Abstract Treatment with fluororacil, epirubicin, and cyclophosphamide followed by weekly paclitaxel (FEC-P) yielded superior disease-free survival than FEC in the adjuvant breast cancer trial GEICAM 9906. We evaluate molecular subtypes predictive of prognosis and paclitaxel response in this trial. Two molecular subtype classifications based on conventional immunohistochemical and fluorescent *in situ* hybridization determinations were used: #1: Four groups segregated according to the combination of hormone receptor (HR) and HER2 status; #2: Intrinsic subtype classification (Triple Negative (TN), HER2, Luminal B and Luminal A). Results: Both subtype classifications yielded prognostic and predictive information. HR

+/HER2– patients (and Luminal A patients) had a significantly better outcome than the other subgroups of patients. The superiority of FEC-P over FEC was clearly more marked in HR-/HER2– patients (TN patients), particularly in the subset with basal phenotype (TN and either EGFR+ or cytokeratins 5/6+). The Luminal A subtype also achieved a significant benefit with FEC-P. The molecular-defined subgroup of TN was clearly predictive of better response to treatment with FEC-P. Luminal A patients had the best prognosis and also have a better outcome with weekly paclitaxel.

Keywords Breast cancer · Adjuvant paclitaxel · Molecular predictors of efficacy

This study is conducted on behalf of the GEICAM 9906 study investigators.

Introduction

Several adjuvant therapy trials comparing anthracycline versus taxane containing regimens have shown an absolute improvement in disease-free survival (DFS) of 4–7% with taxanes [1–6]. Many attempts have been made to identify the molecular peculiarities of the tumors of the patients who may obtain the greater benefit from taxanes [7]. A study by the CALGB group has suggested that patients who obtain the maximum benefit from paclitaxel are those whose tumors overexpress HER2 [8]. Similarly, the classification into four intrinsic subtypes, as defined by Perou et al. [9], (i.e., Luminal A, Luminal B, HER2 and basal-like), has been shown recently to be of prognostic and predictive value. A simple “immunopanel”, based on standard immunohistochemical (IHC) measurements and fluorescent *in situ* hybridization (FISH), has been used recently to segregate the patients from the BCIRG 001 trial into these same subtypes [10]. We have previously reported the 5-year results of GEICAM 9906, an adjuvant trial in node positive breast cancer in which four cycles of FEC followed by eight cycles of weekly paclitaxel yielded a superior 5-year DFS, but not 5-year overall survival (OS), compared to six cycles of FEC [11].

We report, here, an analysis of the prognostic and predictive value of paclitaxel efficacy of two classifications of tumors based on conventional pathological parameters.

Methods

GEICAM 9906 was an adjuvant multi-centered randomized phase III study of six cycles of FEC (control arm)

versus four cycles of FEC followed by eight cycles of weekly paclitaxel (experimental arm) for node-positive breast cancer. The characteristics of the patients have been previously reported [11].

The primary endpoint of the trial was 5-year DFS, according to the definition of Invasive Disease Free Survival (IDFS) in the Standardized Definitions for Efficacy and End Points in Adjuvant Breast Cancer Trials (STEEP) System [12]. Secondary endpoints were: (1) overall survival, defined as the time from randomization until death from any cause; (2) prognostic and predictive value of the molecular markers (HR status and HER2 status); (3) safety.

The study was approved by the institutional review boards of all participating hospitals and by the Spanish Government Health Authorities and was registered at www.clinicaltrials.gov (identifier code: NCT00129922). All patients signed an informed consent form before being enrolled in the trial. Patients were also requested to sign a specific informed consent for molecular analyses of their tumors.

Immunohistochemical and fluorescent *in situ* hybridization analysis of tumors

Paraffin-embedded tumor samples from the primary tumors of the patients who consented were processed centrally. Tumor tissue was analyzed in tissue microarrays of three separate cores (each of 0.6 mm in diameter) from each tumor sample. The hormone receptor status of tumors was evaluated by IHC analysis for progesterone receptor (PR) (anti-progesterone receptor antibody clone PgR636, dilution 1:50, product M3569, DAKO, Carpinteria, CA, USA) and estrogen receptor (ER) (anti-estrogen receptor antibody clone 1D5, dilution 1:35, product M7047, DAKO)

using the DAB Map system (Ventana Medical Systems, Tucson, AZ, USA). Staining was initially scored according to the Allred method [13]. However, to compare the results of our study with those of BCIRG001 [10], we reclassified our samples according to ER+ or PR+ if staining was present in $\geq 1\%$ of tumor nuclei. Tumors were considered HR+ if they were ER+ or PR+.

HER2 status was evaluated by FISH (HER2 FISH pharmDx kit, product K5331, DAKO, Glostrup, Denmark) according to recent recommendations [14]. A positive result was defined as a HER2 gene to chromosome 17 ratio of >2 . A semiquantitative scoring system was employed to evaluate the amount of cells expressing all other markers (Ki67, cytokeratins 5/6 and EGFR). The scoring was 0 = negative; E = rare cells, $<10\%$; 1+ = 10% up to 1/3 of cells; 2+ = between one-third and two-thirds of cells; 3+ = more than two-thirds of cells.

Results for Ki67 were recoded as Ki67high (scores 1+, 2+, 3+), and Ki67low (scores 0, E). Cytokeratins 5/6 and epidermal growth factor were considered positive when any staining was present (scores E, 1+, 2+, 3+).

To analyze the prognostic and predictive value of molecular subgroups, two classification systems based on the pathology parameters defined above (HR status, HER status, plus or minus Ki67) were used

- (1) HR/HER2 classification: four groups were segregated according to the combination of HR and HER2 status (i.e., HR+/HER2+, HR+/HER2−, HR−/HER2+, and HR−/HER2−).
- (2) Intrinsic molecular subtypes: this classification is based in the concept that a simple “immunopanel” of ER, PR, HER2 and Ki67 can serve as a proxy for a more complex genetic subtyping [10]. Patients were classified as: (1) Triple Negative (TN) (ER−, PR−, HER2−); (2) HER2 (ER−, PR−, HER2+); (3) Luminal B (ER+ and/or PR+ and either HER2+ and/or Ki67high); (4) Luminal A (ER+ and/or PR+ and not HER2+ or Ki67high). As an additional exploratory analysis, we assessed the outcome of the subset of patients showing basal phenotype (TN and EGFR positive and/or cytokeratins 5/6+), since this phenotype has been shown to have superior prognostic value to the TN phenotype [15].

The results are presented in accordance with reporting recommendations for tumor marker prognostic studies criteria [16].

Statistical analyses

Survival variables (i.e., relapse and death) were analyzed with the Kaplan–Meier method [17]. Since patients

belonging to some subgroups (i.e., those with hormone receptor-positive tumors) can have late recurrences, we made a 7-year update of the results of the trial in order to have more reliable recurrence data. The log-rank test was used to compare time-to-event data between treatment arms, or between subgroups. Hazard ratios and 95% confidence intervals (95% CI) were obtained from the Cox’s proportional hazards models. The hypotheses tests were two-sided, and the values for alpha and beta accepted as being statistically significantly were 0.05 and 0.2, respectively.

The relative efficacy of FEC-P versus FEC in terms of DFS was analyzed in each of the previously described molecular subgroups. We performed a Cox proportional hazards model to evaluate the effect of chemotherapy on DFS in these subgroups. To rule out any confounding effects of other variables we included the age, menopausal status, tumor size, lymph node status, and hormonal therapy in the model.

Results

At a median follow-up of 7 years, a total of 364 DFS events have been recorded (205 in the FEC arm and 159 in the FEC-P arm (hazards ratio: 0.75; 95% CI: 0.61–0.93; $P = 0.007$). The 7-year DFS was significantly superior in the FEC-P arm (75% vs. 68%; $P = 0.007$ log-rank test). There have been 217 deaths (125 in the FEC arm and 92 in the FEC-P arm (hazards ratio: 0.74; 95% CI: 0.56–0.96; $P = 0.026$). The 7-year OS was also significantly superior in the FEC-P arm (84 vs. 79%; $P = 0.025$ log-rank test) (Fig. 1a, b).

Molecular subtype analysis

Tumor samples for evaluation in a central laboratory were available from 928 (74.5%) of the 1,246 patients in the trial. The demographic and prognostic features, as well as 7-year DFS and OS, of patients whose tumor samples had been centrally tested were similar to those that had not been centrally tested (data not shown).

Figure 2a and b show Kaplan–Meier analyses for DFS in the two molecular classifications. In the HR/HER2 classification (Fig. 2a), HR+/HER2− patients had a significantly better DFS than the rest of the groups ($P < 0.0001$). In the intrinsic subtype classification, Luminal A patients had the best DFS outcomes ($P < .0001$ for Luminal A vs. TN + HER2; and $P < 0.0001$ for Luminal A vs. Luminal B). TN and HER2 had the worst outcomes. Luminal B patients had an intermediate outcome, although the difference with TN + HER2 was not statistically significant (HR for DFS: 0.85; 95% CI: 0.65–1.11; $P = 0.227$).

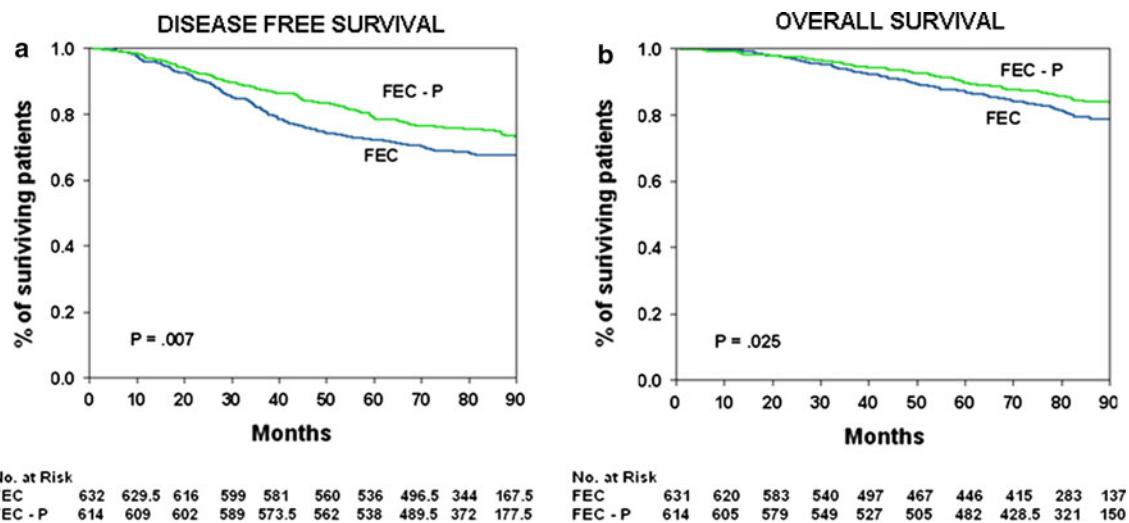

Fig. 1 7-year disease-free survival (DFS) (a), and overall survival (b) of the whole population according to chemotherapy arm

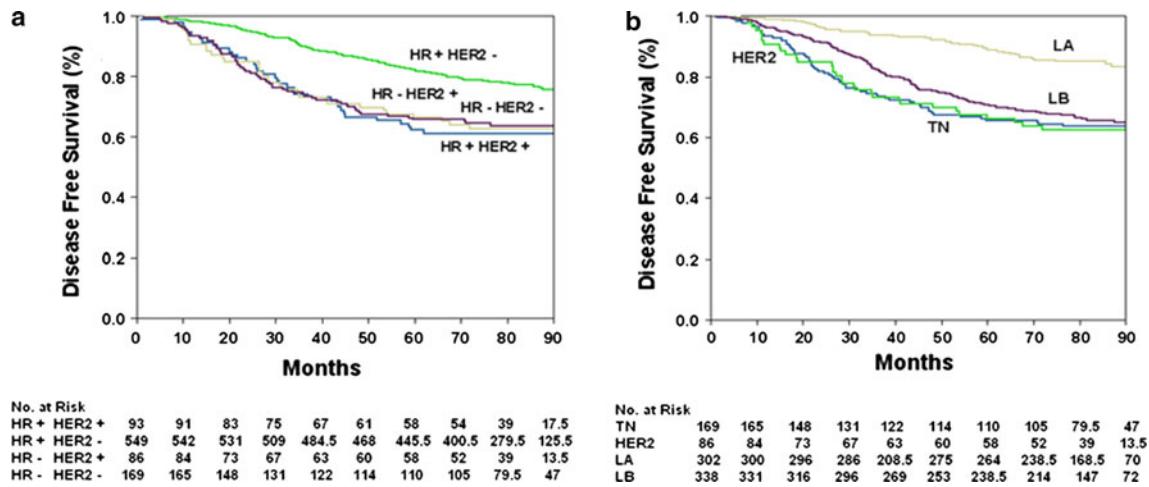

Fig. 2 DFS according to the two classifications. **a** hormone receptor/HER2 classification. **b** intrinsic subtypes (see text)

Figure 3 shows the DFS curves of the four HR/HER2 subgroups segregated with respect to the assigned treatment. FEC-P was statistically significantly superior to FEC only in the HR-/HER2- subgroup. In the intrinsic subtype classification, FEC-P was statistically significantly superior to FEC in the TN and Luminal A subsets (Fig. 4). Since patients had not been stratified according to subtypes, a Cox's regression analysis of DFS was performed to rule out false positive results. The confounding variables included age, menopausal status, tumor size, histologic grade, histologic type, extra-capsular ganglionar invasion, number of lymph nodes, chemotherapy arm, and hormonal therapy. In the TN subgroup, menopausal status ($P = 0.048$), number of axillary lymph nodes involved ($P = 0.049$), and chemotherapy arm ($P = 0.035$) were independent variables predictive of DFS. In the Luminal A subgroup, histologic grade ($P = 0.020$), number of axillary lymph nodes

involved ($P < 0.0001$), hormonal adjuvant therapy ($P = 0.001$) and chemotherapy arm ($P = 0.011$) were independent variables predictive of DFS.

In the small subset of patients showing basal phenotype (TN and EGFR positive and/or cytokeratins 5/6 positive; $n = 79$), FEC-P was significantly superior to FEC, with 7-year DFS of 83 versus 57% ($P = 0.018$) (Fig. 5). In this subgroup, the hazards ratio for DFS was 0.33 (95%CI: 0.12–0.87; $P = 0.024$).

Discussion

The 7-year follow-up update of GEICAM 9906 trial confirms a statistically significant advantage of FEC-P over FEC in terms of DFS (75 vs. 68%) and shows now a significant benefit in OS (84 vs. 79%) not seen in the 5-year

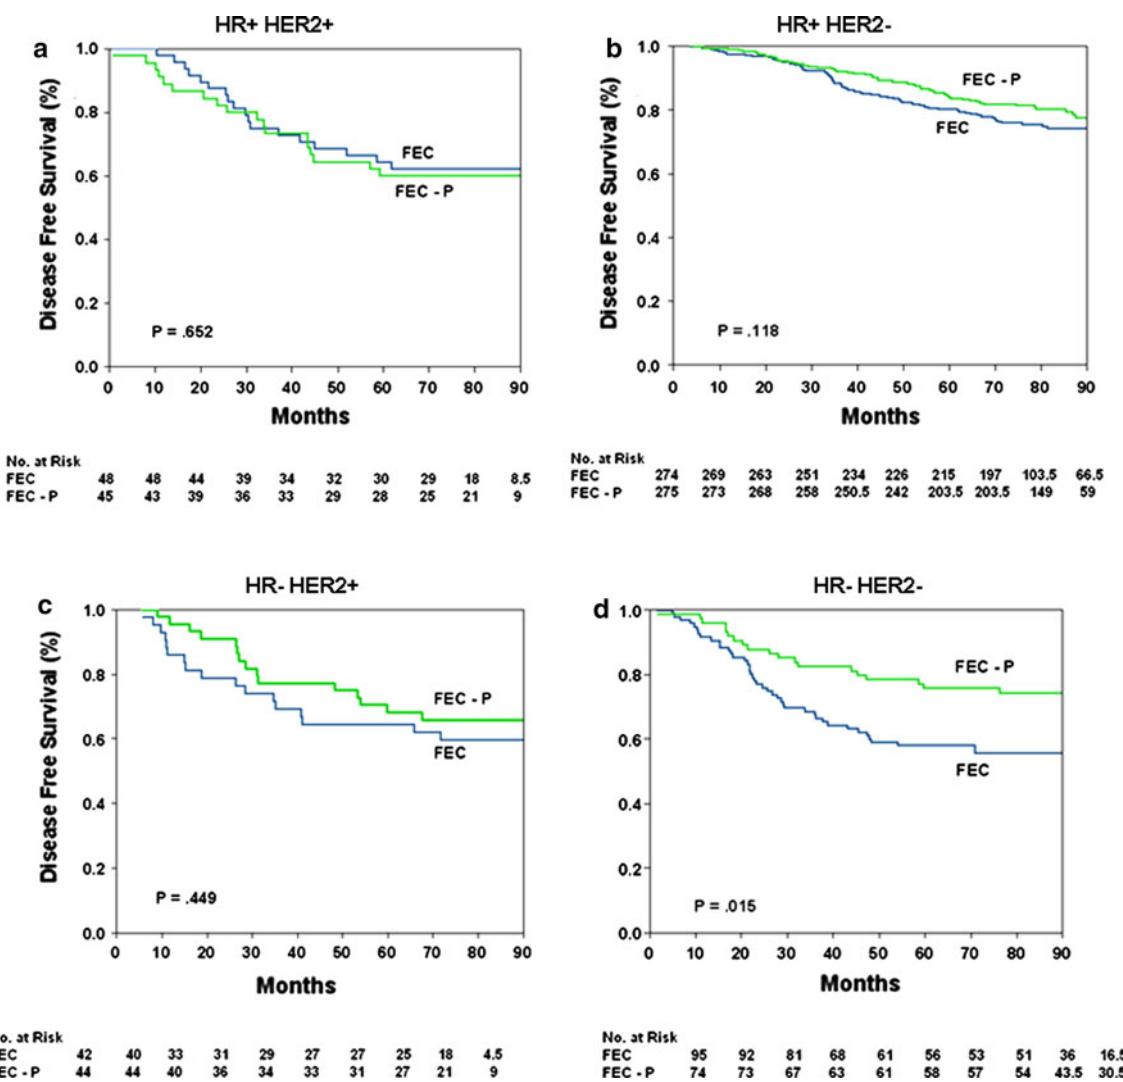

Fig. 3 DFS with FEC and FEC-P in the four subgroups of hormone receptor/HER2 classification (see text)

follow-up. The benefit with FEC-P is, however, small in absolute terms (7% in recurrences and 5% in deaths). Hence, using standard IHC and FISH methods to characterize patients, we attempted to define the subgroup of patients who do actually benefit from paclitaxel. The HR/HER2 classification as well as the intrinsic subtype classification defined groups with good outcomes with chemotherapy with/without additional radiation and hormonal therapy (i.e., the HR+/HER2- and Luminal A, with 7-year DFS of 77 and 85%, respectively). Similarly, both classifications were coincident in showing poor prognosis for HR-/HER2+, and TN patients (7-year DFS of around 63%).

The DFS curves of the four intrinsic subtypes in the GEICAM 9906 are very similar to those of the same subgroup classification in the BCIRG 001 trial [10]. Since the advent of trastuzumab which significantly improves the treatment outcome in HER2+ patients [18, 19], the

prognostic value of these two classifications has become reduced, with only the data of Luminal HER2- and TN patients being of interest today.

The outcomes of the four subgroups (in terms of 3-year DFS) were somewhat similar in both trials: Luminal A (94% GEICAM 9906 vs. 91% BCIRG 001), Luminal B (82 vs. 82%), TN (75 vs. 67%), and HER2 (73 vs. 68%).

Using IHC/FISH classifications, we also sought to identify the subgroup of patients who would most benefit from the additional weekly paclitaxel. Overall, the maximum benefit with FEC-P was seen in the subset of TN patients. In these patients, FEC-P reduced the likelihood of relapse by 47%, and yielded an absolute benefit in 7-year DFS of 18% with respect to FEC (74 vs. 56%). A Cox regression indicated that treatment with FEC-P remained a significant predictor of DFS.

Of considerable note was that in the small subgroup of TN patients showing basal phenotype in our study, FEC-P

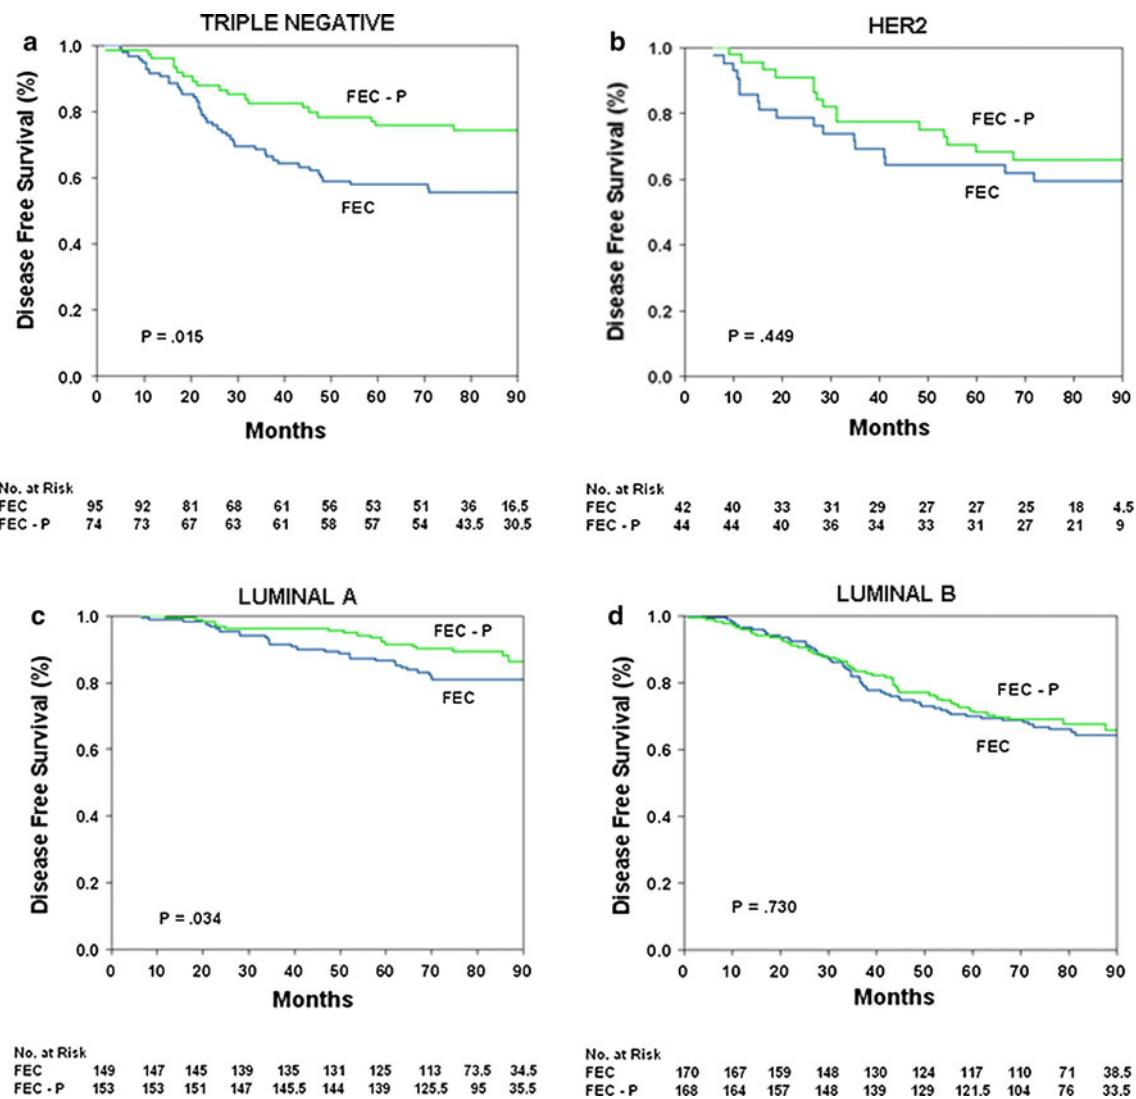

Fig. 4 DFS with FEC and FEC-P in the four subgroups of intrinsic subtype classification (see text)

treatment reduced the likelihood of recurrence by 67% compared to the treatment with FEC, and this difference was statistically significantly ($P = 0.018$) despite the small number of patients in this subgroup. The absolute benefit with FEC-P in terms of 7-year DFS was as high as 26%. Again, a Cox regression analysis showed that treatment with FEC-P was an independent predictor of DFS. The poor outcome in the TN subgroup seen in our study with the standard FEC treatment (7-year DFS of 56%) is similar to that reported by Tan et al. [20], in a similar patient population treated with conventional adjuvant anthracycline-containing combinations as adjuvant therapy of TN tumors is currently being debated since anthracyclines seem to be more efficacious than CMF-like regimens only in HER2 overexpressing tumors [21]. A recent analysis of the Canadian MA5 adjuvant trial in which, overall, six cycles

of CEF were superior to six cycles of CMF [22], showed that patients with basal tumors (defined by IHC methods, as in our study) had a significantly better 5-year OS with CMF than with CEF (71 vs 51%, respectively, $P = 0.009$). The poor outcomes of TN patients with full dose epirubicin-containing combination in all these studies, also seen in the GEICAM 9906 trial, speaks against the use of anthracyclines in TN tumors.

Hayes et al. [8] published their results of the interaction of her2, paclitaxel treatment and outcome in the CALBG 9344 trial which compared four cycles of AC to AC followed by four cycles of paclitaxel. They observed that her2-positivity, regardless of estrogen receptor status, was associated with a significant benefit from paclitaxel administration (HR for recurrence of 0.59; $P = 0.01$). An exploratory analysis of the benefit of paclitaxel based on her2-positivity and estrogen receptor status was also

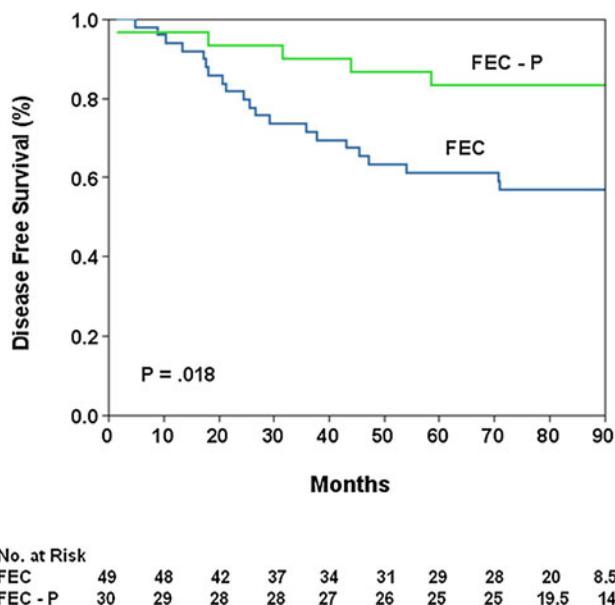

Fig. 5 DFS with FEC and FEC-P in the subgroup of basal-like patients (triple negative plus either cytokeratin 5/6 positive or EGFR positive tumors)

performed, as in our study. In terms of DFS, the benefit of adding paclitaxel to AC was statistically significant in HR-/HER2+ patients ($P = 0.001$) and HR-/HER- patients ($P = 0.002$). HR+/HER2+ obtained a benefit with paclitaxel of borderline significance ($P = 0.058$). The remaining patients (HR+/HER2-), appeared not to benefit from the addition of paclitaxel to AC. Some of the results of the CALGB 9344 trial have not been confirmed by the GEICAM 9906 trial. In our study, FEC-P was not statistically superior to FEC in the subgroups HR+/HER2-, HR-/HER2+ and HR+/HER2+ in the HR/HER2 classification. As in the CALGB 9344 trial, our study found a statistically significant benefit with paclitaxel in patients with HR-/HER- tumors, but the benefit of the addition of paclitaxel in the her2 positive subgroups observed in the CALGB 9344 trial was not clear in our trial. The differences in subtype analyses seen in these two trials could be due to several factors. First, there was an inequality in the CALGB 9344 trial in terms of duration of treatment (four vs. eight cycles); thus the benefit seen could have been due merely to a more protracted chemotherapy regimen rather than a taxane-specific effect. Second, the control arm (four cycles of AC) could be a suboptimal adjuvant treatment regimen, particularly in patients whose tumors overexpress her2. Since her2-positive patients obtain the maximum benefit with anthracyclines [21], the administration of an appropriate anthracycline regimen is of the critical importance for this particular subset of patients. Finally, the differences in subset results of the above-mentioned trials could be due to the reduced study's power to detect

statistically significant treatment differences in those subsets with small number of patients.

In our study, we found an unexpected superiority of FEC-P over FEC in the Luminal A subtype, confirmed in a multivariate analysis that included other relevant variables such as number of axillary lymph nodes involved, tumor grade, menopausal status and hormonal therapy. In the BCIRG 001 trial TAC was not superior to FAC in the Luminal A subset. Similarly, in the French PASC 01 trial, Luminal A patients (hormone receptor positive patients with low Ki 67 expression), apparently did not get any benefit from the addition of sequential docetaxel to FEC [23, 24]. The reasons for this discrepancy remain unclear.

In the BCIRG 001, TAC was associated with a better DFS than FAC in the HER2 subset; albeit the differences did not reach statistical significance ($P = 0.068$) probably due to the sample size ($n = 113$). In the GEICAM 9906 trial, no conclusion can be drawn in this subset due to the same reason (only 86 patients in the HER2 subtype). BCIRG 001 and GEICAM 9906 were coincident in showing an advantage of the taxane arm in the TN patient subpopulation although, in the BCIRG trial, the difference was of borderline significance ($P = 0.051$). A subgroup analysis of the French PACS 01 trial (comparing six cycles of FE100C with three cycles of FE100C followed by three cycles of docetaxel) found that the benefit with docetaxel was mainly confined to the basal-like subtype [23, 24]. The activity of taxanes in TN/basal tumors, seen in all these retrospective analyses, would be particularly relevant since no targeted therapy is currently available for this patient population.

Retrospective subset analyses intended to identify subsets of patients who obtain the maximum benefit from a particular therapy, are now common in adjuvant breast cancer trials. However, the interpretation of results requires caution. For example, multiple, unplanned analyses can lead to spurious treatment correlations (false positive results). Further, the post-hoc segregation of the overall patient population into subsets reduces the study's power to detect statistically significant treatment differences, since many of the subsets become very reduced in size leading to potential false negative results. Finally, there is a real possibility of publication bias, i.e., negative results (lack of association) are seldom submitted for publication by the investigators and, when submitted, are rarely accepted by medical journals. Because of all these caveats, the results of such subset analyses are considered merely hypothesis generating.

Unfortunately, in real life, the majority of the interesting hypotheses generated by retrospective analyses will never be tested in prospective trials. For instance, a prospective trial intending to confirm the lack of superiority of TAC over FAC in Luminal A patients, will probably never be

conducted because of ethical concerns, difficulties in enrolment, together with the protracted trial period and follow-up needed to generate conclusive results. Therefore, a renewed scientific debate on the real value and practical applications of retrospective subset analysis seems increasingly necessary.

In summary, the IHC subgroup analyses of GEICAM 9906 trial, although retrospective and unpowered for some subsets, firmly suggest that the benefit from FEC-P over FEC in 7-year DFS is mainly due to the effect of paclitaxel in the TN/basal phenotypes, an observation common to other taxane studies. The potential benefit seen with paclitaxel in Luminal A patients is intriguing and need to be confirmed in other trials.

Acknowledgments The authors thank Maribel Casas, and María José Escudero (GEICAM) for their assistance in preparing the manuscript. Editorial help was by Peter R. Turner of t-SciMed (Reus, Spain). This work was supported, in part, by grants from Bristol-Myers Squibb and Pharmacia.
