Abstract — In this paper is presented an approach for computing the first natural frequencies of parallel robots. This approach, based on the Rayleigh-Ritz approximation, aims at reducing the model dimension by decreasing the size of the matrices describing the robot mass and stiffness, saving computational time and avoiding inaccuracy due to ill-conditioning. Thus it can be used in the design procedure as well as in real-time control. Simulations are carried out on a PRRRP robot modelled in 3D and comparisons with FEA software are presented.

Keywords: elastodynamic modelling, model dimension reduction, natural frequencies, parallel robots.

I Introduction

Parallel robots have increasingly been used in industry in the last few years, mainly for pick-and-place applications or high-speed machining [1], [2]. This interest is due to their main properties, i.e. their higher rigidity and dynamic capacities compared with their serial manipulator counterparts.

Having a good knowledge of the elastodynamic behaviour of a manipulator (especially its natural frequencies) is a crucial point. In this sense, accurate elastodynamic models are necessary at both the control stage [3]–[5] and design stage [6]–[8], in order to optimize the geometry, as well as the shape of the elements of the manipulator. This will lead to the creation of a mechanism in which vibrations will be minimized.

Several models have been proposed and used in the literature in order to compute the natural frequencies of a mechanism during a preliminary design. Three main general methods can be distinguished:

- Finite element analysis (FEA); the FEA method is proved to be the most accurate and reliable, since the links/joints are modeled with its true dimension and shape [7], [9]–[12]. Its accuracy is limited by the discretization step only. However, because of high computational expenses required for the repeated re-meshing, this method is usually applied at the final design stage for the verification and component dimensioning.
- Matrix structural analysis (MSA) method is a common technique in mechanical engineering [13], [14]; it incorporates the main ideas of the FEA but operates with rather large flexible elements (beams, arcs, cables, etc.). This obviously yields reduction of the computational expense and, in some cases, allows analytical stiffness matrix to be obtained. However, this method can only be applied to links with simple shapes and requires improved skills in FEA.
- Virtual joint methods (VJM) [8], [15], which is also referred to as “lumped modelling”, is based on the expansion of the traditional rigid model by adding virtual joints (localized springs), which describe the elastic deformations of the manipulator components (links, joints and actuators). Such kind of modelling is well adapted for links with complex shapes [16]. Generally, lumped modelling is simpler to use than MSA and provides acceptable accuracy in reduced computational time. It is widely used at the pre-design stage, especially for the analytical parametric analysis. However, due to the large number of virtual joints that have to be modelled in order to obtain good accuracy, such an approach is time-consuming. Moreover, for closed-loop mechanisms with passive joints, the way to assemble the matrices and to model the passive joints in kinematic chains is not straightforward.

The purpose of this paper is to propose a reduced elastodynamic modelling approach on parallel robots for the computation of the natural frequencies only, based on VJM. By keeping the simplicity of use of the VJM, this modelling considerably decreases the dimension of the problem by inverting only 6×6 matrices. It also proposes a straightforward procedure for the modelling of passive joints on parallel robots and for the assembly of the mass and stiffness matrices of closed-loop structures.

This paper will be organised as follows. Section 2 presents the theoretical background necessary in order to reduce the size of the elastodynamic model for the computation of the natural frequencies. In section 3, a numerical example is proposed in order to show the efficiency of our method. Finally, conclusions are drawn in section 4.
II. Theoretical background

A. Problem statement

Let us consider a general parallel manipulator made of \( n \) legs, each leg being composed of \( m \) links, \( m \) passive and one active joints, considered as ideal, i.e. without friction (Fig. 1a). Using the basic idea of VJM [15], let us decompose the \( j \)-th link of the \( i \)-th leg (denoted as the link \( ij \)) where \( j = 1, 2, \ldots, m \) and \( i = 1, 2, \ldots, n \) into \( p_j \) rigid elements and virtual springs (Fig. 1b). The mass and inertia matrix of the \( k \)-th rigid element of link \( ij \) (denoted as the element \( ijk \)) expressed in the local frame attached to this element, are denoted as \( m_{ijk} \) and \( I_{ijk} \), respectively. The displacement of its centre of mass denoted as \( \theta_{ijk} \) in the base frame, resulting from the robot deformations, is decomposed as the vector regrouping all vectors \( \theta_{ijk} \) where the three first components of this vector correspond to the translational displacements along the \( x \), \( y \) and \( z \) axes of the base frame, respectively, and the last three components to the rotational displacements along the same axes. It should be mentioned that in the remainder of the paper, the left superscript “0” will stand for the coordinates expressed in the global frame. If no left superscript is mentioned, the vector is expressed in the local frame attached to the link \( ij \).

The deformations of the \( k \)-th spring of link \( ij \) (denoted as the spring \( ijk \)) are denoted as \( \theta_{ijk} \), the centre of masses \( S_{ijk} \), respectively, and the last three components to the rotational deformations along the same axes. The kinetic energy of the system is equal to:

\[
T = \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{m} \sum_{k=1}^{p_i} q^T \theta_{ijk}^T M_{ijk} \theta_{ijk} = \frac{1}{2} \mathbf{q}^T M_{tot} \mathbf{q} \tag{1}
\]

where \( M_{ijk} = \text{diag}(m_{ijk}, I_{ijk}) \), \( I_{ijk} \) being the identity matrix of dimension \( 3 \times 3 \), \( \mathbf{q} = [q_{11}, q_{12}, \ldots, q_{nmp}]^T \) is the vector regrouping all vectors \( \theta_{ijk} \), \( q \) is the vector regrouping all vectors \( \theta_{ijk} \) (i.e. the velocity of the centre of masses \( S_{ijk} \)) and \( M_{tot} \) is the global stiffness matrix of the system.

The potential (elastic) energy of the system is equal to:

\[
V_e = \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{m} \sum_{k=1}^{p_i} \theta_{ijk}^T K_{ijk} \theta_{ijk} \tag{2}
\]

where \( K_{ijk} \) is the stiffness matrix of the virtual spring \( ijk \).

It is shown in [8], [15] that the deformations \( \theta_{ijk} \) can be related to the displacements of the centres of masses of elements \( ijk \) and \( ij(k+1) \) by the relation:

\[
\theta_{ijk} = \begin{bmatrix} C_{2ijk} & C_{1ijk(k+1)} \end{bmatrix} \begin{bmatrix} \theta_{ijk}^* \end{bmatrix} \tag{3}
\]

where \( C_{2ijk} \) and \( C_{1ijk(k+1)} \) are two \( 6 \times 6 \) matrices. Therefore, (2) can be rewritten as:

\[
V_e = \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{m} \sum_{k=1}^{p_i} \theta_{ijk}^* \begin{bmatrix} C_{2ijk}^T & C_{1ijk(k+1)}^T \end{bmatrix} K_{ijk} \begin{bmatrix} \theta_{ijk}^* \end{bmatrix} = \frac{1}{2} \mathbf{q}^T \mathbf{K}_{w} \mathbf{q} \tag{4}
\]

where \( q \) is the vector regrouping all vectors \( \theta_{ijk} \) and \( \mathbf{K}_{w} \) is the global stiffness matrix of the system.

Starting from these definitions, and considering that the robot is in an equilibrium position and no external forces are applied, the authors of [15] demonstrate that the system is governed by the relation:

\[
M_{tot} \ddot{q} + K_{tot} \dot{q} = 0 \tag{5}
\]

A solution \( \mathbf{q}_l \) of this equation can be found by solving the system:

\[
\left( \omega_l^2 M_{tot} - K_{tot} \right) \mathbf{q}_l = 0 \tag{6}
\]

where \( \mathbf{q}_l \) represents the vectors of the shape of free vibrations of the system for the \( l \)-th natural mode, \( f_l \) and \( \omega_l \) are their corresponding natural frequency and pulsation, respectively.

If the matrix \( \omega_l^2 M_{tot} - K_{tot} \) is singular (which is always the case when \( \omega_l \) is one of the modal pulsation of the robot), \( \mathbf{q}_l \) becomes non-null and is the eigenvector corresponding to the pulsation \( \omega_l \). There is an infinity of vectors \( \mathbf{q}_l \) validating (6) (for a given \( \omega_l \)), but all are proportional to the others. Vector \( \mathbf{q}_l \) is not necessarily dependent of time, but almost represents the amplitude of the vibrations. Therefore, when only the \( l \)-th mode of the system is excited, the displacements of all springs may be written under the form:

\[
\mathbf{q}^* = \mathbf{q}_l \sin(\omega_l t + \varphi_l) \tag{7}
\]
where $\phi_l$ is a phase difference corresponding to the mode $l$. When all modes are excited, the displacement $q$ of all spring centres may be written in the form:

$$ q = \sum_{i=1}^{6d} q_i^* = \sum_{i=1}^{6d} q_i \sin(\omega_l t + \phi_l) \quad (8) $$

The most common way to find the values of the pulsation $\omega_l$ is to solve the eigenvalue problem

$$ \det(\omega_l^2 I - M_{\text{red}} K_{\text{red}}) = 0. \quad (9) $$

where $I$ is an identity matrix of dimension $6 \times 6$, with $d = \sum_{i,j} p_{ij}$.

However, solving this problem involves finding the $6 \times 6$ eigenvalues of the problem and also inverting the $6 \times 6$ matrices $M_{\text{red}}$ constituting the matrix $M_{\text{red}}$, which is highly time-consuming and avoids accuracy results because of the problem dimension.

In order to avoid such kind of drawbacks [16] has recently proposed (for elastostatic modelling only) a new procedure to compute the deformations of the robot when a force is applied at the end-effector. This procedure computes a stiffness (and also compliance) matrix $K_r$ (and $S_r$, resp.) of dimension 6 that represents the behaviour of the robot in terms of deformations. Moreover, during the procedure, only inversions of $6 \times 6$ dimensional matrices are involved, which considerably reduces computational time and avoids accuracy problems due to ill-conditioning of the large global stiffness matrix. Thus, the global $6 \times 6$ dimensional problem defined with respect to all variables $q$ has been reduced to a $6 \times 6$ dimensional problem defined with respect to platform deflections $\delta t$ only. As a result, the entire robot can locally be seen as a virtual spring of dimension $6$ that deforms when applying a wrench on the end-effector.

Starting from these considerations, it would be interesting to reduce the dimension of the problem by expressing Eq. (6) as a function of the reduced stiffness matrix $K_r$, of the platform deflections $\delta t$ and, also, as a function of a reduced mass matrix that will be denoted as $M_r$, which could represent the global behaviour of the robot in terms of natural frequencies. The remainder of the paper will focus on this problem.

B. Rayleigh-Ritz approximation

Another way to find the natural pulsation $\omega_l$ of the mode $l$ would be to know the exact amplitude $\Phi_l$ of the displacements $q_l$ for this mode. For the natural mode $l$, the potential and kinetic energies of the system are given by:

$$ V = \frac{1}{2} q^T K_r q \quad \text{and} \quad T = \frac{1}{2} q^T M_r q \quad (12) $$

From the principle of energy conservation, it follows that

$$ \max(V_e) - \max(T) = 0, \text{ i.e. } q^T (\omega_l^2 M_{\text{red}} - K_{\text{red}}) q = 0 \quad (11) $$

which is a univariate equation in $\omega_l$.

It is obvious that the exact knowledge of the amplitude $q_l$ is an impossible task without a direct measure on the system of all the displacements of the robot nodes. However, this vector may be approximated by another denoted as $\hat{q}_l$ that is close to the exact amplitude $q_l$. Introducing this approximated vector $\hat{q}_l$ into (10) will allow us to find a corresponding value of $\hat{\omega}_l$ and, as a result, $f_l$ which is the approximated natural frequency of the system. Such kind of elastodynamic problem resolution is called the Rayleigh-Ritz method [17].

The better the approximation, the more accurate the value of $\hat{\omega}_l$. The designer’s skills in terms of understanding and analysis of robot physical behaviour are of the utmost importance. In this sense, let us recall that the first natural frequencies are associated with the highest level of energy due to vibrations, and represent the highest displacements of the structure. Therefore, in design optimization loops, it is essential to maximize the value of the first frequency.

Using the Rayleigh-Ritz approximation in order to compute the first natural frequencies, the stresses for which the maximal displacements appear have to be found. From our experience in elastic behaviour of robots, it is assumed that a good approximation of these maximal displacements will be the deformation of the robot with a load applied at the end-effector, and it can be shown in the following that this hypothesis is valid. Using this assumption, the displacements $q_l$ of all springs can be computed as a function of the end-effector displacements $\delta t$, i.e. it is possible to define a matrix $J_q$ such as:

$$ q_l = J_q \delta t \quad (12) $$

As a result, introducing (12) into (11) will lead to

$$ \delta t^T (\omega_l^2 J_q^T M_{\text{red}} J_q - J_q^T K_{\text{red}} J_q) \delta t = 0 \quad (13) $$

where the matrices $J_q^T M_{\text{red}} J_q$ and $J_q^T K_{\text{red}} J_q$ are of dimension $6$. It should be mentioned here that, in the case where an external load is applied at the end-effector only, the term $J_q^T K_{\text{red}} J_q$ is equal to the reduced stiffness matrix $K_r$ of the robot. Therefore, (13) can be rewritten as:

$$ \delta t^T (\omega_l^2 M_r - K_r) \delta t = 0 \quad (14) $$

In the following sections it is explained how to obtain expressions (12) and (14).

C. Reduction of the link mass matrix

It is possible to decompose the previously cited task into two sub-problems. First, the displacements of each spring in the beam $ij$ can be expressed as a function of the displacement of its extremities. Then, one can express the
beam extremity displacements as a function of the platform displacements \( \delta t \). Using this approach will allow for a reduction in the size of the link mass matrices, and thus avoiding creating global mass matrices \( \mathbf{M}_{\text{tot}} \) with very large dimension.

Two main ways can be followed to reduce the size of the link mass matrices. The first one consists in discretizing the link \( ij \) into \( p_{ij} \) rigid links and springs and to express their displacements as a function of the beam extremity displacements. However, such numerical method must be repeated for each link and, thus, increases the size of the algorithm and decreases its efficiency. As a result, it is preferred to use the following procedure which allows analytical expressions to be obtained for the reduced link mass matrices.

Let us consider the link \( ij \), modelled as a beam (Fig. 2). At this beam is attached a local frame represented by the vectors \( \mathbf{x}_{ij}, \mathbf{y}_{ij} \) and \( \mathbf{z}_{ij} \). Before any deformation of the system, the beam \( ij \) is linked (rigidly or by a passive joint) to beams \( i(j-1) \) and \( i(j+1) \) at points \( O_{ij} \) and \( O_{ij+1} \), respectively (Fig. 2). After deformation of the robot, the beam extremity located at \( O_{ij} \) is displaced from \( \mathbf{q}_{ij} = [q_{ij}^y, q_{ij}^z, \cdots, q_{ij}^y] \) and the one located at \( O_{ij+1} \) is displaced from \( \mathbf{q}_{ij+1} = [q_{ij+1}^y, q_{ij+1}^z, \cdots, q_{ij+1}^y] \), where the first three components of each vector correspond to the translational displacements along local \( \mathbf{x}_{ij}, \mathbf{y}_{ij} \) and \( \mathbf{z}_{ij} \) axes, respectively, and the last three components to the rotational displacements along the same axes.

The general formula for the kinetic energy of an elastic Bernoulli beam is equal to [14]:

\[
T_{ij} = \frac{1}{2} \int_0^{L_{ij}} \rho_{ij} \mathbf{\dot{q}}_{ij}^T \mathbf{Q}_{ij} \mathbf{\dot{q}}_{ij} dx
\]

with \( \mathbf{Q}_{ij} = \text{diag}(A_y, A_y, A_y, I_y^T, I_y^T) \). In this expression, \( \mathbf{q}_{ij} \) represents the velocity of the beam cross-section located at position \( x \) from the local reference frame (Fig. 2). \( L_{ij} \) is the length of the beam \( ij \), \( \rho_{ij} \) the mass density at cross-section \( x \), \( A_y \) its area, \( I_y^T \) its torsional constant and \( I_y^T \) the quadratic momentum along \( \mathbf{y}_{ij} \) and \( \mathbf{z}_{ij} \), respectively.

For the \( l \)-th natural mode, and from (7), the kinetic energy can be rewritten as:

\[
T_{ij} = \frac{1}{2} \omega_l^2 \cos^2 (\omega ot + \phi) \int_0^{L_{ij}} \rho_{ij} \mathbf{\dot{q}}_{ij}^T \mathbf{Q}_{ij} \mathbf{\dot{q}}_{ij} dx
\]

\( \mathbf{q}_{ij} \) being the amplitude of the displacement of the beam cross-section located at position \( x \) from the local reference frame (Fig. 2).

In the Rayleigh-Ritz approximation, considering that the deformations due to the natural vibrations are similar to those obtained when an external load is applied at the robot end-effector only, each link of the structure will deform due to the stresses transmitted through the robot joints at points \( O_{ij} \). As a result, the deformations \( \mathbf{\delta}_{ij} \) of the beam cross-section (Fig. 2) can be approximated by the deformations of a tip-loaded beam, given by [14]:

\[
\mathbf{\delta}_{ij} = \text{diag}(f_{ij}, g_{ij}, g_{ij}, f_{ij}, h_{ij}) \mathbf{\delta}_{ij}^2
\]

where \( \mathbf{\delta}_{ij}^2 = \mathbf{\delta}_{ij}(x = L_{ij}) \) represents the deformation of the beam at its tip and

\[
\begin{align*}
 f_{ij}(x) &= x / L_{ij}, \\
 g_{ij}(x) &= 0.5x^2 (3L_{ij} - x) / L_{ij}^3, \\
 h_{ij}(x) &= x (L_{ij} - 0.5x) / L_{ij}^2.
\end{align*}
\]

As a result, the global displacement \( \mathbf{q}_{ij} \) of the beam cross-section at \( x \) can be expressed as a sum of two terms:

\[
\mathbf{q}_{ij} = \left[ \begin{array}{c}
 I_3 \\
 \mathbf{D}_{ij} \\
 I_3
\end{array} \right] \mathbf{q}_{ij}^0 + \mathbf{\delta}_{ij} \text{ where } \mathbf{D}_{ij} = \left[ \begin{array}{c}
 0 \\
 0 \\
 -x
\end{array} \right]
\]

In this sum, the left terms corresponds to the displacement of the undeformed beam due to the displacement of the node located at \( O_{ij} \).

In the hypothesis that the beam cross-section is constant, introducing (17) and (19) into (16), and integrating, leads to:

\[
T_{ij} = \frac{1}{2} \omega_l^2 \cos^2 (\omega ot + \phi) \mathbf{\left[ \left( \mathbf{q}_{ij}^0 \right)^T \mathbf{\delta}_{ij}^2 \right]} \mathbf{\left[ \mathbf{M}_{ij} \mathbf{q}_{ij} \right]}
\]

where \( \mathbf{M}_{ij} = \left[ \begin{array}{c}
 \mathbf{M}_{ij}^1 \\
 \mathbf{M}_{ij}^2
\end{array} \right] \) with

\[
\begin{align*}
\mathbf{M}_{ij}^1 &= \left[ \begin{array}{c c c c c c c}
 m_{ij} / 2 & 0 & 0 & 0 & 0 & 0 \\
 m_{ij} & 0 & 0 & 0 & 0 & 0 \\
 0 & m_{ij} & 0 & 0 & 0 & 0 \\
 0 & 0 & m_{ij} & 0 & 0 & 0 \\
 0 & 0 & 0 & m_{ij} & 0 & 0 \\
 0 & 0 & 0 & 0 & m_{ij} / 2 & 0
\end{array} \right]
\end{align*}
\]

\[
\begin{align*}
\mathbf{M}_{ij}^2 &= \text{diag} \left[ \begin{array}{c c c c c c c}
 0 & 0 & 0 & 0 & 0 & 0 \\
 0 & 1 & 0 & 0 & 0 & 0 \\
 0 & 0 & 2 & 0 & 0 & 0 \\
 0 & 0 & 0 & 1 & 0 & 0 \\
 0 & 0 & 0 & 0 & 1 & 0 \\
 0 & 0 & 0 & 0 & 0 & 1
\end{array} \right] \left[ \begin{array}{c c c}
 \frac{3m_{ij}}{4} & \frac{3m_{ij}}{4} & \frac{3m_{ij}}{4} \\
 \frac{1}{140} & \frac{1}{140} & \frac{1}{140} \\
 \frac{1}{3} & \frac{1}{3} & \frac{1}{3}
\end{array} \right]
\end{align*}
\]

Fig. 2. Displacements and elastic deformations of a beam.
It should be mentioned that, in the case where the section of the beam is not constant, (18) to (21) are no more correct. In this case, the deformation of the beam and its kinetic energy should be obtained numerically. From (17), it can be shown that:

$$\delta_{ij} = q_{ij} - \left[ I_3 \ D_{(i,j)} \right] q_{ij}'',$$

which leads to:

$$\left[ \begin{array}{c} q_{ij} \\ \delta_{ij} \\ q_{ij}'' \end{array} \right] = \left[ \begin{array}{ccc} I_3 & 0 & 0 \\ 0 & 0 & I_3 \end{array} \right] \left[ \begin{array}{c} q_{ij} \\ \delta_{ij} \\ q_{ij}'' \end{array} \right] = \left[ \begin{array}{ccc} I_3 & D_{(i,j)} \end{array} \right] \left[ \begin{array}{c} q_{ij} \\ \delta_{ij} \\ q_{ij}'' \end{array} \right].$$

Introducing (23) into (20) leads to:

$$T_y = \frac{1}{2} \alpha \cos^2 (\omega t + \phi_y) \left[ q_{ij}'' \right] T_{ij} M_{ij} q_{ij}$$

Expressing vectors $q_{ij}''$ ($v = 1, 2$) in the base frame, (24) becomes:

$$T_y = \frac{1}{2} \alpha \cos^2 (\omega t + \phi_y) \left[ q_{ij}'' \right] T_{ij} M_{ij} q_{ij}$$

where $T_{red} = R_{yij} \left[ q_{ij}'' \right] T_{ij} M_{ij} q_{ij} \ R_{yij}$ and $R_{yij}$ is the rotation matrix from the local frame of beam $ij$ to the global frame, i.e.

$$\left[ \begin{array}{c} q_{ij}' \\ q_{ij}'' \end{array} \right] = R_{yij} \left[ \begin{array}{c} q_{ij}' \\ q_{ij}'' \end{array} \right].$$

To show the validity of the approach, let us compare the obtained equations when they are applied on a single beam fixed at one extremity $O_{1i}$, i.e. $q_{ii}' = 0$. For the numerical example, it is considered that this beam has the following characteristics:

- length $L = 1$ m
- hollow circular cross-section of external diameter 40 mm and internal diameter 30 mm
- material: steel (Young modulus $E = 204$ GPa, Poisson coefficient $\nu = 0.3$, density $\rho = 8020$ kg/m$^3$)

For such an element, beam theory gives the following expressions for the natural frequencies [17]:

- 1st natural frequency due to transverse displacements:
  $$f_y = \frac{3.516}{2\pi L^2} \sqrt{\frac{E I}{m}} = 35.28 \text{ Hz}$$

where $m$ is the mass of the beam and $F$ its quadratic momentum along $y$ axis.

- 2nd natural frequency due to longitudinal displacements:
  $$f_z = \sqrt{E/\rho} (4L) = 1260.86 \text{ Hz}$$

- 1st natural frequency due to torsional displacements:
  $$f_{\theta} = \frac{\sqrt{E G I}}{3m} (4L) = 781.95 \text{ Hz}$$

where $G$ is shear modulus, $E$ its quadratic momentum along $y$ axis and $F$ its torsional constant.

Applying the previously developed equations to this case by considering that the reduced mass matrix $M_r = M_{red}$ is given at (21c) and the stiffness matrix $K_r$ is expressed in [16] as:

$$K_r = \left[ \begin{array}{ccccc} ES & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -6EI'/L \\ 0 & 0 & 0 & 0 & GI''/L \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 4E'I''/L & 0 & 0 \end{array} \right],$$

it is found:

- 1st natural frequency due to transversal displacements: 35.78 Hz (error of 1.4%)
- 1st natural frequency due to longitudinal displacements: 1390.30 Hz (error of 10.27%)
- 1st natural frequency due to torsional displacements: 862.23 Hz (error of 10.27%)

As a conclusion, the proposed reduced model is accurate enough for the computation of the first natural frequency due to transversal displacements, which is also the first natural frequency of the beam. Let us now reduce the size of the total mass matrix of the robot.

D. Reduction of the robot mass matrix

Using the results of the previous section, the total kinetic energy of the system is given by:

$$T = \sum_{ij} T_y = \frac{1}{2} \alpha \cos^2 (\omega t + \phi_y) \sum_{ij} \left[ q_{ij}' \right] T_{ij} M_{ij} q_{ij}$$

with $M_{tot} = \text{diag}(M_{11}, M_{12}, \ldots, M_{nm})$ and

$$q_i' = \left[ q_{i1}', q_{i2}' \right] \ldots \left[ q_{im}', q_{im}' \right]$$

It is necessary to express the relationships linking all vectors $q_{ij}'$ ($v = 1, 2$) to the end-effector displacements $\delta t$. From [16], this displacement is equal to:

$$\delta t = J_0 \theta_i + J_{pi} p_i,$$

where $\theta_i$ represents the deformations of all virtual springs of the leg $i$ and $p_i$ the displacements of its passive joints, and $J_0$ and $J_{pi}$ are Jacobian matrices relying these displacements to the displacement $\delta t$. These matrices can be obtained by the differentiation of the global transformation matrix $T_i$ of the chain $i$ including rigid, passive and elastic coordinates [16]. The way to obtain these matrices is explained in more depth in the next section. It should be mentioned that the dimension of $J_{pi}$ is $6 \times m$, $m$ being the number of passive joints of the leg, with $m < 6$ (because one leg of a parallel robot cannot have more than five passive degrees of freedom (DOF)).

From [16], it can also be shown that:

$$\delta t = J_{0i} \theta_i + J_{pi} p_i$$
where $S_{ij}$ is a block-diagonal matrix regrouping all the compliance matrices of each virtual spring, and $f_i$ is the force applied on the $i$ that involves the displacement $\delta t$. The expression of $f_i$ is such as

$$f_i = K_i \delta t$$  \hspace{1cm} (32)

$K_i$ being the global stiffness matrix of the leg $i$. Introducing (32) into (31) leads to:

$$\left( I - J_{ni} S_{ij} J_{ij}^T K_i \right) \delta t = J_{pi} p_i.$$ \hspace{1cm} (33)

Therefore, the displacements $p_i$ of the robot passive joints due to the displacement $\delta t$ are equal to:

$$p_i = \left( J_{pi}^T J_{pi} \right)^{-1} J_{pi}^T \left( I - J_{ni} S_{ij} J_{ij}^T K_i \right) \delta t = J_{pi} \delta t.$$ \hspace{1cm} (34)

Let us now compute the displacements $\theta_i^2$ of the virtual spring located at the extremity of the link $ij$. This spring $ij$ is preceded by $j-1$ other virtual springs and passive joints. The deformations of the $j$ springs (including the one at the link extremity) will be denoted as $\theta_{ij}$, and the displacements of the $j-1$ passive joints $p_{ij}$, respectively. They can be related to the displacement $\theta_i^2$ by the Jacobian matrices $J_{ij}$ as

$$\theta_i^2 = J_{ij} \theta_{ij} + J_{pi} p_{ij}.$$ \hspace{1cm} (35)

These matrices may be computed in a similar way to the matrices $J_{ij}$ and $J_{pi}$, but by considering the truncated chain $i$ going from the base to the virtual spring $ij$. The deformations $\theta_{ij}$ involve constraints into the $j$ virtual springs of the truncated chain that are denoted as $\tau_{ij}$. Their expressions may be found from the relationship [16]:

$$S_{ij} \tau_{ij} = \theta_{ij},$$ \hspace{1cm} (36)

where $S_{ij}$ is a block-diagonal matrix regrouping all the compliance matrices of the $j$ virtual springs of the truncated chain. Introducing (34) into (33) leads to:

$$\theta_i^2 = J_{ij} \theta_{ij} + J_{pi} p_{ij}.$$ \hspace{1cm} (37)

Let us consider now the entire leg $i$ of the mechanism. The constraints $\tau_i$ applied to the springs due to the force $f_i$ applied on the platform are given by [16],

$$\tau_i = \begin{bmatrix} \tau_{ij} \\ \tau_{ip} \end{bmatrix} = J_{ij}^T f_i = \begin{bmatrix} J_{ij}^T \\ J_{pi}^T \end{bmatrix} f_i,$$ \hspace{1cm} (38)

where $J_{ij}$ corresponds to the $j$ first columns of matrix $J_i$. Introducing (38) into (37),

$$\theta_i^2 = J_{ij} \theta_{ij} + J_{pi} p_{ij}.$$ \hspace{1cm} (39)

Moreover, the passive displacements $p_{ij}$ are known from expression (32). Considering that $J_{pi}$ represents the matrix composed of the $j$ first lines of $J_{pi}$ given at (32), it follows that

$$\theta_i^2 = J_{ij} \theta_{ij} + J_{pi} p_{ij}.$$

Once all $\theta_i^2$ are found, the vectors $\theta_i^1$ can be computed. Indeed, displacement $\theta_i^2$ is nothing none than displacement $\theta_i^{(i-1)}$ plus the small deflection of the passive joint located at $O_j$, i.e.:

$$\theta_i^1 = \theta_i^2 + \delta p_i.$$ \hspace{1cm} (40)

where $\delta p_i$ is the value of the displacement of the passive joint located at $O_j$ and $\theta_i^2$ is a unit screw corresponding to its twist. Introducing (34) and (40) into (41):

$$\theta_i^1 = J_{ii} \delta t + \delta p_i J_{pp} \delta t = \begin{bmatrix} J_{ii}^1 \\ J_{pp}^1 \end{bmatrix} \delta t$$ \hspace{1cm} (42)

where $J_{pp}$ is the $j$-th line of matrix $J_{pp}$ given at (32).

Thus, from (40) and (42), one can express vector $q$ given at (29) as a function $\delta t$ as follows:

$$q = \begin{bmatrix} J_{ii}^1 \delta t \\ J_{ii}^2 \delta t \end{bmatrix} \delta t$$ \hspace{1cm} (43)

Introducing this relation into (29) will lead to:

$$T = \frac{1}{2} \alpha^2 \cos^2 (\omega t + \phi) \delta t^T M \delta t$$ \hspace{1cm} (44)

where the expression of $M$ is given at (14).

As a result, from (14), finding the robot natural frequencies relies on solving the 6 dimensional eigenvalues problem

$$\det \left( \alpha^2 I_6 - M \right) = 0.$$ \hspace{1cm} (45)

Let us now apply this method using an example.

### III. Case study

In this section, the example of the planar $P R R R P^2$ manipulator with two parallel prismatic axes (Fig. 3) will be treated. Let us first compute the global 3D stiffness matrix $K_i$ of the robot.

The method presented in [16] states that each leg may be decomposed into a sequence of rigid links and virtual 6-DOF springs, which includes:

- (a) a rigid link between the manipulator base and the $i$th actuating joint (part of the base platform);
- (b) a 1-DOF actuating joint allowing one translation $\rho_{io}$;
- (c) a rigid foot;
- (d) a 6-DOF virtual spring describing the foot stiffness;
- (e) a 1-DOF passive $R$-joint at the beginning of the leg allowing one rotation with angle $\rho_{ri}$;
- (f) a rigid leg linking the foot and the end-effector;
- (g) a 6-DOF virtual spring describing the leg stiffness;
- (h) a 1-DOF passive $R$-joint at the end of the leg 2 (not for leg 1) allowing one rotation with angle $\rho_{r2}$;
- (i) a rigid link from the manipulator leg to the end-effector (part of the movable platform).

From these assumptions, the matrix regrouping the stiffness matrices of all segments of the leg $i$ has the following form [16]:

$$K_{ri} = \begin{bmatrix} K_{foot}^i \\ \end{bmatrix}$$ \hspace{1cm} (46)

In the paper, $P$ stands for an actuated prismatic pair and $R$ for a passive revolute joint.
For obtaining matrices $J_{\theta}$ and $J_{\rho}$ of (31), let us now consider the corresponding mathematical expression defining the end-effector location subject to variations of all the above defined coordinates of a single kinematic chain $i$ may be written as follows:

$$
\begin{align*}
T^i &= T_{\text{Base}}^i V_a V_i^T \left( \rho_{10} \right) T_{\text{Foot}}^i V_s \left( \theta_{11}, ..., \theta_{16} \right) V_i^T \left( \rho_{11} \right) T_{\text{Leg}}^i \\
T^2 &= T_{\text{Base}}^2 V_a V_{i_2} V_i^T \left( \rho_{20} \right) T_{\text{Foot}}^2 V_s \left( \theta_{21}, ..., \theta_{26} \right) V_i^T \left( \rho_{21} \right) T_{\text{Leg}}^2 \\
&\cdot V_i \left( \theta_{221}, ..., \theta_{266} \right) V_{r_2} \left( \rho_{22} \right) T_{\text{Tool}}^2
\end{align*}
$$

where the matrix function $V_a ()$ is an elementary translation along $y$, the matrix functions $V_j()$ ($j = 1, 2$) are elementary rotations around $z$, the spring matrix $V_r ()$ is composed of six elementary transformations defined by the coordinates $(\theta_{ij}, ..., \theta_{ij})$ of the virtual joints $(i, j = 1, 2)$. Matrices $T_{\text{Base}}^i$, $T_{\text{Foot}}^i$ and $T_{\text{Leg}}^i$ represents the rigid displacements of the base, foot and leg, respectively [16] (Fig. 3).

The matrix $J_{\theta}$ may be obtained from the derivation of the matrix $T$ with respect to the spring parameters $\theta_{ij}$ ($\nu = 1$ to 6), at the point $\theta_{ij} = 0$, considering that

$$
\frac{\partial T^i}{\partial \theta_{ij}} = H^L_j \frac{\partial V_i}{\partial \theta_{ij}} \left( \theta_{ij} \right) H^R_j = \begin{bmatrix}
0 & -\phi'_{ix} & \phi'_{iy} & p'_{ix} \\
\phi'_{ix} & 0 & -\phi'_{iy} & p'_{iy} \\
-\phi'_{iy} & \phi'_{ix} & 0 & p'_{iz} \\
0 & 0 & 0 & 0
\end{bmatrix}
$$

where the first and the third multipliers are the constant homogenous matrices which do not include the displacement $\theta_{ij}$, and the second multiplier corresponds to the derivative of the elementary translation or rotation corresponding to $\theta_{ij}$. In the right-hand term, symbol “” denotes the first derivative of the variables with respect to $\theta_{ij}$. Therefore, $\phi'_{ix}$, $\phi'_{iy}$ and $p'_{ix}$ (resp. $\phi'_{ix}$, $\phi'_{iy}$ and $\phi'_{iz}$) correspond to the small translations along (resp. rotations about) $x$, $y$, and $z$ axes of the extremity of the leg $i$ due to the variation of the parameter $\theta_{ij}$.

The Jacobians $J_{\theta}$ can be computed in a similar manner, but the derivatives are evaluated in the neighborhood of the “nominal” values of the passive joint coordinates $\rho_{ij}$ corresponding to the rigid case (these values are obtained from the inverse kinematics).

Finally, the stiffness matrix $K_i$ of the leg $i$, which relates the deformations $\delta t$ to the force $f_i$ can be computed by direct inversion of relevant 7 by 7 (8 by 8 in the case of the leg 2) matrix in the left hand side of the following equation [16]

$$
\begin{bmatrix}
S_{\theta} & J_{\theta}
\end{bmatrix}
\begin{bmatrix}
f_i
\end{bmatrix} = \left[ \delta t \right], \quad S_{\rho} = J_{\rho} \left( K_i \right) J_{\rho}^T
$$

and by extracting the 6 by 6 sub-matrix with indices corresponding to $S_{\rho}$.

After the stiffness matrices $K_i$ for all kinematic chains are computed, the stiffness of the entire manipulator can be found by simple addition:

$$
K = \sum_{i=1}^{n} K_i.
$$

Using expressions (46) to (51), all relations of sections II.C and II.D can be computed. Let us now compare the results obtained by the presented procedure with a more general method.

For this simulation, each link is modelled as a beam of constant cross-section. The stiffness matrix expressions for beams are given in [16]. Then, the following numerical parameters are used:
- length of segments: $AB = AC = 0.5$ m, $a = 0.33$ m, $d = 0.1$ m;
- Young modulus: $E_{\text{foot}} = E_{\text{Leg}} = 210$ GPa; Poisson coefficients: $\nu_{\text{foot}} = \nu_{\text{Leg}} = 0.3$;
- Each beam has the same cross-section represented by a circle of radius 0.05 m;
- Material density: $\rho_{\text{foot}} = \rho_{\text{Leg}} = 7800$ kg/m$^3$.

Our model will be compared with one created using the FEA software Castem [19]. In the FEA model, all links are modelled using 3D beam finite elements (10 elements by beam). As for one fixed position along $x$ axis of the robot, the configuration is invariant for any position along $y$ axis, only the position along $x$ axis will vary. The results are presented in Table 1.

In this table, it is shown that, for our model, the value of the first natural frequency is obtained with at most 4% error. This is almost sufficient for using such algorithm in...
design procedure. Moreover, this percentage decreases to 0.9% for the second natural frequency. However, the value of the third frequency has quite a large percentage of uncertainty. Indeed, this is due to the fact that the displacements due to the two first frequencies are very close from the displacement of the robot when a load is applied at the end effector, which is not the case for the third frequency.

These results confirm the validity of our hypotheses and of our approach. It should be also mentioned that the Castem software computes the results in 0.09s while our approach takes 0.006 s, i.e. our procedure runs 15 times faster (for a Pentium 2.53 GHz, 4 Gb of RAM). Even if both computation times are very small in this example, in design optimization loops, for which thousands of possible configurations are tested, this saving of time is of the utmost importance.

IV. Conclusions

This paper has presented an approach for computing the first natural frequencies of parallel robots. The approach, based on the Rayleigh-Ritz approximation, aims at reducing the model dimension by decreasing the size of the matrices describing the robot mass and stiffness. This saves computational time, avoiding inaccuracy due to ill-conditioning and thus can be used in design procedure as well as in real-time control. Simulations have been carried out on a $PRRRP$ robot modelled in 3D and comparisons have been achieved with FEA software. The obtained results confirm the validity of the proposed procedure and shows that the algorithm runs 15 times faster than a classical FEA method.
