondary structure of the fibril. Figure 6 shows the CD spectra obtained for the AAKLVFF solution and dried film. The spectrum for the dried film is dominated by a negative maximum at 217 nm, which denotes a β-sheet structure [23]. In contrast, the CD spectrum for the solution contains a red-shifted negative maximum at 228 nm and a positive band at 209 nm. Such spectra are often ascribed to β-turn structures [23-25], however it seems unlikely that a very short peptide like AAKLVFF could
adopt such a structure, considering in particular the unit cell obtained from X-ray
diffraction (vide infra). We can alternatively interpret the CD spectrum from the
solution on the basis that the positive maximum due to n - π* aromatic stacking
interactions between phenylalanine residues in solution [4,5] causes a red-shift of the
negative maximum at 217 nm due to β-sheet structure.

XRD was used to provide further evidence of amyloid fibril formation and to
gain an insight into their secondary structure. Dried stalks of peptide were prepared
by drying a thread of 1 wt % AAKLVFF solution between the ends of two waxed
capillaries. The sample was partially aligned by stretching the thread before the
drying process started, and the resulting XRD pattern (Figure 7) shows a well-defined
“cross-β” pattern\(^1\) with, unusually for amyloid fibrils, multiple orders of reflection. This
facilitates determination of the unit cell, which was performed using the software
CLEARER [14]. The results provided an orthorhombic unit cell, with unit axis \(a = 9.6\)
Å, \(b = 18.6\) Å and \(c = 43.7\) Å. The values of the observed and calculated reflections
corresponding to the indexation of the XRD pattern in Figure 7, is shown in Table 1. It
is possible to understand the values of the orthorhombic unit cell axis in terms of the
AAKLVFF packing within the β-sheet. Within that frame, the cell axis \(a\) represents the
peptide backbone separation within a β-strand [4] while the cell axis \(b\) corresponds to
the spacing of two beta sheets (with relatively small side groups, and efficient
packing).[4] Assuming that all the peptide residues are in the β-sheet, the cell axis \(c\)
corresponds to two AAKLVFF molecules (each AAKLVFF molecule is \(7 \times 3.4 = 23.8\)
Å long assuming a 7 residue antiparallel β-sheet). Scheme 2 shows the packing of
the AAKLVFF β-sheets within the unit cell, according to the indexation of the XRD
data in Figure 7. In this way, the peptide β-strand is made by the repetition in space
of the unit cell in Scheme 2, such that the resulting strand is twisted along a unique
central according to the model for the peptide fibril discussed above in relation to FT-IR
results. The dimensions of the orthorhombic cell determined for AAKLVFF fibrils
are very similar to those reported in the literature for fibrils of KFFEAAAKKFFE, i.e., $a = 9.5 \, \text{Å}$, $b = 21.3 \, \text{Å}$ and $c = 48.1 \, \text{Å}$ [14]. The $c$ axis is larger than for AAKLVFF, consist with the greater length of the 12 residue peptide.

According to XRD results, the thickness of two $\beta$-sheets of AAKLVFF is $\sim 18.6$ Å. TEM and HR-TEM show that the average width of an AAKLVFF fibril is $(63 \pm 18)$ nm, and that each fibre is made of three $(21 \pm 6)$ nm wide protofilaments. The thickness of the ribbons is approximately ten times lower than its width (Fig.1). It appears that the fibrils observed in TEM are higher order aggregates of tape-like protofilaments, containing multiple repeats of the unit cell $b$ and $c$ axes orthogonal to the fibril ($a$) axis. It would seem likely that the beta-sheets are arranged in a flat configuration with hydrophobic residues (especially phenylalanine) on one face and in the interior of the individual tapes and that the $b$ axis is associated with the ribbon thickness, although this is not unambiguous.

4. Summary

The self assembly of AAKLVFF in water has been investigated. This study builds on our previous work on AAKLVFF in methanol solutions, for which nanotube formation is observed [6]. It is remarkable that only the substitution of the methanol by water is enough to give rise to a distinct motif, i.e. peptide fibrils. The peptide fibrils are quite clearly resolved by TEM and HR TEM, while their semi-flexible nature is revealed by DLS. FT-IR and CD show that AAKLVFF fibrils consist of tape-like $\beta$-sheets twisted around a common main axis. This model for the peptide fibre agrees with the structure of AAKLVFF nanotubes in methanol, where the $\beta$-strands are also twisted along a common main axis but giving rise to the formation of a nanotube (i.e. with a hollow core around the common main axis) formation. FT-IR and CD results
were supported by XRD data, which provided additional evidence for the packing of AAKLVFF into β-strands.

AAKLVFF forms very well defined fibrils, assembled from smaller sub-units in aqueous solution and may be a model system for further studies in amyloid fibrillisation.

Acknowledgements

We thank Dr Rebecca Green (Dept of Pharmacy, University of Reading) for access to the FTIR instrument, Dr. Louise C. Serpell (Dept. of Biochemistry, Univ. of Sussex) for providing a copy of the software CLEARER and Mr. Nick Spencer (Biocentre, Univ. of Reading) for assistance with XRD experiments.
