Summary

A proper hypothalamus-pituitary-testis axis with normal androgen synthesis and action is a prerequisite for normal testicular descent. Various defects in this axis may result in cryptorchidism but endocrine abnormalities are rarely detected. Androgens regulate testicular descent but androgen action alone is not sufficient for normal testicular descent. The regulation of androgen production is influenced both by placental human chorionic gonadotropin (hCG) and pituitary luteinizing hormone (LH). There is evidence that the longer pregnancy continues, the more important role pituitary LH may have. INSL3 (insulin-like hormone-3) is suggested to be the main regulator of gubernacular development and therefore an apparent regulator of testicular descent. INSL3 production is also related to LH, and reduced INSL3 action is a possible cause for cryptorchidism. Cryptorchid boys have normal testosterone levels with slightly but significantly elevated LH levels as compared to healthy boys. This high gonadotropin drive may compensate for mild Leydig cell dysfunction in cryptorchidism.

Keywords: Luteinizing hormone; Testosterone; INSL3; Testicular descent;

Cryptorchidism

Introduction

Development of normal male genitalia is a complex series of events including a unique process of testicular descent from intra-abdominal location into the bottom of the scrotum. Usually testes reach the scrotum during the last few weeks of pregnancy or soon after birth (Ghirri *et al.*, 2002). However, disorders in this process are common and cryptorchidism (undescended testis) is the most common congenital abnormality of newborn boys affecting 2-9 % of boys at birth (Boisen *et al.*, 2004; Toppari and Kaleva, 1999). Seasonal variation and great regional differences in the incidence of cryptorchidism point to environmental effects behind the disorder (Kaleva *et al.*, 2005a; Boisen *et al.*, 2004).

There is evidence that testicular descent occurs in two phases, of which only the latter (inguinoscrotal) phase is androgen dependent (Fig. 1). This is suggested by the observation that hypogonadotropic hypogonadism and androgen insensitivity often result in cryptorchidism but usually only the inguinoscrotal descent has failed to occur and the testes are located in the inguinal region (Boehmer *et al.*, 2001). The critical role of androgens in testicular descent is suggested also by the fact that a high percentage of cryptorchidism resolves spontaneously (Boisen *et al.*, 2004) during the period of high serum gonadotropin and steroid hormone levels at the age of 1 - 3 months (Andersson *et al.*, 1998).

human chorionic gonadotropin and luteinizing hormone

Gonadotropin-releasing hormone (GnRH) regulates the production of pituitary gonadotropins, FSH and LH, which are the main regulators of postnatal testicular action. LH stimulates Leydig cells to produce testosterone, while FSH regulates Sertoli cell function. In rodents, testosterone production starts independently from endogenous circulating gonadotropins and Leydig cells become dependent on gonadotropins shortly after birth (El-Gehani *et al.*, 1998; O'Shaughnessy *et al.*, 1998). Unlike in rodents, human fetal testis binds hCG (human chorionic gonadotropin) and physiologic levels of hCG stimulate testosterone production already at early pregnancy, at least from 14 weeks of gestation (Huhtaniemi *et al.*, 1977). Because hypogonadotropic hypogonadism often results in cryptorchidism regardless of normal placental hCG production, endogenous fetal pituitary LH (luteinizing hormone) seems to be a more important regulator of fetal testosterone synthesis in late pregnancy (Quinton *et al.*, 2001). The fact that hypogonadotropic hypogonadism is one of the reasons for cryptorchidism also contributes to the confusion in studies in which varying results have been reported about the endocrine status of cryptorchid boys, i.e. hypogonadotropic and hypergonadotropic patients have been mixed together. Hypogonadotropic hypogonadism is rare, whereas cryptorchidism is very common, and most cases have slightly elevated gonadotropin levels (Suomi *et al.*, 2006).

Variant-LH (V-LH) is a common genetic variant of LH with two point mutations in its β -subunit gene (Pettersson *et al.*, 1992). V-LH represents a biologically less active form of LH (Lamminen and Huhtaniemi, 2001) and it is associated with slower progression of

puberty in healthy boys (Raivio *et al.*, 1996). Despite reduced biological activity of V-LH, the prevalence of V-LH was not higher among cryptorchid boys (26.9 %) as compared to healthy controls (26.1 %) but the proportion of boys with homozygous V-LH was two times higher in cryptorchid group (6.5 % vs. 2.8 %) (Kaleva *et al.*, 2005b). Differently from the control boys, the prevalence of V-LH among cryptorchid boys increased steadily with gestational age (GA <37 weeks: 6.7 %; GA 37 – 39 weeks: 20.9 %; and GA 40-42 weeks 42.9 %). These results support the theory that the longer pregnancy continues, the more important role LH may have for testicular descent. The weaker V-LH is not as effective as wild type LH to stimulate normal testicular descent in late pregnancy. The increasing relative importance of pituitary LH, in comparison to hCG, is also supported by the finding that testosterone dependent penile growth is not affected in hypothalamic / pituitary dysfunction before the second half of gestation (Feldman and Smith, 1975), leading to micropenis but not hypospadias.

Decreased serum testosterone and LH levels have been reported in some studies on cryptorchidism (Bollerslev *et al.*, 1986; Job *et al.*, 1988) but endocrine abnormalities are not always detected. However, cryptorchidism is not one specific entity, but various forms of cryptorchidism (congenital with/without spontaneous descent, mild vs. severe, acquired cryptorchidism) might show distinct hormonal patterns which differ from each other (Suomi *et al.*, 2006). In our study, a clear pattern of hormonal changes was seen in Finnish cryptorchid boys. Their inhibin B values were significantly lower and FSH values were significantly higher as compared to healthy controls. In addition, the effect of cryptorchidism on FSH and inhibin B levels correlated with the severity of the ailment.

Significantly lower testosterone levels were seen in severely and persistently cryptorchid boys whereas in milder forms of cryptorchidism normal testosterone levels were detected. However, cryptorchid boys had significantly increased LH as compared to controls. This high gonadotropin drive suggests a mild Leydig cell dysfunction in cryptorchidism. Moreover, we found reduced androgen bioactivity at three months of age in severe cryptorchidism (Raivio *et al.*, 2003).

Insulin-like hormone-3

It is known, that the androgen receptor is expressed in the male reproductive tract and adequate androgen action is obligatory, but not sufficient alone, for normal testicular descent. High androgen levels in congenital adrenal hyperplasia do not induce ovarian descent. In male rat fetus, androgens cause the regression of the cranial suspensory ligament and regulate the gubernacular outgrowth together with INSL-3 (Emmen *et al.*, 1998; Emmen *et al.*, 2000). INSL-3 (insulin-like hormone-3, also known as relaxin-like factor (RLF)) is an apparent regulator of testicular descent in rodents. Male mice mutant for INSL-3 were cryptorchid (Zimmermann *et al.*, 1999) whereas in female mice the overexpression of INSL-3 caused ovarian descent (Adham *et al.*, 2002). LGR-8 (also known as GREAT) is a receptor for INSL-3 (Kumagai *et al.*, 2002) and in mouse its mutation caused cryptorchidim similar to deletions of the INSL-3 gene (Overbeek *et al.*, 2001). Studies performed in men suggest that INSL3 and its receptor LGR8 are also involved in testicular descent in human embryogenesis (Ferlin *et al.*, 2003; Gorlov *et al.*, 2002; Tomboc *et al.*, 2000). In human, several polymorphisms in INSL-3 / LGR-8 genes

have been identified but deleterious mutations are only occasionally associated with cryptorchidism (Koskimies et al., 2000; Roh et al., 2003; Adham and AgoulNIK, 2004) .

INSL3 circulates in adult men (Bay et al., 2005; Ferlin and Foresta, 2005) which suggests that INSL3 has endocrine functions also in adulthood. INSL3 is a sensitive marker of Leydig cell function (Foresta et al., 2004) but its production is regulated by LH differently from that of testosterone (Bay et al., 2005). In rodents, INSL3 prevents apoptosis of germ cells during spermatogenesis (Kawamura et al., 2004). In our material cryptorchidism was associated with reduced INSL3 levels at the age of three months (unpublished data). A high gonadotropin drive together with reduced INSL3 levels suggests an impaired Leydig cell function and supports the theory of a mild primary testicular disorder at least in severe cryptorchidism.
