Abstract: Iron-based layered double hydroxides (LDHs) obey to the general chemical formula $[M^{II}(1-x)M^{III}x(OH)_2]x^+ \cdot [(x/n) An^-, m H_2O]x^-$ and contain a minimum of 50 % of iron, i.e. FeII or FeIII, in the cationic sheets. As LDHs contain FeII species, these are interesting minerals for several applications such as the reduction of anionic pollutants or the degradation of organic pollutants. They are mostly prepared either by coprecipitation of dissolved species or by oxidation of hydroxylated FeII species. The synthesis routes are visualised in binary and ternary mass-balance diagrams. The LDH[FeII-FeIII] crystals are well crystallised hexagonal plates, the size of which diminishes rapidly when divalent or trivalent cations substitute iron. The LDH[FeII-FeIII-CO₃] transforms into a mixture of magnetite Fe₃O₄ and siderite FeCO₃ in alkaline conditions, but the adsorption of silicate or phosphate anions on the lateral faces of the crystal prevents this decomposition. In oxic conditions, two mechanism of transformation are identified depending upon the kinetics: (i) fast in situ oxidation within the solid, (ii) dissolution-precipitation of the LDH that leads to the formation of ferric oxyhydroxides such as goethite (FeOOH).

ABSTRACT

Iron-based layered double hydroxides (LDHs) obey to the general chemical formula $[M^{II}_{(1-x)}M^{III}_x(OH)_2]^{x+} \cdot [(x/n) A^{n-}, m H_2O]^{x-}$ and contain a minimum of 50 % of iron, i.e. Fe^{II} or Fe^{III}, in the cationic sheets. As LDHs contain Fe^{II} species, these are interesting minerals for several applications such as the reduction of anionic pollutants or the degradation of organic pollutants. They are mostly prepared either by coprecipitation of dissolved species or by oxidation of hydroxylated Fe^{II} species. The synthesis routes are visualised in binary and ternary mass-balance diagrams. The LDH[Fe^{II}-Fe^{III}] crystals are well crystallised hexagonal plates, the size of which diminishes rapidly when divalent or trivalent cations substitute iron. The LDH[Fe^{II}-Fe^{III}-CO₃] transforms into a mixture of magnetite Fe₃O₄ and siderite FeCO₃ in alkaline conditions, but the adsorption of silicate or phosphate anions on the lateral faces of the crystal prevents this decomposition. In oxic conditions, two mechanism of transformation are identified depending upon the kinetics: (i) fast *in situ* oxidation within the solid, (ii) dissolution-precipitation of the LDH that leads to the formation of ferric oxyhydroxides such as goethite (αFeOOH).

1. Introduction

Mixed M^{II} - M^{III} layered double hydroxides (LDHs) minerals are described by the general formula $[M^{II}_{(1-x)}M^{III}_x(OH)_2]^{x+} \cdot [(x/n) A^{n-}, m H_2O]^{x-}$ where M^{II} and M^{III} are metallic cations present in brucite-type layers $Mg(OH)_2$, A^{n-} is an intercalated anion or a negatively charged molecule and x is the molar fraction of the trivalent cation and also the electrostatic charge of both the brucite-type layers and the anionic interlayers. Most commonly, the values of x are found in the range [0.2-0.33] (Khan and O'Hare, 2002). Recently, the researchers have shown the increasing interest for the synthesis and the characterisation of LDHs since these materials can be used for many potential applications. For example, LDHs are well known for their capacity to exchange various types of inorganic anions (Miyata, 1983; Khan and O'Hare, 2002). More recent studies have shown that LDHs can easily incorporate organic and bioorganic molecules such as ascorbic acid (Aisawa et al., 2007), urease (Vial et al., 2008), DNA (Oh et al., 2006) and even ferritin (Clemente-León et al., 2008). A particular type of LDHs which contains only iron as a cation in the brucite-type layers is called Green Rust (GR), i.e. the $LDH[Fe^{II}-Fe^{III}]$. GR is an intermediate compound that forms during the Fe^{II} species oxidation in solution (Feitknecht and Keller, 1950). For example, carbonated GR was observed as a corrosion product in water drain by Stampfl (1969). In 1996, a natural sample found in a hydromorphic soil in the forest of Fougères (Brittany, France) was identified to be homologous to green rust by using Mössbauer and Raman spectroscopies (Trolard et al. 1997). This mineral was then named fougérite (IMA 2003-057). More recently, three new occurrences were found: one in coal mine drainage sediment in South Wales (Bearcock et al., 2006) and two others in Denmark (Christiansen et al., 2009). In this last study, an X-ray diffraction pattern that corresponds to synthetic carbonated GR was presented for the first time. The properties of GR, i.e. the $LDH[Fe^{II}-Fe^{III}]$, were also studied because of its ability to reduce several anionic pollutants such as nitrate (Hansen, 2001), chromate (Loyaux-

Lawniczak et al., 2000; Bond et al., 2003; Legrand et al., 2004) and seleniate (Refait et al. 2000, 2005a; Hiroshi et al. 2009). Finally, GR was shown to promote the reduction/oxidation of an azo dye and therefore its removal from water (Kone et al., 2009) and the Fenton-like oxidation of phenol at neutral pH (Hanna et al., 2009).

In this paper, we will focus on the description of the synthesis routes and transformation of LDHs that contain a minimum of 50 % of iron atoms in the brucite-like sheets, i.e. compound for which the ratio $n(\text{Fe}) / \{n(\text{M}^{\text{II}}) + n(\text{M}^{\text{III}})\}$ is higher than 50 %. Similar to the terminology commonly used for metallic alloys, these compounds are called iron-based LDHs. Of course, the LDH[Fe^{II}-Fe^{III}] represent the framework of this LDHs category. The partial substitution of the Fe^{II} or Fe^{III} cations by other divalent or trivalent species may easily occur giving rise to ternary systems such as the LDH[{Fe^{II}-M^{II}}-Fe^{III}] or the LDH[Fe^{II}-{Fe^{III}-M^{III}}]. To our knowledge, three types of partial substitutions were studied: Fe^{II} by Ni^{II} (Refait et al., 1993, 2005b), Fe^{II} by Mg^{II} (Refait et al., 2001) and more recently Fe^{III} by Al^{III} (Ruby et al., 2008). Fully substituted compounds that correspond to minerals such as pyroaurite Mg₆Fe₂(OH)₁₆CO₃·4H₂O (Allmann et al., 1968) or reevesite Ni₁₈Fe₆(OH)₄₈(CO₃)₃·12H₂O, (De Waal and Viljoen, 1971) are not *stricto sensu* iron-based LDHs and the synthesis of such compounds will not be considered here. By comparison with other LDHs, we will try to show specifically the iron-based LDH in terms of formation and transformation modes in both oxic and anoxic conditions.

2. Synthesis methods and characterisation

2.1. Formation paths: general description

2.1.1. M^{II}-M^{III} mass balance diagram

The formation paths of iron based LDHs can be illustrated in the mass-balance diagram presented in figure 1. Initially, this diagram was devised for interpreting pH titration curves obtained during the coprecipitation of Fe^{II} and Fe^{III} soluble species in sulphated aqueous

medium (Ruby et al., 2003) but it can easily be generalised to any type of divalent and trivalent cations. The ordinate $R = n(\text{OH}^-) / [n(\text{M}^{\text{II}}) + n(\text{M}^{\text{III}})]$ represents the number of hydroxyl species per mole of iron that are consumed during the precipitation of a given compound and the abscissa $x = n(\text{M}^{\text{III}}) / [n(\text{M}^{\text{II}}) + n(\text{M}^{\text{III}})]$ is the molar fraction of trivalent cations. The position of the aqueous species $\text{M}^{\text{II}}_{\text{aq}}$, $\text{M}^{\text{III}}_{\text{aq}}$ and solid compounds $\text{M}^{\text{II}}(\text{OH})_2$, the LDH $[\text{M}^{\text{II}}-\text{M}^{\text{III}}]$, the spinel $\text{M}^{\text{II}}\text{M}^{\text{III}}\text{O}_4$ and the oxyhydroxide $\text{M}^{\text{III}}\text{OOH}$ are presented in Fig. 1. The synthesis of LDHs is most commonly achieved by the addition of a basic solution to a mixture of soluble species $\{\text{M}^{\text{II}}_{\text{aq}}, \text{M}^{\text{III}}_{\text{aq}}\}$. It corresponds to the vertical path [AD] illustrated in figure 1. The major advantage of this method is that the value of x of the initial solution can be adjusted accurately in order to determine the LDHs composition flexibility.

LDHs may also contain a unique metallic cation which exists in two oxidation degrees M^{II} and M^{III} . Most of the transition metals of the 3d level, *i.e.* Ti, V, Cr, Mn, Fe, Co and Ni, have this property. Such LDHs can potentially be prepared by a precipitation/oxidation pathway illustrated in figure 1. The synthesis is realised in two steps: (i) A basic solution is added to soluble M^{II} species that precipitates to form either a suspension of a $\text{M}^{\text{II}}(\text{OH})_2$ solid compound or a $\{\text{M}^{\text{II}}(\text{OH})_2, \text{M}^{\text{II}}_{\text{aq}}\}$ mixture by following the path [BC], (ii) the divalent species are then oxidised to form the LDH $[\text{M}^{\text{II}}-\text{M}^{\text{III}}]$ along the path CD. As it will be discussed in section 2.2.2., the slope of line CD depends on the nature of the oxidant. The easiest way to do such an oxidation is to simply agitate the $\text{M}^{\text{II}}(\text{OH})_2$ suspension in contact with air and to control the redox potential E_h of the suspension in order to follow the different oxidation steps. Other oxidants such as hydrogen peroxide H_2O_2 , iodine I_2 or persulphate $\text{S}_2\text{O}_8^{2-}$ can also be used, the advantage here is to know the oxidation degree of the product by controlling the amount of added oxidant. The precipitation/oxidation pathway was used for the preparation of both the LDH $[\text{Fe}^{\text{II}}-\text{Fe}^{\text{III}}]$ (Hansen, 2001; Genin et al., 2006a) and the LDH $[\text{Co}^{\text{II}}-\text{Co}^{\text{III}}]$ (Ma et al., 2008).

2.1.2. Formation of ternary LDH $[Fe^{II}, \{Fe^{III}, M^{III}\}]$ and $LDH[\{Fe^{II}, M^{II}\}, Fe^{III}]$

Iron-based LDHs, where a partial substitution of the Fe^{III} or Fe^{II} cations occurs, are synthesised by the same kind of pathways described for binary $LDH[Fe^{II}-Fe^{III}]$, *i.e.* by coprecipitation or by oxidation. Such syntheses can be represented in a ternary mass-balance diagram (Fig. 2). This representation was initially proposed to study the coprecipitation of $[\{Fe^{II}, \{Fe^{III}, Al^{III}\}]]$ mixtures in sulphated aqueous solution (Ruby et al., 2008). The diagram is an equilateral triangle and the composition of any point is easily obtained by plotting the perpendicular to the triangle sides as usually done when studying the phase diagram of ternary alloys (bottom of Fig. 2a). The number of moles of hydroxyl per mole of total cations $R = n(OH^-) / n(M_{tot})$ that is necessary to form a given compound is situated on the perpendicular to the triangle base. The formation pathways of the M^{III} -substituted LDHs are presented in figure 2a. The domain of the ternary $LDH[\{Fe^{II}, M^{II}\}, Fe^{III}]$ is situated in between the two segments corresponding to the $LDH[Fe^{II}-Fe^{III}]$ and the $LDH[Fe^{II}-M^{III}]$. On figure 2b, the formation pathways of M^{II} -substituted LDHs are shown. The domain of the $LDH[\{Fe^{II}, M^{II}\}, Fe^{III}]$ is situated in between the segments corresponding to the $LDH[Fe^{II}-Fe^{III}]$ and the $LDH[\{Fe^{II}, M^{II}\}, Fe^{III}]$ with $x(M^{II}) = 0.5$. In both cases, the most trivial way to prepare such a compound is to prepare a mixture of soluble species, *i.e.* $[\{Fe^{II}, \{Fe^{III}, M^{III}\}]]$ or $[\{Fe^{II}, M^{II}\}, Fe^{III}]$ with the desired molar fractions, and to add a basic solution at a ratio $R = n(OH^-) / n(M_{tot})$ close to 2. This coprecipitation syntheses route corresponds to a vertical segment that starts into the domain of the ternary LDH and is situated perpendicularly to the triangle base. The $LDH[\{Fe^{II}, \{Fe^{III}, M^{III}\}]]$ could also be obtained by a partial oxidation of an $LDH[Fe^{II}-M^{III}]$ (Fig 4a), but to our knowledge such a method has not yet been tested. In sulphated medium, the coprecipitation of the $LDH[Fe^{II}-Al^{III}]$ leads unfortunately to an amorphous compound (Ruby et al., 2008) that is difficult to use as a starting product for an oxidation experiment. The oxidation path presented in figure

2b was used to prepare the LDH[$\{\text{Fe}^{\text{II}}, \text{Ni}^{\text{II}}\}, \text{Fe}^{\text{III}}\}$] (Refait et al., 1993). In these experiments, a mixture of soluble species $\{\text{Fe}^{\text{II}}_{\text{aq}}, \text{Ni}^{\text{II}}_{\text{aq}}\}$, i.e. point A, is precipitated to form a mixture of $\{\text{Fe}(\text{OH})_2, \text{Ni}(\text{OH})_2\}$ in point B. In a second step, the Fe^{II} species are oxidised by air to form the LDH[$\{\text{Fe}^{\text{II}}, \text{Ni}^{\text{II}}\}, \text{Fe}^{\text{III}}\}$] by following the path BC. During this oxidation reaction, the quantity of Ni^{II} remains constant since Fe^{II} species are much more easily oxidised by dissolved O_2 . A similar way of syntheses was used to prepare a fully substituted LDH($\text{Co}^{\text{II}}\text{-Fe}^{\text{III}}$) by oxidation of an LDH($\text{Co}^{\text{II}}\text{-Fe}^{\text{II}}$) (Ma et al., 2007). Iodine I_2 was chosen as an oxidant because the standard redox potential of the I_2/I^- couple is situated in between the E° values of the $\text{Fe}^{\text{II}}/\text{Fe}^{\text{III}}$ and $\text{Co}^{\text{II}}/\text{Co}^{\text{III}}$ couples. By this way, only the Fe^{II} species of the LDH($\text{Co}^{\text{II}}\text{-Fe}^{\text{II}}$) were oxidised and a pure and well crystallised LDH($\text{Co}^{\text{II}}\text{-Fe}^{\text{III}}$) was observed.

2.2. Synthesis of the LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}$] (green rust)

2.2.1. Coprecipitation of soluble Fe^{II} and Fe^{III} species

The coprecipitation method was used to determine the composition flexibility of the LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4$] (Ruby et al., 2003) and the LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-CO}_3$] (Ruby et al., 2006b). These experiments were conducted in a gas-tight reactor with continuous N_2 bubbling in aqueous solution in order to avoid the oxidation of ferrous ions Fe^{II} . A systematic study of the titration of Fe^{II} and Fe^{III} by NaOH in a sulphated aqueous medium showed that only the LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4$] with a unique composition $x = 0.33$ was formed by this synthesis route (Ruby et al., 2003). When the coprecipitation was realised at values of $x > 0.33$ or $x < 0.33$, $\{\text{LDH}[\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4\text{-}x=0.33], \text{Fe}_3\text{O}_4\}$ and $\{\text{LDH}[\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4\text{-}x=0.33], \text{Fe}(\text{OH})_2\}$ mixtures are respectively formed. Nevertheless, the formation of a LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4$] with a ratio $x = 0.25$ was achieved by performing an anionic exchange of a chlorinated LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-Cl}^-$] precipitated at the same x value (Hansen et al., 2001). Some flexibility of composition was also observed for the LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-CO}_3$] that can be prepared in the range $x \in [\sim 0.25, 0.33]$.

For the preparation of the LDH[Fe^{II}-Fe^{III}-CO₃] at $x = 0.25$, it was necessary to prepare the initial solution by dissolving FeCl₃ and FeCl₂ salts followed by the addition of a Na₂CO₃ solution. Indeed, if Fe₂(SO₄)₃ and Fe^{II}SO₄ salts were dissolved into the initial solution, the LDH[Fe^{II}-Fe^{III}-SO₄] precipitates before the LDH[Fe^{II}-Fe^{III}-CO₃] during the alkalisation process and only the LDH[$x = 0.33$] is obtained.

2.2.2 Oxidation of Fe(OH)₂ and {Fe(OH)₂, Fe^{II}} mixture

Another easy way to prepare the LDH[Fe^{II}, Fe^{III}] is to perform an aerial oxidation of a suspension that contains Fe(OH)₂ precipitates. In sulphated and chlorinated aqueous medium (Genin et al., 2006a), it was observed that only the suspensions that contain a specific amount of soluble Fe^{II} species led to the formation of 100 % of the LDH. For example in sulphated medium, this excess of Fe^{II}_{aq} is described by the following chemical reaction:

Therefore, the initial Fe^{II}_{aq} solution was partially precipitated by adding a NaOH solution with a ratio $r = n(\text{OH}^-) / n(\text{Fe}^{\text{II}})$ of exactly 5/3. If Fe^{II} species were precipitated with a ratio r equal to 2, i.e. the pure Fe(OH)₂ is formed without any excess of Fe^{II}_{aq}, the oxidation led to the precipitation of pure magnetite. r values in the range]5/3, 2[led to the formation of {LDH[Fe^{II}-Fe^{III}-SO₄], Fe₃O₄} mixtures. Other experiments were carried out by using persulphate anions S₂O₈²⁻ as an oxidant (Ruby et al., 2006a). In this case; the oxidation of pure Fe(OH)₂ led to the formation of 100 % of LDH[Fe^{II}, Fe^{III}] according to the following reaction :

By comparing the results obtained with several oxidants (Ruby et al., 2006a), a general rule was obtained that the thermodynamically favourable reactions were pH independent, as it is

the case for reactions (1) and (2). If the reduction of the oxidant corresponds to the general half reaction:

The specific ratio $r = n(\text{OH}^-) / n(\text{Fe}^{\text{II}})$ of the initial solution that has to be chosen for preparing 100 % of the LDH with a Fe^{III} molar fraction x is given by the general formula (Ruby et al., 2006a):

$$r = 2 - (\nu/n) x \quad (4)$$

For example, for the redox couple O_2/OH^- , the half reaction is $\text{O}_2 + \text{H}_2\text{O} + 2e^- + 2 \text{OH}^-$ and $(\nu/n) = 1$. For preparing the LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}$] at a x value of 1/3, the r value is therefore equal to 5/3 according to equation (4) which is in good agreement with the experimental observations.

2.2.3 Reactivity of Fe^{II} species with ferric oxyhydroxides

The LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}$] can also be formed by controlling the reactivity of Fe^{II} species with ferric oxyhydroxides such as lepidocrocite $\gamma\text{-FeOOH}$ (Tamura et al., 1985) or ferrihydrite (Hansen, 2001). In these experiments, soluble Fe^{II} species were introduced into a suspension that contains the ferric oxyhydroxide at a pH close to 7. This pH allows a sufficient hydroxylation rate of the Fe^{II} species necessary to activate the reaction. The LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4$] can also be prepared by fixing the hydroxylation rate $R = n(\text{OH}^-)/[n(\text{Fe}^{\text{II}}) + n(\text{Fe}^{\text{III}})]$ at a exact value of 7 with a basic solution such as NaOH (Ruby et al., 2003). This ratio corresponds to the formation of a mixture $\{\text{FeOOH}, 2 \text{Fe}(\text{OH})_2\}$ that was hypothesised to be the precursor of the formation of the LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4$]. A heterogeneous reaction that would occur at the surface of the ferric oxyhydroxide was described by Ruby et al. (2006).

2.3. Characterisation of iron-based layered double hydroxides

2.3.1 Morphology of the crystals

Non-substituted LDH[Fe^{II}-Fe^{III}] prepared at room temperature either by the coprecipitation or the oxidation experiments are constituted by well-defined hexagonal plates with a lateral size D situated in the range [100 - 500] nm and a thickness d of $\sim$ [10 - 50] nm as observed by transmission electron microscopy (TEM) (Fig. 3a). The ratio D/d was found to be close to 10 for the LDH[Fe^{II}-Fe^{III}-SO₄²⁻] and close to 5 for the LDH[Fe^{II}-Fe^{III}-CO₃²⁻] (Ruby et al., 2006b). For this reason, it was possible to see a high proportion of the LDH[Fe^{II}-Fe^{III}-CO₃²⁻] crystals with their basal plane situated perpendicularly to the TEM grid (Fig 3a). Diffraction of isolated crystals along the [001] zone axis was performed and this allows us to determine the parameter a of the hexagonal cell ($a \sim 3.2$ Å).

The substitution of the trivalent or the divalent cation by another chemical element gives rise to a rapid decrease of the crystal size as observed in Fig. 3b&c. For example the substitution of half of the Fe^{III} cations by Al^{III} into the LDH[Fe^{II}-Fe^{III}-SO₄] induces a decrease of the lateral crystal size of ~ 10 nm (Fig. 3b). A more drastic effect is observed if the divalent Fe^{II} species are fully substituted by Ni^{II} (Fig. 3c). In this case the LDH consists of crystallised nanoparticles and only a thermal heating in the range [100°C-180°C] allows us to obtain bigger crystals with a hexagonal shape (not shown). Note that thermal treatment in this range of temperature of iron-based LDH leads to a decomposition into {Fe₃O₄, Fe(OH)₂} or {Fe₃O₄, FeCO₃} mixture. Therefore, thermal treatment is unfortunately of no use for increasing the crystal size of iron-based LDHs.

2.3.2. Crystallographical structure

The structure of the LDH[Fe^{II}-Fe^{III}-SO₄], LDH[Fe^{II}-Fe^{III}-Al^{III}-SO₄] and LDH[Fe^{II}-Fe^{III}-CO₃] were recently investigated by high resolution X-ray diffraction experiments performed at the European Synchrotron Radiation Facility (ESRF) (Aissa et al., 2006; Ruby et al., 2008). Diffractograms of the LDH[Fe^{II}-Fe^{III}-SO₄] and the LDH[Fe^{II}-Fe^{III}-CO₃] are presented in figure 4. The position of the peaks shows that the two LDHs exhibit a quite different crystallographical structure that was determined with Rietveld refinements. The LDH[Fe^{II}-Fe^{III}-SO₄] crystallises in the hexagonal structure, space group $P\bar{3}1m$, and the unit cell is characterised by the parameters $a = 5.50683(3)$ Å and $c = 10.9664(2)$ Å; where c is equal to the interlayer spacing d along the $[001]$ axis. The LDH[Fe^{II}-Fe^{III}-CO₃] crystallises in the trigonal structure, space group $R\bar{3}m$, and the corresponding hexagonal triple cell is characterised by the parameters $a = 3.17588(2)$ Å and $c = 22.7123(3)$ Å; the interlayer spacing is now $d = c/3 = 7.57$ Å. The interlayer spacing d of the LDH[Fe^{II}-Fe^{III}-SO₄] is larger because it contains a double layer of oriented sulphated anions and water molecules (Ruby et al., 2008). Therefore, the structure of these two LDHs can be distinguished very easily by X-ray diffraction and were denominated by Bernal et al. (1954). green rust 1 ($R\bar{3}m$) and green rust 2 ($P\bar{3}1m$). For instance, the position of the most intense (003) peak of the LDH[Fe^{II}-Fe^{III}-CO₃] is situated at a much lower angle than the (0001) peak of the LDH[Fe^{II}-Fe^{III}-SO₄] simply because of the difference of interlayer spacing (Fig. 4).

2.3.3. Speciation of iron with Mössbauer spectroscopy

⁵⁷Fe Mössbauer spectroscopy is a powerful technique for determining accurately the relative proportion of Fe^{II} and Fe^{III} species of iron-based LDHs. It is also very useful to detect the formation of by-products that contain iron such as ferrous hydroxide Fe(OH)₂, siderite FeCO₃, magnetite Fe₃O₄ and the various ferric oxyhydroxides. This technique is only

sensitive to the ^{57}Fe nucleus present in the material. For example, the Mössbauer spectrum of the $\text{LDH}[\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4]$ recorded at 78 K is shown in figure 5a. It is characterised by a paramagnetic Fe^{II} doublet D_1 with a large quadrupole splitting $\Delta = 2.91 \text{ mm s}^{-1}$ and another Fe^{III} doublet D_2 with a much smaller quadrupole splitting $\Delta = 0.47 \text{ mm s}^{-1}$. The relative area of the doublet D_2 gives directly the value of the Fe^{III} molar fraction of the LDH; here $x = 34 \%$. The substitution of the divalent or trivalent cations by another element can also be followed indirectly with Mössbauer spectroscopy. For example, the spectrum of the $\text{LDH}[\text{Fe}^{\text{II}}\text{-}\{\text{Fe}^{\text{III}}, \text{Al}^{\text{III}}\}\text{-SO}_4]$ with a molar ratio $n(\text{Al}^{\text{III}})/n(\text{Fe}^{\text{III}})$ of 1 is presented in figure 5b. As expected, one observes a significant decrease of the relative area of doublet D_1 and the apparition of a new ferrous doublet D_3 . The origin of doublet D_2 was attributed to Fe^{II} species having Al^{III} ions as first neighbours (Ruby et al., 2008).

3. Transformation of iron-based layered double hydroxides

3.1. Decomposition in anoxic condition

Iron-based LDHs may transform under anoxic conditions, particularly in basic solution. Two types of transformation were observed depending on the pH conditions (Ruby et al., 2003, 2006b). At room temperature, the $\text{LDH}[\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4]$ decomposes at $\text{pH} \sim 11$ according to the following reaction :

The $\text{LDH}[\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-CO}_3]$ transforms into a carbonated aqueous medium at $\text{pH} \sim 10$ according to the following reaction:

The $\text{LDH}[\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4]$ precipitates generally at a pH close to 7 both in the coprecipitation and the oxidation experiments and therefore reaction (5) can easily be

avoided. On the contrary, the LDH[Fe^{II}-Fe^{III}-CO₃] precipitates in alkaline solution in a pH range situated between 8 and 10 and the partial transformation described in reaction (6) occurs within a few days. The introduction of very small amount of phosphate or silicate anions in the solution prevents completely the decomposition of the LDH (Ruby et al., 2006b). This effect was demonstrated to be due to the adsorption of the phosphate species on the lateral faces of the LDH[Fe^{II}-Fe^{III}-CO₃] crystals (Bocher et al., 2003). This adsorption inhibits the release of the carbonate species from the LDH structure.

3.2. Oxidation reactions

3.2.1. *In situ* transformation within the solid

The LDH[Fe^{II}-Fe^{III}] can be oxidised *in situ* within the solid LDH[Fe^{II}-Fe^{III}] if either a strong oxidant such as H₂O₂ is used or if the oxidation is performed in a strongly aerated medium. In these conditions, the redox potential E_h measured in the suspension increases quickly and the oxidation can be achieved in approximately 1 hour (Fig. 6a). If the starting material is the LDH[Fe^{II}-Fe^{III}-CO₃], a continuous range of LDH related compounds with a variable composition of x will form. The general chemical formula of these compounds is Fe^{II}_{6(1-x)}Fe^{III}_{6x}O₁₂H_{2(7-3x)}CO₃ with x situated in the range [1/3-1] (Génin et al., 2006b). Reflexion Mössbauer spectra of the compounds at $x = 0.33$ and $x = 0.5$ are presented in Fig. 7. The two ferrous doublets D_1 and D_2 were attributed to Fe^{II} species having respectively water molecules and carbonate species in their close neighbourhoods. The apparition of a new doublet D_4 at x values higher than 0.33 (Fig. 7b) was attributed to Fe^{III} species in an octahedral coordination where a partial deprotonation of the Fe-OH bonding occurred. This hypothesis was confirmed by X-ray photoelectron spectroscopy by recording the evolution of the O1s spectrum (Mullet et al.). A progressive decrease of the OH⁻ component is observed when the ratio x increases (Fig 8). This deprotonation process was also supported by the X-

ray diffraction patterns that exhibit a contraction of a few percentage of the crystallographical cell and a progressive disordering of the structure. The hexagonal morphology of the crystal was shown to be conserved by TEM attesting that the oxidation occurred within the solid. The compound is therefore not longer *stricto sensu* a layered double hydroxide but rather a oxyhydroxycarbonate that has a crystallographical structure strongly related to the initial LDH[Fe^{II}-Fe^{III}-CO₃] at $x = 0.33$.

3.2.2. Dissolution-precipitation mechanism

If the kinetics of the aerial oxidation of the LDH[Fe^{II}-Fe^{III}] is slower, the evolution of the redox potential (Fig. 6b) is quite different in comparison with the one observed in figure 6a. Slow oxidation is achieved by introducing a small amount of O₂ bubbling into the suspension and the end of oxidation lasts now approximately 7 hours. The curves present initially a small hook followed by two plateaus separated by an equivalent point E. Point E corresponds to the end of the oxidation reaction and its position is shifted on the right of the time scale if the O₂ bubbling diminishes (not shown). In carbonated medium, most of the time goethite α -FeOOH is the end-product of oxidation. On the contrary to the oxyhydroxycarbonate oxidation product observed in section 3.2.1, the crystallographical structure and morphology of goethite (needles) is quite different if compared to the initial LDH structure. Therefore, the mechanism of formation involved here is rather a dissolution-precipitation process. The presence of the first E_h plateau shows that a redox equilibrium exists between the LDH[Fe^{II}-Fe^{III}-CO₃] and goethite during the quasi-totality of the oxidation process. Therefore a simple measure of the redox potential of the suspension can be used as a guide to know which kind of oxidation mechanism is involved, i.e. *in situ* oxidation or dissolution-precipitation.

4. Conclusion

Iron-based layered double hydroxides, i.e. the LDHs[$\{\text{Fe}^{\text{II}}\text{-M}^{\text{II}}\}, \{\text{Fe}^{\text{III}}\text{-M}^{\text{III}}\}$] that contain an iron molar fraction higher than 50 %, are synthesised either by the coprecipitation of dissolved cations or by the oxidation of hydroxylated divalent cations. The non-substituted LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}$], commonly called green rust, prepared at room temperature by both methods exhibits well crystallised hexagonal crystals. Partial substitution of the Fe^{II} or the Fe^{III} species by other cations leads to a rapid decrease of crystal size. The LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-SO}_4$] contains a bi-layer of oriented sulphated anions and water molecules in the interlayer spacing. The LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-CO}_3$] contains only one layer of CO_3^{2-} and water molecules inside the interlayer. Thermal treatments or alkaline conditions ($\text{pH} > 9$) activate the decomposition of iron-based LDHs into biphasic mixtures. Adsorption of small quantity of phosphate or silicate anions on the lateral faces of the crystals slowed down this transformation for the LDH[$\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}\text{-CO}_3$]. In oxic conditions, kinetically fast reactions lead to an *in-situ* transformation of the LDH that transforms into an oxyhydroxysalt by the deprotonation of hydroxyl groups. On the contrary to most of the other LDHs, iron-based LDHs have a redox flexibility in the range $[1/3\text{-}1]$ for the Fe^{III} molar fraction x . If the kinetics of the oxidation is slower, the LDH transforms into a ferric oxyhydroxide by a dissolution-precipitation mechanism. The structural characterisation of iron-based LDHs has been investigated by several techniques such as high resolution X-ray diffraction, transmission electron microscopy and X-ray photoelectron and Mössbauer spectroscopies. Future works could be devoted to use iron-based LDHs for reducing anionic pollutants in conditions closer to field conditions, e.g. column reactors. Therefore the formation and reactivity of such compounds as coatings at the surface of minerals (e.g. quartz or clays) could be the subject of further studies.
