Running title: MMP-9 and sleep apnea
Abstract

**Background:** Matrix metalloproteinase-9 (MMP-9) plasma levels correlate with C-reactive protein (CRP) concentrations and they are both increased in adults with obstructive sleep apnea (OSA). No studies have evaluated MMP-9 levels in children with sleep apnea and CRP is not consistently elevated in pediatric OSA. The aim of this investigation was to evaluate the association of severity of OSA, adiposity and CRP with MMP-9 plasma levels in Greek children.

**Methods:** Consecutive children with snoring who underwent polysomnography and were found to have OSA (obstructive apnea-hypopnea index-OAHI \( \geq 1 \) episode/hour) were recruited. Subjects without OSA (OAHI < 1 episode/hour) were included for comparison. Morning plasma MMP-9 and CRP were measured.

**Results:** Twenty nine children with moderate-to-severe OSA (age 5.4 ± 1.5 years; OAHI 13.9 ± 13.0 episodes/hour), 55 participants with mild OSA (6.4 ± 2.6 years; OAHI 2.4 ± 1.1 episodes/hour) and 22 subjects without OSA (6.8 ± 2.6 years; OAHI 0.6 ± 0.2 episodes/hour) were studied. Children with moderate-to-severe OSA were similar to those with mild OSA or without OSA regarding ln-transformed MMP-9 values (5.87 ± 0.60 vs. 5.84 ± 0.55 vs. 5.80 ± 0.46; p>0.05) and CRP concentrations (0.22 ± 0.29 mg/dL vs. 0.21 ± 0.36 vs. 0.13 ± 0.16 mg/dL; p>0.05). In multiple linear regression, body mass index (p=0.027) and CRP levels (p=0.008), but not OAHI or \( \text{SpO}_2 \) nadir (p>0.05), were significantly related to MMP-9 values.

**Conclusions:** Adiposity and systemic inflammation unrelated to OSA severity, modulate MMP-9 levels in Greek children.
Introduction

Obstructive sleep-disordered breathing (SDB) with its associated nocturnal intermittent hypoxemia is considered an oxidative stress disorder characterized by release of inflammatory mediators, increased leukocyte adherence to endothelial cells, reduced nitric oxide availability and ultimately endothelial dysfunction and vascular injury. 1-3 Systemic inflammation and monocyte migration into the vascular wall have central roles in the pathogenesis of atherosclerosis and can potentially explain the epidemiologic association between obstructive sleep apnea and risk of cardiovascular events. 4-6

Matrix metalloproteinase-9 (MMP-9) contributes to degradation of the extracellular matrix and to vascular remodelling and its plasma levels correlate with indices of systemic inflammation like C-reactive protein (CRP). 7,8 Studies in adult sleep apneics have associated CRP and MMP-9 serum levels with severity of SDB and with the degree of adiposity. 9-12 In addition, monocytes isolated from adults with severe sleep apnea have higher production of MMP-9 than monocytes from control subjects. 13 Treatment of sleep apnea with nasal continuous positive airway pressure diminishes serum levels of MMP-9 and its production from monocytes. 11,13

There are no published studies assessing MMP-9 plasma concentrations in children with obstructive SDB. It is expected that increased levels of CRP will be accompanied by elevated concentrations of MMP-9. 8 However, the strength of the association between severity of intermittent upper airway obstruction during sleep and CRP in childhood may vary according to the ethnic population studied. 14-19 It is known that Greek and Australian children with SDB have lower serum CRP concentrations than United States (US) children with SDB of similar severity. 14,17,19,20 Thus, the aim of this investigation was to assess whether severity of
intermittent upper airway obstruction during sleep, morning plasma concentration of CRP and degree of adiposity are significantly related to morning plasma MMP-9 levels in Greek children with OSA. It was hypothesized that children with OSA have increased MMP-9 levels.

Patients and Methods

Participants and clinical evaluation

The study protocol was approved by the Larissa University Hospital Ethics Committee and parents of participants provided informed consent. Consecutive children with history of snoring and adenotonsillar hypertrophy, who underwent polysomnography and were found to have obstructive sleep apnea (OSA) were recruited in the study prior to adenotonsillectomy. OSA was defined as an obstructive apnea-hypopnea index (OAHIs) ≥ 1 episode/hour. Subjects with hypertrophic tonsils and without snoring, who underwent polysomnography to rule out OSA and who had OAHIs < 1 episode/hour were included in the study for comparison (group without OSA). Exclusion criteria for participation in the study were: i) symptoms or signs of acute or chronic inflammation (e.g. recurrent tonsillitis); ii) history of cardiovascular, neuromuscular or genetic disorders; and iii) use of sympathomimetics, corticosteroids or leukotriene modifiers.

Study participants underwent a detailed physical examination with measurement of weight and standing height. Body mass index (BMI) and BMI z-score were calculated. Obesity was defined as BMI z-score > 1.645. 21

Polysomnography

Participants underwent overnight polysomnography in the Sleep Disorders Laboratory of Larissa University Hospital. The following parameters were recorded: electroencephalogram (C3/A2, C4/A1, O1/A2); right and left oculogram; submental
and tibial electromyogram; body position; electrocardiogram; thoracic and abdominal wall motion; oronasal airflow (3-pronged thermistor); and oxygen saturation of hemoglobin.

Arousals were scored according to recommendations provided in the American Academy of Sleep Medicine Manual. 22 Obstructive apnea was defined as a >90% fall in the airflow signal amplitude compared to the pre-event baseline, lasting for at least 2 missed breaths and in the presence of continued or increased inspiratory effort. 22 An apnea was considered as mixed if part of the event was associated with absent inspiratory effort and the remaining part with the presence of respiratory movements. Hypopnea was scored when there was a decrease in the airflow signal amplitude of at least 50% compared to the pre-event baseline, that lasted for at least 2 missed breaths and which was associated with an arousal or ≥3% desaturation. 22 OAHI was equal to the average number of obstructive and mixed apneas and hypopneas per hour of sleep.

**Measurement of plasma MMP-9 and CRP**

Venipuncture was completed in the morning after polysomnography. The blood sample was collected into a tube containing heparin and was immediately centrifuged. Part of the supernatant (platelet-free plasma) was aliquoted and frozen at -70º C for later measurement of MMP-9 concentration, and the remaining sample was processed for determination of CRP level.

A high sensitivity immunonephelometric method with lowest detection limit of 0.0175 mg/dL (N High Sensitivity CRP; Dade Behring, Marburg, Germany) was used for quantification of CRP levels. MMP-9 concentration was measured with a commercially available solid phase ELISA (Quantikine MMP-9 Immunoassay; R&D Systems Inc., Minneapolis, MN). The assay has a lowest detection limit of 0.156
ng/mL, intra-assay coefficient of variation 1.9%-2.9% and inter-assay coefficient of variation 6.9%-7.9%.

Data analysis

Morning plasma MMP-9 level was the primary outcome measure of the current investigation. MMP-9 concentrations were log-transformed (natural logarithm) to approach a normal distribution. Three study groups were formed: i) subjects without OSA (OAHI < 1 episode/hour); ii) children with mild OSA (OAHI = 1-5 episodes/hour); and iii) subjects with moderate-to-severe OSA (OAHI > 5 episodes/hour).

The 3 study groups were compared in terms of subjects’ characteristics, polysomnography indices, CRP and MMP-9 plasma levels. One-way analysis of variance (ANOVA) followed by post-hoc tests (Bonferroni’s test) was carried out for comparisons of study groups regarding continuous variables and $\chi^2$ test (Yate’s correction) for comparisons regarding categorical characteristics. Analysis of covariance was also used to compare the 3 study groups in terms of ln-transformed MMP-9 taking under consideration the fact that these groups differed significantly in BMI z-score.

Univariate Pearson’s correlation was applied to evaluate the association of ln-transformed MMP-9 with BMI z-score, polysomnography indices, and CRP. Multiple linear regression analysis was completed to assess whether age, gender, BMI z-score, and OAHI or SpO$_2$ nadir were related to ln-transformed MMP-9 concentrations. Multivariable analysis was repeated after including CRP as an additional independent variable in the regression analysis model.

Results

Subjects’ characteristics and polysomnography findings
Eighty four children with OSA and 22 subjects without OSA were recruited. The 3 study groups did not differ in terms of age and gender. Ninety eight (92.5%) of all children were younger than 10 years old. Participants with moderate-to-severe OSA had significantly higher BMI z-score than participants without OSA (Table 1). Polysomnography findings for each study group are summarized in Table 1.

**Morning concentrations of MMP-9 and CRP**

Children with moderate-to-severe OSA, mild OSA or without OSA were similar regarding MMP-9 and CRP plasma concentrations (Table 2 and Figure 1).

Analysis of covariance confirmed that the 3 study groups did not differ in ln MMP-9 values even after adjustment for BMI z-score ($p=0.833$). Adjusted mean (± standard deviation) ln-transformed MMP-9 values for subjects with moderate-to-severe OSA, mild OSA or without OSA were: $5.85 \pm 0.54$, $5.81 \pm 0.54$ or $5.90 \pm 0.58$, respectively.

There was no correlation of ln-transformed MMP-9 levels with OAHI ($r= -0.03; p=0.779$), respiratory arousal index ($r= -0.07; p=0.456$), oxygen desaturation of hemoglobin index ($r= -0.04; p=0.703$) or $SpO_2$ nadir ($r=0.03; p=0.733$).

In contrast, ln-transformed MMP-9 levels were significantly associated with BMI z-score ($r=0.21; p=0.032$) and CRP ($r=0.28; p=0.004$). In multiple regression analysis, BMI z-score and CRP level—but not severity of SDB—were related to ln-transformed morning MMP-9 concentrations (Table 3).

**Discussion**

In the present study it has been demonstrated that low-grade systemic inflammation, as reflected by CRP, and degree of adiposity affect MMP-9 plasma levels in Greek children with OSA, whereas these levels are not modulated by severity of OSA. This finding is in contrast to the reported association of MMP-9
with severity of OSA in adults but in line with the previously described low CRP serum levels in Greek children with sleep apnea. The absence of a relationship between MMP-9 and polysomnography indices in Greek children supports further the concept that different ethnic pediatric populations with OSA undergo activation of diverse inflammatory and oxidative stress pathways.

Matrix metalloproteinases (MMPs) are a family of zinc-dependent endopeptidases that degrade extracellular matrix proteins. MMPs are excreted as zymogens that are activated by proteinases and their action is modified by tissue inhibitors (TIMPs). They are involved in the inflammatory processes related to atherosclerosis and plasma concentration of MMP-9 is a predictor of cardiovascular mortality in patients with coronary disease. More specifically, MMPs promote degradation of the vascular basement membrane allowing monocyte infiltration and smooth muscle cell migration into the vascular wall, ultimately resulting in vascular remodeling and atheromatic plaque formation. Furthermore, MMP-9 expression in the myocardium increases in parallel with the growing left ventricle myocardial mass in patients with ventricular pressure overload.

Three studies in adults with OSA have identified increased serum MMP-9 concentrations or enhanced MMP-9 production by monocytes. Tazaki et al reported that MMP-9 serum levels and enzyme activity measured by gelatin zymography were higher in men with moderate-to-severe OSA than in patients with mild OSA or in obese controls. MMP-9 levels and activity were positively correlated with BMI and serum concentrations of interleukin-6 (IL-6) or tumor necrosis factor-alpha (TNF-alpha) and these levels decreased after treatment with nasal continuous positive airway pressure.
A variety of cells including monocytes, macrophages, neutrophils and endothelial cells release pro-MMP-9 after stimulation by inflammatory cytokines like IL-6 and TNF-alpha. Hence, it is possible that hypoxemia-triggered production of IL-6 and TNF-alpha in sleep apneics promotes synthesis of MMP-9. Since IL-6 also regulates the synthesis of CRP, it is not surprising that MMP-9 and CRP are significantly correlated with each other in male subjects with OSA and their levels increase with increasing severity of sleep apnea. Augmented production of TNF-alpha and MMP-9 from peripheral blood monocytes in severe OSA decreases following treatment with nasal continuous positive airway pressure.

Similar to findings in adults, in the current report, CRP and the degree of adiposity were significantly associated with MMP-9 plasma concentrations. In vitro experiments involving peritoneal macrophages from rats have revealed that CRP enhances gene expression of MMP-9. Moreover, in healthy obese and lean children and adolescents MMP-9 levels increase linearly with increasing BMI. A two-week high fiber and low-fat diet along with daily exercise have a lowering effect on MMP-9 serum concentrations in overweight children.

Although blood pressure elevation and changes in cardiac structure and function are the main effects of pediatric OSA on the cardiovascular system, it is conceivable that sleep apnea is also associated with changes in collagen turnover of the vascular wall as it has been postulated for obese children and adolescents with elevated MMP-9 concentrations. Nevertheless, as opposed to results from investigations in adults, MMP-9 levels in this study were not affected by severity of OSA, despite the presence of a positive correlation between plasma MMP-9 and CRP concentrations.
A number of reasons could explain the discrepant results of the current study compared to findings of previous reports on MMP-9 levels in adult sleep apneics. First, adults with sleep apnea have more severe intermittent hypoxemia in comparison to children with SDB and this difference may be responsible for the higher prevalence of systemic inflammation in the former than in the latter. Second, OSA is usually present for more years and hence its complications are more likely frequent in adults than in young children. Third, there is emerging evidence for two variants or types of pediatric OSA. There appears to be a phenotype in older and obese children and adolescents resembling sleep apnea in adults, with low-grade systemic inflammatory response, insulin resistance, dyslipidemia and inadequate improvement after adenotonsillectomy. The majority of participants of the present study were younger than 10 years old and probably belonged to the classical sleep apnea phenotype with adenotonsillar hypertrophy, less intense systemic inflammatory response and apparent improvement after adenotonsillectomy.

In addition, different inflammatory and oxidative stress pathways may be activated among populations with OSA and different genetic background or environmental exposures. US children with obstructive SDB have increased concentrations of circulating vascular endothelial growth factor (VEGF), IL-6 and CRP, whereas VEGF and CRP appear unaffected by severity of OSA in Greek children. In contrast, excretion of uric acid, an important antioxidant and free radical scavenger, is accentuated in Greek children with SDB but it is not modulated by severity of OSA in US children. Finally, urine excretion of cysteinyl leukotrienes is related to severity of SDB in Greek children. Thus, genetic variability and environmental factors may be responsible for the differential oxidative
stress and inflammatory responses to intermittent upper airway obstruction during sleep. 47

One potential limitation of the current study is that use of nasal thermistry to monitor airflow without measurement of nasal pressure may have underestimated the frequency of hypopneas. Also, the 3 study groups were not matched in terms of BMI z-score. However, analysis of covariance confirmed that children with moderate-to-severe OSA, mild OSA or without OSA had similar MMP-9 values even after adjustment for BMI z-score. Finally, only plasma MMP-9 levels but not activity of the enzyme were measured. While the three groups of study participants did not differ in terms of MMP-9 concentrations, it is plausible that they were different regarding MMP-9 activity due to variable levels of TIMPs.

The present study represents the first attempt in the pediatric literature to assess the potential association between sleep apnea and MMP-9 levels. In the study design, the sample size has not been calculated since there is no prior estimate of the variability and the clinically significant difference of MMP-9 values (primary outcome measure) in children with and without OSA. In such novel cohort studies, the number of participants is usually determined by patient availability and resources.

In conclusion, MMP-9 plasma levels in Greek children with sleep apnea are affected by adiposity and by low-grade systemic inflammation unrelated to OSA. Severity of intermittent upper airway obstruction during sleep does not appear to influence MMP-9 concentrations in the studied pediatric population.

RESPONSE TO REVIEWERS’ COMMENTS

Reviewer 2

1. “These authors investigated MMP-9 levels in plasma, however they did not investigate MMP-9 activity using specific protease assays. It is quite plausible that while the MMP-9 levels did not differ amongst different severities of OSA, MMP-9 activity may differ, and reflect potentially different levels of TIMPs (tissue inhibitors of metalloproteinases). In previous studies, both MMP-9 concentrations and activity levels were elevated in adults with OSA.”

This limitation has been discussed in the revised manuscript: “Finally, only plasma MMP-9 levels but not activity of the enzyme were measured. While the three groups of study participants did not differ in terms of MMP-9 concentrations, it is plausible that they were different regarding MMP-9 activity due to variable levels of tissue inhibitors of TIMPs.” (p. 11, par. 1)

2. “Also, there is no mention of inclusion or exclusion of children with hypertension or any other cardiovascular disease, or children on agents that alter cardiovascular status (sympathomimetics, etc). Since children with altered vasomotor tone may potentially have altered inflammatory profiles, it is important this potential confounder be discussed.”

None of the participants had a diagnosis of cardiovascular disease or was using sympathomimetics. This important point was clarified in the revised paragraph listing the exclusion criteria for participation in the study. (p. 4, par. 2)

3. “Similarly, children with altered metabolic profiles secondary to OSA or obesity may have differing degrees of inflammation which may reflect in MMP-9 levels. Was this investigated by this group? If not, the authors need to mention that the potential of metabolic disease, or the presence of the metabolic syndrome for that matter, may have influenced the study’s findings.”

Please also see our response to comment #4. Although some of the studied children were obese, our participants could be mostly classified to the “classical” pediatric OSA phenotype. In this phenotype, insulin resistance and dyslipidemia due to sleep apnea are infrequent.

4. “Finally, were all children with OSA who were undergoing polysomnography for snoring also found to have adenotonsillar hypertrophy, or were there children who had undergone adenotonsillectomy with residual sleep disordered breathing. Certainly there is emerging evidence that there are two variants or types of sleep apnea in children. There appears to be an older, obese phenotype that does not respond to adenotonsillectomy, and...
these children resemble the adult phenotype. The classical phenotype of young children who respond to adenotonsillectomy, fit a potentially different inflammatory phenotype. As such I believe the authors need better descriptive data of their 84 children with OSA to draw conclusions and make use of the data.”

It was clarified in the revised Methods section that all children with OSA had adenotonsillar hypertrophy and were studied prior to adenotonsillectomy. In addition, the majority of our children were younger than 10 years old and probably belonged to the “classical” pediatric OSA phenotype. The Discussion section was expanded to include the important comment made by the reviewer:

“Third, there is emerging evidence for two variants or types of pediatric OSA. 41 There appears to be a phenotype in older and obese children and adolescents resembling sleep apnea in adults, with a low-grade systemic inflammatory response, insulin resistance, dyslipidemia and inadequate improvement after adenotonsillectomy. The majority of participants of the present study were younger than 10 years old and probably belonged to the classical sleep apnea phenotype with adenotonsillar hypertrophy, less intense systemic inflammatory response and apparent improvement after adenotonsillectomy.” (p. 10, par. 1)

5. “In my opinion, the figure 1 is redundant and not needed. Also, the authors do not explicitly state a hypothesis.”

A hypothesis has been included in the revised manuscript:
“It was hypothesized that children with OSA have increased MMP-9 levels.” (p. 4, par. 1)

6. “Grammatical Errors:
   Page 2, Line 13 should read: The Aim of this investigation
   Page 3, Line 25: The first entry of MMP-9 should not be abbreviated
   Page 3, Line 58: The first entry of US children should not be abbreviated.”

Grammatical errors were corrected.

Running title: MMP-9 and sleep apnea
Abstract

**Background:** Matrix metalloproteinase-9 (MMP-9) plasma levels correlate with C-reactive protein (CRP) concentrations and they are both increased in adults with obstructive sleep apnea (OSA). No studies have evaluated MMP-9 levels in children with sleep apnea and CRP is not consistently elevated in pediatric OSA. The aim of this investigation was to evaluate the association of severity of OSA, adiposity and CRP with MMP-9 plasma levels in Greek children.

**Methods:** Consecutive children with snoring who underwent polysomnography and were found to have OSA (obstructive apnea-hypopnea index-OAHI ≥ 1 episode/hour) were recruited. Subjects without OSA (OAHI < 1 episode/hour) were included for comparison. Morning plasma MMP-9 and CRP were measured.

**Results:** Twenty nine children with moderate-to-severe OSA (age 5.4 ± 1.5 years; OAHI 13.9 ± 13.0 episodes/hour), 55 participants with mild OSA (6.4 ± 2.6 years; OAHI 2.4 ± 1.1 episodes/hour) and 22 subjects without OSA (6.8 ± 2.6 years; OAHI 0.6 ± 0.2 episodes/hour) were studied. Children with moderate-to-severe OSA were similar to those with mild OSA or without OSA regarding ln-transformed MMP-9 values (5.87 ± 0.60 vs. 5.84 ± 0.55 vs. 5.80 ± 0.46; p>0.05) and CRP concentrations (0.22 ± 0.29 mg/dL vs. 0.21 ± 0.36 vs. 0.13 ± 0.16 mg/dL; p>0.05). In multiple linear regression, body mass index (p=0.027) and CRP levels (p=0.008), but not OAHI or SpO₂ nadir (p>0.05), were significantly related to MMP-9 values.

**Conclusions:** Adiposity and systemic inflammation unrelated to OSA severity, modulate MMP-9 levels in Greek children.
Introduction

Obstructive sleep-disordered breathing (SDB) with its associated nocturnal intermittent hypoxemia is considered an oxidative stress disorder characterized by release of inflammatory mediators, increased leukocyte adherence to endothelial cells, reduced nitric oxide availability and ultimately endothelial dysfunction and vascular injury. 1-3 Systemic inflammation and monocyte migration into the vascular wall have central roles in the pathogenesis of atherosclerosis and can potentially explain the epidemiologic association between obstructive sleep apnea and risk of cardiovascular events. 4-6

Matrix metalloproteinase-9 (MMP-9) contributes to degradation of the extracellular matrix and to vascular remodelling and its plasma levels correlate with indices of systemic inflammation like C-reactive protein (CRP). 7,8 Studies in adult sleep apneics have associated CRP and MMP-9 serum levels with severity of SDB and with the degree of adiposity. 9-12 In addition, monocytes isolated from adults with severe sleep apnea have higher production of MMP-9 than monocytes from control subjects. 13 Treatment of sleep apnea with nasal continuous positive airway pressure diminishes serum levels of MMP-9 and its production from monocytes. 11,13

There are no published studies assessing MMP-9 plasma concentrations in children with obstructive SDB. It is expected that increased levels of CRP will be accompanied by elevated concentrations of MMP-9. 8 However, the strength of the association between severity of intermittent upper airway obstruction during sleep and CRP in childhood may vary according to the ethnic population studied. 14-19 It is known that Greek and Australian children with SDB have lower serum CRP concentrations than United States (US) children with SDB of similar severity. 14,17,19,20 Thus, the aim of this investigation was to assess whether severity of
intermittent upper airway obstruction during sleep, morning plasma concentration of CRP and degree of adiposity are significantly related to morning plasma MMP-9 levels in Greek children with OSA. **It was hypothesized that children with OSA have increased MMP-9 levels.**

**Patients and Methods**

**Participants and clinical evaluation**

The study protocol was approved by the Larissa University Hospital Ethics Committee and parents of participants provided informed consent. Consecutive children with history of snoring and adenotonsillar hypertrophy, who underwent polysomnography and were found to have obstructive sleep apnea (OSA) were recruited in the study prior to adenotonsillectomy. OSA was defined as an obstructive apnea-hypopnea index (OAHI) ≥ 1 episode/hour. Subjects with hypertrophic tonsils and without snoring, who underwent polysomnography to rule out OSA and who had OAHI < 1 episode/hour were included in the study for comparison (group without OSA). Exclusion criteria for participation in the study were: i) symptoms or signs of acute or chronic inflammation (e.g. recurrent tonsillitis); ii) history of cardiovascular, neuromuscular or genetic disorders; and iii) use of sympathomimetics, corticosteroids or leukotriene modifiers.

Study participants underwent a detailed physical examination with measurement of weight and standing height. Body mass index (BMI) and BMI z-score were calculated. Obesity was defined as BMI z-score > 1.645.

**Polysomnography**

Participants underwent overnight polysomnography in the Sleep Disorders Laboratory of Larissa University Hospital. The following parameters were recorded: electroencephalogram (C3/A2, C4/A1, O1/A2); right and left oculogram; submental
and tibial electromyogram; body position; electrocardiogram; thoracic and abdominal
wall motion; oronasal airflow (3-pronged thermistor); and oxygen saturation of
hemoglobin.

Arousals were scored according to recommendations provided in the
American Academy of Sleep Medicine Manual. Obstructive apnea was defined as
a >90% fall in the airflow signal amplitude compared to the pre-event baseline, lasting
for at least 2 missed breaths and in the presence of continued or increased inspiratory
effort. An apnea was considered as mixed if part of the event was associated with
absent inspiratory effort and the remaining part with the presence of respiratory
movements. Hypopnea was scored when there was a decrease in the airflow signal
amplitude of at least 50% compared to the pre-event baseline, that lasted for at least 2
missed breaths and which was associated with an arousal or ≥3% desaturation. OAHI was equal to the average number of obstructive and mixed apneas and
hypopneas per hour of sleep.

**Measurement of plasma MMP-9 and CRP**

Venipuncture was completed in the morning after polysomnography. The
blood sample was collected into a tube containing heparin and was immediately
centrifuged. Part of the supernatant (platelet-free plasma) was aliquoted and frozen at
-70º C for later measurement of MMP-9 concentration, and the remaining sample was
processed for determination of CRP level.

A high sensitivity immunonephelometric method with lowest detection limit
of 0.0175 mg/dL (N High Sensitivity CRP; Dade Behring, Marburg, Germany) was
used for quantification of CRP levels. MMP-9 concentration was measured with a
commercially available solid phase ELISA (Quantikine MMP-9 Immunoassay; R&D
Systems Inc., Minneapolis, MN). The assay has a lowest detection limit of 0.156
ng/mL, intra-assay coefficient of variation 1.9%-2.9% and inter-assay coefficient of variation 6.9%-7.9%.

**Data analysis**

Morning plasma MMP-9 level was the primary outcome measure of the current investigation. MMP-9 concentrations were log-transformed (natural logarithm) to approach a normal distribution. Three study groups were formed: i) subjects without OSA (OAHI < 1 episode/hour); ii) children with mild OSA (OAHI = 1-5 episodes/hour); and iii) subjects with moderate-to-severe OSA (OAHI > 5 episodes/hour).

The 3 study groups were compared in terms of subjects’ characteristics, polysomnography indices, CRP and MMP-9 plasma levels. One-way analysis of variance (ANOVA) followed by post-hoc tests (Bonferroni’s test) was carried out for comparisons of study groups regarding continuous variables and $\chi^2$ test (Yate’s correction) for comparisons regarding categorical characteristics. Analysis of covariance was also used to compare the 3 study groups in terms of ln-transformed MMP-9 taking under consideration the fact that these groups differed significantly in BMI z-score.

Univariate Pearson’s correlation was applied to evaluate the association of ln-transformed MMP-9 with BMI z-score, polysomnography indices, and CRP.

Multiple linear regression analysis was completed to assess whether age, gender, BMI z-score, and OAHI or SpO$_2$ nadir were related to ln-transformed MMP-9 concentrations. Multivariable analysis was repeated after including CRP as an additional independent variable in the regression analysis model.

**Results**

**Subjects’ characteristics and polysomnography findings**
Eighty four children with OSA and 22 subjects without OSA were recruited. The 3 study groups did not differ in terms of age and gender. Ninety eight (92.5%) of all children were younger than 10 years old. Participants with moderate-to-severe OSA had significantly higher BMI z-score than participants without OSA (Table 1). Polysomnography findings for each study group are summarized in Table 1.

**Morning concentrations of MMP-9 and CRP**

Children with moderate-to-severe OSA, mild OSA or without OSA were similar regarding MMP-9 and CRP plasma concentrations (Table 2 and Figure 1). Analysis of covariance confirmed that the 3 study groups did not differ in ln MMP-9 values even after adjustment for BMI z-score (p=0.833). Adjusted mean (± standard deviation) ln-transformed MMP-9 values for subjects with moderate-to-severe OSA, mild OSA or without OSA were: 5.85 ± 0.54, 5.81 ± 0.54 or 5.90 ± 0.58, respectively.

There was no correlation of ln-transformed MMP-9 levels with OAHI (r= -0.03; p=0.779), respiratory arousal index (r= -0.07; p=0.456), oxygen desaturation of hemoglobin index (r= -0.04; p=0.703) or SpO₂ nadir (r=0.03; p=0.733). In contrast, ln-transformed MMP-9 levels were significantly associated with BMI z-score (r=0.21; p=0.032) and CRP (r=0.28; p=0.004). In multiple regression analysis, BMI z-score and CRP level-but not severity of SDB-were related to ln-transformed morning MMP-9 concentrations (Table 3).

**Discussion**

In the present study it has been demonstrated that low-grade systemic inflammation, as reflected by CRP, and degree of adiposity affect MMP-9 plasma levels in Greek children with OSA, whereas these levels are not modulated by severity of OSA. This finding is in contrast to the reported association of MMP-9
with severity of OSA in adults but in line with the previously described low CRP
serum levels in Greek children with sleep apnea.\textsuperscript{11,13,17,18} The absence of a
relationship between MMP-9 and polysomnography indices in Greek children
supports further the concept that different ethnic pediatric populations with OSA
undergo activation of diverse inflammatory and oxidative stress pathways.

Matrix metalloproteinases (MMPs) are a family of zinc-dependent
endopeptidases that degrade extracellular matrix proteins.\textsuperscript{23} MMPs are excreted as
zymogens that are activated by proteinases and their action is modified by tissue
inhibitors (TIMPs).\textsuperscript{24,25} They are involved in the inflammatory processes related to
atherosclerosis and plasma concentration of MMP-9 is a predictor of cardiovascular
mortality in patients with coronary disease.\textsuperscript{26,27} More specifically, MMPs promote
degradation of the vascular basement membrane allowing monocyte infiltration and
smooth muscle cell migration into the vascular wall, ultimately resulting in vascular
remodeling and atheromatic plaque formation.\textsuperscript{7,28,29} Furthermore, MMP-9
expression in the myocardium increases in parallel with the growing left ventricle
myocardial mass in patients with ventricular pressure overload.\textsuperscript{30}

Three studies in adults with OSA have identified increased serum MMP-9
concentrations or enhanced MMP-9 production by monocytes.\textsuperscript{11-13} Tazaki et al
reported that MMP-9 serum levels and enzyme activity measured by gelatin
zymography were higher in men with moderate-to-severe OSA than in patients with
mild OSA or in obese controls.\textsuperscript{11} MMP-9 levels and activity were positively
correlated with BMI and serum concentrations of interleukin-6 (IL-6) or tumor
necrosis factor-alpha (TNF-alpha) and these levels decreased after treatment with
nasal continuous positive airway pressure.
A variety of cells including monocytes, macrophages, neutrophils and endothelial cells release pro-MMP-9 after stimulation by inflammatory cytokines like IL-6 and TNF-alpha. Hence, it is possible that hypoxemia-triggered production of IL-6 and TNF-alpha in sleep apneics promotes synthesis of MMP-9. Since IL-6 also regulates the synthesis of CRP, it is not surprising that MMP-9 and CRP are significantly correlated with each other in male subjects with OSA and their levels increase with increasing severity of sleep apnea. Augmented production of TNF-alpha and MMP-9 from peripheral blood monocytes in severe OSA decreases following treatment with nasal continuous positive airway pressure.

Similar to findings in adults, in the current report, CRP and the degree of adiposity were significantly associated with MMP-9 plasma concentrations. In vitro experiments involving peritoneal macrophages from rats have revealed that CRP enhances gene expression of MMP-9. Moreover, in healthy obese and lean children and adolescents MMP-9 levels increase linearly with increasing BMI. A two-week high fiber and low-fat diet along with daily exercise have a lowering effect on MMP-9 serum concentrations in overweight children.

Although blood pressure elevation and changes in cardiac structure and function are the main effects of pediatric OSA on the cardiovascular system, it is conceivable that sleep apnea is also associated with changes in collagen turnover of the vascular wall as it has been postulated for obese children and adolescents with elevated MMP-9 concentrations. Nevertheless, as opposed to results from investigations in adults, MMP-9 levels in this study were not affected by severity of OSA, despite the presence of a positive correlation between plasma MMP-9 and CRP concentrations.
A number of reasons could explain the discrepant results of the current study compared to findings of previous reports on MMP-9 levels in adult sleep apneics. First, adults with sleep apnea have more severe intermittent hypoxemia in comparison to children with SDB and this difference may be responsible for the higher prevalence of systemic inflammation in the former than in the latter. Second, OSA is usually present for more years and hence its complications are more likely frequent in adults than in young children. Third, there is emerging evidence for two variants or types of pediatric OSA. 41 There appears to be a phenotype in older and obese children and adolescents resembling sleep apnea in adults, with low-grade systemic inflammatory response, insulin resistance, dyslipidemia and inadequate improvement after adenotonsillectomy. The majority of participants of the present study were younger than 10 years old and probably belonged to the classical sleep apnea phenotype with adenotonsillar hypertrophy, less intense systemic inflammatory response and apparent improvement after adenotonsillectomy.

In addition, different inflammatory and oxidative stress pathways may be activated among populations with OSA and different genetic background or environmental exposures. US children with obstructive SDB have increased concentrations of circulating vascular endothelial growth factor (VEGF), IL-6 and CRP, whereas VEGF and CRP appear unaffected by severity of OSA in Greek children. 42-44 In contrast, excretion of uric acid, an important antioxidant and free radical scavenger, is accentuated in Greek children with SDB but it is not modulated by severity of OSA in US children. 45 Finally, urine excretion of cysteinyl leukotrienes is related to severity of SDB in Greek children. 46 Thus, genetic variability and environmental factors may be responsible for the differential oxidative
stress and inflammatory responses to intermittent upper airway obstruction during sleep. \(^{47}\) One potential limitation of the current study is that use of nasal thermistry to monitor airflow without measurement of nasal pressure may have underestimated the frequency of hypopneas. Also, the 3 study groups were not matched in terms of BMI z-score. However, analysis of covariance confirmed that children with moderate-to-severe OSA, mild OSA or without OSA had similar MMP-9 values even after adjustment for BMI z-score. Finally, only plasma MMP-9 levels but not activity of the enzyme were measured. While the three groups of study participants did not differ in terms of MMP-9 concentrations, it is plausible that they were different regarding MMP-9 activity due to variable levels of TIMPs.

The present study represents the first attempt in the pediatric literature to assess the potential association between sleep apnea and MMP-9 levels. In the study design, the sample size has not been calculated since there is no prior estimate of the variability and the clinically significant difference of MMP-9 values (primary outcome measure) in children with and without OSA. In such novel cohort studies, the number of participants is usually determined by patient availability and resources.

In conclusion, MMP-9 plasma levels in Greek children with sleep apnea are affected by adiposity and by low-grade systemic inflammation unrelated to OSA. Severity of intermittent upper airway obstruction during sleep does not appear to influence MMP-9 concentrations in the studied pediatric population.
