ABSTRACT

Collagen is the principal constituent of extra-cellular, connective tissue. It is a tightly-packed but flexible bundle of proteins that constitutes a material. The collagen molecule is a triple helix made of three, intertwined polypeptide chains, associated with $\sqrt{3}$ and its rational convergents. Accordingly, the collagen fibril, a long, periodic bundle of finite collagen molecules, has a transverse structure based on two underlying, perpendicular hexagonal lattices. It is the Archimedean, square-triangle tiling $3^2.4.3.4$, in both "overlap" and "gap" regions, with small orthorhombic distortions imposed as rational approximants of the two perpendicular lattices. The three-dimensional structure is a periodic, rotating stack of gap and overlap regions, with a ten-fold rotation symmetry.

Keywords: collagen, twist grain boundary, close-packing, moiré

1. COLLAGEN: CHAIN, MOLECULE, FIBRIL

Collagen is the principal constituent of extra-cellular, connective tissue. It is made of fibrils, that are close-packed bundles of long molecules. Each molecule consists of three intertwined polypeptide chains, forming a right-handed helix (Fig.1b.c). Each chain is a nearly periodic sequence of amino acids (a.a)-[Gly-X-Y]-..., where the a.a X and Y are predominantly Pro or HPro. The collagen chain is a protein with a periodic (in Gly) primary structure and a left-handed helix that is altogether its sole secondary structure and its ternary structure (Fig.1a). Three chains join as a molecule, and the molecules assemble into a material.

The collagen molecules assemble into fibrils. Longitudinally, the molecules are separated by gaps, and the fibril is a periodic alternance of *overlap* and *gap* regions, as indicated in Fig.1d. The transverse structure is topologically, in both regions, the Archimedean square-triangle tiling $3^2.4.3.4$, also known as the main skeleton of the Frank-Kasper sigma phase, and observed by Okuyama et al. [1] in a single crystal of [Gly-Pro-Pro]₁₀. The three-dimensional structure of native collagen is a rotating stack of successive overlap-gap-overlap..., separated by boundaries of twist dislocations. The stack is periodic, as is observed.

The essential physical and geometrical features to be included in the structure of the collagen fibril are:

- a) Close-packing of amino acids in a bundle of periodic, polypeptide chains.

b) Flexibility of the fibril, compatible with close-packing. (Long, cylindrical molecules pack tightest as an hexagonal lattice. But such a bundle would be completely rigid. Flexibility requires that i) each molecule has five nearest neighbours instead of six, and that ii) there is a gap between two molecules stacked on top of each other (Fig.1e).)

c) Fibrils of arbitrary length.

d) Intertwining of the chains within the molecule at a constant rate.

Points c) and d) suggest a pattern of molecules along the fibril, and of amino acids within the collagen molecule, that is either periodic or inflationary (quasicrystalline). Diffraction, [1,2,4] indicates that the pattern is periodic, but a chain of amino acids packs naturally as a Boerdijk-Coxeter helix, that contains several approximants of $1+\sqrt{3}$ [5]. These observations are not incompatible. The (longitudinal and transverse) structure of collagen is ultimately periodic, but its unit cell exhibits many successive approximants of $\sqrt{3}$.

2. THE BOERDIJK-COXETER HELIX AND THE COLLAGEN CHAIN

Helices, and dense packing of spherical objects are two closely related geometrical problems. The simplest means of packing tightly a chain of connected spheres (representing amino acids) of arbitrary length is the Boerdijk-Coxeter (B-C) « helix » [5]. It is a stacking of regular tetrahedra, the elementary unit of four close-packed spheres. The stacking can be viewed as an hexagonal lattice (triangular tiling, unit vectors $\mathbf{k} = \mathbf{l} + \mathbf{m}$) on a cylinder. Three families (k, l, m) of helical chains of connected vertices, of different pitch and chirality, are winding around the cylinder. (The natural numbers $k = l + m \geq l \geq m \geq 0$ give the number of helical chains in each family. The B-C helix is (3,2,1) in this – phyllotactic – notation). The cylinder is cut along its axis, the lattice vector $\mathbf{b}$, and flattened. Figure 2 represents the collagen chain (one of the $l=2$ left-handed helices along $\mathbf{l}$), but the flattest chain along $\mathbf{m}$ and the three chains along $\mathbf{k}$ joining the *Gly*, *X* and *Y*, are visible. The base of the cylinder is the lattice vector $\mathbf{a} = \mathbf{l}\mathbf{m} - \mathbf{m}\mathbf{l} = 2\mathbf{m} - \mathbf{l}$.

The regular tetrahedron is not a three-dimensional space-filler. Perfect, close-packing of spheres is only possible in positively curved space [6], where the three helices along $\mathbf{k}$ in Fig. 2 are great circles with 10 vertices each. Moreover, as a one-dimensional structure in Euclidean space, the B-C helix is not periodic, not even quasiperiodic and thus extensible through a sequence of approximants : The number of vertices per turn (rate of winding) of the flattest chain is $2\pi/[\cos^{-1}(-2/3)]$, that is neither a rational number describing a periodic structure, extensible by repetition of the unit, nor a quadratic irrational describing a structure with constant winding rate, extensible by inflation. But the chain with quadratic irrational winding rate $1+\sqrt{3}$ has exactly the same rational approximants through the first 112 vertices and 41 turns ; notably 30/11, represented in Fig. 2.

The cylinder can be unwound on an hexagonal lattice, where the various helical chains are lattice vectors along the directions $\mathbf{m}, \mathbf{l}$ and $\mathbf{k}$: The flattest helix $A\mathbf{m} = w\mathbf{a} + \mathbf{b}$ has winding rate A/w . The left-handed collagen chain $A'\mathbf{l} = w'\mathbf{a} + \mathbf{b}$ has winding rate A'/w' . The steepest helix winds once around the cylinder : $(w-1)\mathbf{mk} = \mathbf{a} + \mathbf{b}$. Here, the natural integers $A, A', (w-1)m$ are the numbers of vertices on each helix, and w, w' and 1 are their winding number. All the possibilities are given by the natural integer $s, A = slk, A' = smk, w = sl + 1, w' = sm - 1$, and the cylinder contains smk vertices ($\mathbf{a} \times \mathbf{b} = smk \mathbf{m} \times \mathbf{k}$).

The B-C helix and the collagen chain has $(k,l,m) = (3,2,1)$; A/w , an approximant of $1+\sqrt{3}$, has denominator 1, 3, 4, 11, 15, 41, 56, But its winding number $w = 2s + 1$ must be odd ≥ 5 , since $w' = s - 1 \geq 1$, so that, the collagen chain has either $s = 5, w = 11, A'/w' = 15/4$ (Fig. 2), $A/w = 30/11$, or $s = 7, w = 15, A'/w' = 21/6 = 7/2, A/w = 42/15$ (one vertex must be

added to the next approximant $41/15$ of $1+\sqrt{3}$, to complete the periode of the structure : it is on the collagen chain $21/6$ along **l**, and on the steepest helix $14/1$ along **k**). Moreover, the underlying cylinder is perpendicular to its base, $\mathbf{b.a} = 0$. The helix $7/2$ ($21/6$ for chemical periodicity), periodic in Euclidean space, is thus the basic helix of collagen (identified by [1]).

The three chains intertwine to constitute the collagen molecule, a triple helix with a core consisting of the side-groups of the Gly, a B-C helix of H atoms [5].

3. TRANSVERSE STRUCTURES (GAP, OVERLAP)

The geometric and numerical interdependence between close-packing, tiling by equilateral triangles, $\sqrt{3}$ and its rational approximants is central to the structure of collagen. The transverse structure of collagen (the packing of the molecules across the fibril of Fig. 1f) is also based on approximants of $1+\sqrt{3}$. Lattices of approximants of $\sqrt{3}$ are readily obtained by superposition of two hexagonal lattices at 90° . One obtains a moiré pattern of coincidence points (Fig.3) which consists of four copies of the gap structure, shown in Fig. 4a. A vertex now represents a collagen molecule. The gap structure is, topologically, the Archimedean square-triangle tiling $3^2.4.3.4$. The axes of the unit cell and the diagonals of the « squares » mark the 6 reticular directions of the two underlying hexagonal lattices. All edges have equal length, but there is a slight distortion (the unit cell is 1% rectangular and the squares are 8% rhombi) imposed by $\sqrt{3}$ (12-fold quasicrystallography). This is the structure observed by Okuyama et al. [1] in a single crystal of $[Gly-Pro-Pro]_{10}$, with an orthorhombic distortion of 2%.

Vertex coordination of 5 makes the fibril flexible, provided that there are gaps between molecules stacked on top of each other (Fig.1e), so that the transverse structure is alternatively overlap and gap as one moves along the fibril. It has been established [7] that out of five molecules in the overlap, only four extend into the gap. Bouligand [2] has suggested that gap and overlap have the same square-triangle tiling but at two different scales, and rotated by a topological angle of $\tan^{-1}(1/2)$. He has backed his suggestion with diffraction data, and has given an elegant model (Fig.5) of the gap-overlap interface (a twist grain boundary in the fibril) and of the mechanism whereby the termination of one molecule out of five in the overlap leaves the square-triangle tiling topologically invariant (c to a).

From the gap structure, it is straightforward to construct the unit cell of the overlap structure on the underlying hexagonal lattice (Fig.4b), given the ratio between the areas of the unit cells ($112/90$, half a triangle in the gap short of $5/4$), and the topological angle of rotation ($\tan^{-1}(1/2)$ seen in Fig.6 and in Fig.5b). The roles of the slightly distorted structures are exchanged : the unit cell is 8% rhombic and the squares are 15% rectangular. It is now the edges (no longer all equal) and the diagonals of the rhombi that are along 6 reticular directions. The overlap structure has two perpendicular mirror axes defining a rectangular unit cell (they bound a fundamental domain). Several points are aligned and regularly spaced : the diagonal of the square is a third of the distance to points (2,-1) or (-1,2) of the unit cell grid. Finally, a similar overlap structure ($\sqrt{3}$ smaller) can be drawn on the same underlying lattice (rotated by 90°) with the «square » of the gap as unit cell.

The Table below lists the geometric manifestations (square and unit cell of the $3^2.4.3.4$ square-triangle tiling) of the various approximants to $\sqrt{3}$ in the overlap and gap structures [8]. The vertices are joined by lattice vectors in both underlying hexagonal lattices. If two vertices lie on one of the 6 reticular directions (symmetry axis) of the underlying lattices, an approximant is obtained from their distance measured on both lattices (the sides of a rectangle [...] on one lattice). If the vertices do not lie on a symmetry axis, they constitute, on one

lattice, an equilateral rhombus, with nearly equal diagonals on symmetry axes and nearly orthogonal side vectors. This yields two approximants (a) and (b). The last column gives the (orthorhombic or monoclinic) distortion, namely the ratio between $\sqrt{3}$ and its approximant.

j	$\sqrt{3} \approx$	overlap	gap	distortion
1	2/1	[square] unit cell (a)	square (a)	1.155
2	5/3	[mirror unit cell]		1.04
3	7/4	unit cell (b)	square (b) [unit cell]	1.01

For reference:

4	19/11	BC helix
5	26/15	inflated BC helix

The ratio in sizes of the two structures is 1.115, smaller than the topological value of $\sqrt{5/4} = 1.118$, but larger than the experimental ratio of 1.08 [2]. This discrepancy remains unexplained.

Fig.6 shows how the overlap and gap structures match as a twist grain boundary with an important coincidence site lattice, containing points $n(2,-1)$ or $n(-1,2)$ of the overlap unit cell grid and points $n(2,0)$ of the gap unit cell grid (n integer), thereby measuring the angle of rotation in Bouligand's mechanism (Fig.5). The overlap supercell containing 20 vertices and 5 unit cells, with sides $(2,-1)$ and $(-1,-2)$, fits almost exactly with the square of 2×2 gap unit cells, that contains 16 vertices. The rotation angle of $26.996^\circ = \alpha + \gamma$ is the metric equivalent of the topological rotation of $\tan^{-1}(1/2)$. (Direction $(1,0)$ of the overlap grid makes an angle $\alpha = \tan^{-1}(\sqrt{3}/6)$ with the underlying hexagonal lattice ; just as $\beta = \tan^{-1}(\sqrt{3}/9)$ for direction $(2,-1)$, that is also the diagonal of the square, or direction $(1,0)$ in the gap grid.) The rotation between two successive overlap structures across the gap, is double, namely $3\pi/10$. Note that in the unit cell of the rotated structure, the small and large rhombi have exchanged positions. Consequently, the angle of the next rotation is the complementary (to $2\pi/3$) of $3\pi/10$. The collagen fibril, a periodic stack overlap-gap-overlap-gap-..., exhibits both 10 and 12-fold rotations.

The flexibility of a long, tightly packed collagen fibril, regardless of its length or girth, is the effect of the regular alternance of gap and overlap regions with five neighbors to each molecule, that are the main features of our model.

Fig.1

Structure of collagen at various scales (from Bouligand [2,3]). a) A single chain Gly-X-Y forms a left-handed helix, with a curved axis. Dots indicate the positions of successive amino acids. Their side-groups are pointing outwards; every third one is a glycine (gly) located on the concave side of the axis. b) A collagen molecule is a right-handed triple helix of 3 intertwined, left-handed polypeptide chains. c) A simpler representation of the right-handed triple helix. Its width is 1 nm, its length, 300 nm. d) The collagen molecule is often represented by an arrow of length 300 nm. e) The molecules are stacked on top of each other, with a gap of 35 nm, and regularly spaced on a lattice (transverse scale dilated relatively to longitudinal scale). The longitudinal coordinates of molecules u and u' are the same. One distinguishes gap and overlap levels, g and o respectively, so that to each five molecules in o correspond only four in g. There is a regular stagger of molecules by a length $D = g + o = 67$ nm. f) A crude representation of the lattice as a cylinder (by identifying u and u'). This is only schematic as the collagen fibril is a lattice, showing the 67 nm stagger, but with a unit cell that accommodates gap and overlap levels. Notice the right-handed chirality of the Gly core and of the triple-helix collagen molecule, opposite to the left-handed chirality of the single collagen chain (Fig. 2).

 Fig.2

The B-C helix represented as a hexagonal lattice on a cylinder, cut along its axis (vertical gray lines) and flattened. The single collagen chain is a left-handed helix winding in the **I** direction. The axis *Gly-X* of helix $7/2$ is perpendicular to the base, so that a stack of three segments $7/2$ constitutes one period of the collagen chain in Euclidean space.

 Fig.3

Superposition of two hexagonal lattices at 90° yields a moiré pattern of coincidence points. By construction, they are the rational approximants of $\sqrt{3}$. The brightest points (corners of a square unit cell, with eight inner points) constitute four, translated copies of the gap structure, shown in Fig. 4a. The corners of the square unit cell belong to all four copies, the corners of the central square, to one copy each, and the corners of the intermediate square tilted at 45° , to two copies. Alternatively, one can view the square cell as decorated with (1/4 of) a dodecagonal wheel around each corner. Each copy of the gap structure contributes five points to the wheel.

ABSTRACT

Collagen is the principal constituent of extra-cellular, connective tissue. **It is a tightly-packed but flexible bundle of proteins that constitutes a material.** The collagen molecule is a triple helix made of three, intertwined polypeptide chains, associated with $\sqrt{3}$ and its rational convergents. Accordingly, the collagen fibril, a long, periodic bundle of finite collagen molecules, has a transverse structure based on two underlying, perpendicular hexagonal lattices. It is the Archimedean, square-triangle tiling $3^2.4.3.4$, in both "overlap" and "gap" regions, with small orthorhombic distortions imposed as rational approximants of the two perpendicular lattices. The three-dimensional structure is a periodic, rotating stack of gap and overlap regions, with a ten-fold rotation symmetry.

Keywords: collagen, twist grain boundary, close-packing, moiré

1. COLLAGEN: CHAIN, MOLECULE, FIBRIL

Collagen is the principal constituent of extra-cellular, connective tissue. It is made of fibrils, that are close-packed bundles of long molecules. Each molecule consists of three intertwined polypeptide chains, forming a right-handed helix (Fig.1b.c). Each chain is a nearly periodic sequence of amino acids (a.a)-[Gly-X-Y]-..., where the a.a X and Y are predominantly *Pro* or *HPro*. **The collagen chain is a protein with a periodic (in Gly) primary structure and a left-handed helix that is altogether its sole secondary structure and its ternary structure (Fig.1a). Three chains join as a molecule, and the molecules assemble into a material.**

The collagen molecules assemble into fibrils. Longitudinally, the molecules are separated by gaps, and the fibril is a periodic alternance of *overlap* and *gap* regions, as indicated in Fig.1d. The transverse structure is topologically, in both regions, the Archimedean square-triangle tiling $3^2.4.3.4$, also known as the main skeleton of the Frank-Kasper sigma phase, and observed by Okuyama et al. [1] in a single crystal of [Gly-*Pro-Pro*]₁₀. The three-dimensional structure of native collagen is a rotating stack of successive overlap-gap-overlap..., separated by boundaries of twist dislocations. The stack is periodic, as is observed.

The essential physical and geometrical features to be included in the structure of the collagen fibril are:

- a) Close-packing of amino acids in a bundle of periodic, polypeptide chains.

b) Flexibility of the fibril, compatible with close-packing. (Long, cylindrical molecules pack tightest as an hexagonal lattice. But such a bundle would be completely rigid. Flexibility requires that i) each molecule has five nearest neighbours instead of six, and that ii) there is a gap between two molecules stacked on top of each other (Fig.1e).)

c) Fibrils of arbitrary length.

d) Intertwining of the chains within the molecule at a constant rate.

Points c) and d) suggest a pattern of molecules along the fibril, and of amino acids within the collagen molecule, that is either periodic or inflationary (quasicrystalline). Diffraction, [1,2,4] indicates that the pattern is periodic, but a chain of amino acids packs naturally as a Boerdijk-Coxeter helix, that contains several approximants of $1+\sqrt{3}$ [5]. These observations are not incompatible. The (longitudinal and transverse) structure of collagen is ultimately periodic, but its unit cell exhibits many successive approximants of $\sqrt{3}$.

2. THE BOERDIJK-COXETER HELIX AND THE COLLAGEN CHAIN

Helices, and dense packing of spherical objects are two closely related geometrical problems. The simplest means of packing tightly a chain of connected spheres (representing amino acids) of arbitrary length is the Boerdijk-Coxeter (B-C) « helix » [5]. It is a stacking of regular tetrahedra, the elementary unit of four close-packed spheres. The stacking can be viewed as an hexagonal lattice (triangular tiling, unit vectors $\mathbf{k} = \mathbf{l} + \mathbf{m}$) on a cylinder. Three families (k, l, m) of helical chains of connected vertices, of different pitch and chirality, are winding around the cylinder. (The natural numbers $k = l + m \geq l \geq m \geq 0$ give the number of helical chains in each family. The B-C helix is (3,2,1) in this – phyllotactic – notation). The cylinder is cut along its axis, the lattice vector $\mathbf{b}$, and flattened. Figure 2 represents the collagen chain (one of the $l=2$ left-handed helices along $\mathbf{l}$), but the flattest chain along $\mathbf{m}$ and the three chains along $\mathbf{k}$ joining the *Gly*, *X* and *Y*, are visible. The base of the cylinder is the lattice vector $\mathbf{a} = \mathbf{lm} - \mathbf{ml} = 2\mathbf{m} - \mathbf{l}$.

The regular tetrahedron is not a three-dimensional space-filler. Perfect, close-packing of spheres is only possible in positively curved space [6], where the three helices along $\mathbf{k}$ in Fig. 2 are great circles with 10 vertices each. Moreover, as a one-dimensional structure in Euclidean space, the B-C helix is not periodic, not even quasiperiodic and thus extensible through a sequence of approximants : The number of vertices per turn (rate of winding) of the flattest chain is $2\pi/[\cos^{-1}(-2/3)]$, that is neither a rational number describing a periodic structure, extensible by repetition of the unit, nor a quadratic irrational describing a structure with constant winding rate, extensible by inflation. But the chain with quadratic irrational winding rate $1+\sqrt{3}$ has exactly the same rational approximants through the first 112 vertices and 41 turns ; notably 30/11, represented in Fig. 2.

The cylinder can be unwound on an hexagonal lattice, where the various helical chains are lattice vectors along the directions $\mathbf{m}, \mathbf{l}$ and $\mathbf{k}$: The flattest helix $A\mathbf{m} = w\mathbf{a} + \mathbf{b}$ has winding rate A/w . The left-handed collagen chain $A'\mathbf{l} = w'\mathbf{a} + \mathbf{b}$ has winding rate A'/w' . The steepest helix winds once around the cylinder : $(w-1)\mathbf{mk} = \mathbf{a} + \mathbf{b}$. Here, the natural integers $A, A', (w-1)m$ are the numbers of vertices on each helix, and w, w' and 1 are their winding number. All the possibilities are given by the natural integer $s, A = slk, A' = smk, w = sl + 1, w' = sm - 1$, and the cylinder contains smk vertices ($\mathbf{a} \times \mathbf{b} = smk \mathbf{m} \times \mathbf{k}$).

The B-C helix and the collagen chain has $(k,l,m) = (3,2,1)$; A/w , an approximant of $1+\sqrt{3}$, has denominator 1, 3, 4, 11, 15, 41, 56, But its winding number $w = 2s + 1$ must be odd ≥ 5 , since $w' = s - 1 \geq 1$, so that, the collagen chain has either $s = 5, w = 11, A'/w' = 15/4$ (Fig. 2), $A/w = 30/11$, or $s = 7, w = 15, A'/w' = 21/6 = 7/2, A/w = 42/15$ (one vertex must be

added to the next approximant $41/15$ of $1+\sqrt{3}$, to complete the periode of the structure : it is on the collagen chain $21/6$ along **l**, and on the steepest helix $14/1$ along **k**). Moreover, the underlying cylinder is perpendicular to its base, $\mathbf{b.a} = 0$. The helix $7/2$ ($21/6$ for chemical periodicity), periodic in Euclidean space, is thus the basic helix of collagen (identified by [1]).

The three chains intertwine to constitute the collagen molecule, a triple helix with a core consisting of the side-groups of the Gly, a B-C helix of H atoms [5].

3. TRANSVERSE STRUCTURES (GAP, OVERLAP)

The geometric and numerical interdependence between close-packing, tiling by equilateral triangles, $\sqrt{3}$ and its rational approximants is central to the structure of collagen. The transverse structure of collagen (the packing of the molecules across the fibril of Fig. 1f) is also based on approximants of $1+\sqrt{3}$. Lattices of approximants of $\sqrt{3}$ are readily obtained by superposition of two hexagonal lattices at 90° . One obtains a moiré pattern of coincidence points (Fig.3) which consists of **four** copies of the gap structure, shown in **Fig. 4a**. A vertex now represents a collagen molecule. The gap structure is, topologically, the Archimedean square-triangle tiling $3^2.4.3.4$. The axes of the unit cell and the diagonals of the « squares » mark the 6 reticular directions of the two underlying hexagonal lattices. All edges have equal length, but there is a slight distortion (the unit cell is 1% rectangular and the squares are 8% rhombi) imposed by $\sqrt{3}$ (12-fold quasicrystallography). This is the structure observed by Okuyama et al. [1] in a single crystal of $[Gly-Pro-Pro]_{10}$, with an orthorhombic distortion of 2%.

Vertex coordination of 5 makes the fibril flexible, provided that there are gaps between molecules stacked on top of each other (Fig.1e), so that the transverse structure is alternatively overlap and gap as one moves along the fibril. It has been established [7] that out of five molecules in the overlap, only four extend into the gap. Bouligand [2] has suggested that gap and overlap have the same square-triangle tiling but at two different scales, and rotated by a topological angle of $\tan^{-1}(1/2)$. He has backed his suggestion with diffraction data, and has given an elegant model (Fig.5) of the gap-overlap interface (a twist grain boundary in the fibril) and of the mechanism whereby the termination of one molecule out of five in the overlap leaves the square-triangle tiling topologically invariant (c to a).

From the gap structure, it is straightforward to construct the unit cell of the overlap structure on the underlying hexagonal lattice (Fig.4b), given the ratio between the areas of the unit cells ($112/90$, half a triangle in the gap short of $5/4$), and the topological angle of rotation ($\tan^{-1}(1/2)$ seen in Fig.6 and in Fig.5b). The roles of the slightly distorted structures are exchanged : the unit cell is 8% rhombic and the squares are 15% rectangular. It is now the edges (no longer all equal) and the diagonals of the rhombi that are along 6 reticular directions. **The overlap structure has two perpendicular mirror axes defining a rectangular unit cell (they bound a fundamental domain). Several points are aligned and regularly spaced : the diagonal of the square is a third of the distance to points (2,-1) or (-1,2) of the unit cell grid.** Finally, a similar overlap structure ($\sqrt{3}$ smaller) can be drawn on the same underlying lattice (rotated by 90°) with the «square » of the gap as unit cell.

The Table below lists the geometric manifestations (**square and unit cell of the $3^2.4.3.4$ square-triangle tiling**) of the various approximants to $\sqrt{3}$ in the overlap and gap structures [8]. The vertices are joined by lattice vectors in both underlying hexagonal lattices. If two vertices lie on one of the 6 reticular directions (symmetry axis) of the underlying lattices, an approximant is obtained from their distance measured on both lattices (**the sides of a rectangle [...] on one lattice**). If the vertices do not lie on a symmetry axis, they constitute,

on one lattice, an equilateral **rhombus**, with nearly equal diagonals on symmetry axes and nearly orthogonal side vectors. This yields two approximants (a) and (b). The last column gives the (orthorhombic or monoclinic) distortion, namely the ratio between $\sqrt{3}$ and its approximant.

j	$\sqrt{3} \approx$	overlap	gap	distortion
1	2/1	[square] unit cell (a)	square (a)	1.155
2	5/3	[mirror unit cell]		1.04
3	7/4	unit cell (b)	square (b) [unit cell]	1.01

4	19/11	BC helix
5	26/15	inflated BC helix

The ratio in sizes of the two structures is 1.115, smaller than the topological value of $\sqrt{(5/4)} = 1.118$, but larger than the experimental ratio of 1.08 [2]. This discrepancy remains unexplained.

Fig.6 shows how the overlap and gap structures match as a twist grain boundary **with an important coincidence site lattice, containing points $n(2,-1)$ or $n(-1,2)$ of the overlap unit cell grid and points $n(2,0)$ of the gap unit cell grid (n integer), thereby measuring the angle of rotation in Bouligand’s mechanism (Fig.5).** The overlap supercell containing 20 vertices and 5 unit cells, with sides $(2,-1)$ and $(-1,-2)$, fits almost exactly with the square of 2×2 gap unit cells, that contains 16 vertices. **The rotation angle of $26.996^\circ = \alpha + \gamma$ is the metric equivalent of the topological rotation of $\tan^{-1}(1/2)$.** (Direction $(1,0)$ of the overlap grid makes an angle $\alpha = \tan^{-1}(\sqrt{3}/6)$ with the underlying hexagonal lattice ; just as $\beta = \tan^{-1}(\sqrt{3}/9)$ for direction $(2,-1)$, that is also the diagonal of the square, or direction $(1,0)$ in the gap grid.) The rotation between two successive overlap structures across the gap, is double, namely $3\pi/10$. Note that in the unit cell of the rotated structure, the small and large rhombi have exchanged positions. Consequently, the angle of the next rotation is the complementary (to $2\pi/3$) of $3\pi/10$. The collagen fibril, a periodic stack overlap-gap-overlap-gap-....., exhibits both 10 and 12-fold rotations.

The flexibility of a long, tightly packed collagen fibril, regardless of its length or girth, is the effect of the regular alternance of gap and overlap regions with five neighbors to each molecule, that are the main features of our model.

Figure captions

Fig.1

Structure of collagen at various scales (from Bouligand [2,3]). a) A single chain *Gly-X-Y* forms a left-handed helix, with a curved axis. Dots indicate the positions of successive amino acids. Their side-groups are pointing outwards; every third one is a glycine (gly) located on the concave side of the axis. b) A collagen molecule is a right-handed triple helix of 3 intertwined, left-handed polypeptide chains. c) A simpler representation of the right-handed triple helix. Its width is 1 nm, its length, 300 nm. d) The collagen molecule is often represented by an arrow of length 300 nm. e) The molecules are stacked on top of each other, with a gap of 35 nm, and regularly spaced on a lattice (transverse scale dilated relatively to longitudinal scale). The longitudinal coordinates of molecules *u* and *u'* are the same. One distinguishes gap and overlap levels, *g* and *o* respectively, so that to each five molecules in *o* correspond only four in *g*. There is a regular stagger of molecules by a length $D = g + o = 67$ nm. f) A crude representation of the lattice as a cylinder (by identifying *u* and *u'*). This is only schematic as the collagen fibril is a lattice, showing the 67 nm stagger, but with a unit cell that accommodates gap and overlap levels. Notice the right-handed chirality of the *Gly* core and of the triple-helix collagen molecule, opposite to the left-handed chirality of the single collagen chain (Fig. 2).

Fig.2

The B-C helix represented as a hexagonal lattice on a cylinder, cut along its axis (vertical gray lines) and flattened. The single collagen chain is a left-handed helix winding in the **I** direction. The axis *Gly-X* of helix 7/2 is perpendicular to the base, so that a stack of three segments 7/2 constitutes one period of the collagen chain in Euclidean space.

%(should be put on the right of Fig.1)%

Fig.3

Superposition of two hexagonal lattices at 90° yields a moiré pattern of coincidence points. By construction, they are the rational approximants of $\sqrt{3}$. The brightest points (**corners of a square unit cell, with eight inner points**) constitute **four, translated** copies of the gap structure, shown in Fig. 4a. **The corners of the square unit cell belong to all four copies, the corners of the central square, to one copy each, and the corners of the intermediate square tilted at 45°, to two copies. Alternatively, one can view the square cell as decorated with (1/4 of) a dodecagonal wheel around each corner. Each copy of the gap structure contributes five points to the wheel.**

Fig.4

The unit cells of the square-triangle $3^2.4.3.4$ transverse structures of the collagen, drawn on an hexagonal lattice. A vertex represents the collagen molecule. a) Gap. b) Overlap. c) A smaller overlap structure, with the square of the gap structure as unit cell, drawn on the hexagonal lattice rotated by 90°. It is similar to b), but smaller by $\sqrt{3}$. Also drawn (grey) is the associated Voronoi tiling,

%(should be put on the right of Fig.3)%

Fig.5

The gap-overlap interface in a crystalline collagen fibril (schematic) (from Bouligand [2]). Gap (a) and overlap (c) structures are topologically identical, square-triangle patterns. (b) indicates how the gap structure deforms to intercalate new molecules (o) in the overlap, or, reciprocally, how one molecule (o) out of every 5 in the overlap terminates leaving the pattern invariant.
