Abstract

Embryo production was reduced in female grass shrimp exposed to sediments with added coal fly ash and to sediments collected from an estuarine station containing high PAH concentrations due to its proximity to a highway storm drain. Grass shrimp embryos exposed to pore water from the high PAH and high metal sediments showed both reduced hatching and increases in DNA strand breaks (comet assay). Sediments with added coal fly ash had high concentrations of vanadium and selenium which may have contributed to effects similar to those observed with sediments with high PAH. The embryo pore water bioassay (hatching/ DNA strand breaks) gave results comparable to those observed for reproduction effects (reduced embryo production/embryo hatching) with female grass shrimp exposed to whole sediment.

Grass shrimp are an important component of the estuarine food web in the southeast United States. Grass shrimp embryos, enclosed in egg sacs, go through 10 stages while attached to the female pleopods. After stage 10 a free swimming zoea emerges from the egg sac. Several DNA lesions (e.g. strand breaks, modified bases, DNA-DNA crosslinks, DNA-protein crosslinks) are produced after exposure to genotoxicants, e.g. metals and PAHs. Reduced embryo production observed when grass shrimp are exposed to metals and PAHs (Lee et al., 2004) may be linked to damaged DNA. In the present study comparisons were made between reproduction processes in grass shrimp exposed to sediments containing coal combustion residues or highway runoff and hatching rates/ DNA strand breaks (comet assay) in embryos exposed to pore water from these sediments.

Sediments were collected from three stations in an estuary in Hilton Head, South Carolina (USA): station A – next to a highway storm drain; station B -100 m away from the drain; station C – 500m away from the drain. For coal fly ash exposure experiments, 400 g of coal fly ash from power plants in Augusta, GA (USA) or from Candiota, Rio Grande do Sul (Brazil) was blended with 2000 g of reference sediment. Coal ash is one of the residues from coal combustion and is composed primarily of metal oxides. Reference

sediment was from the Skidaway River estuary (Savannah, GA) (USA). Pore water was collected by centrifugation of sediments at 1000 X g for 30 min. Sediments to be analyzed for PAHs in sediment were freeze dried, extracted with methylene chloride and extracts passed through a silica gel column. The PAH fractions from the silica gel column were analyzed with a Hewlett Packard 6890 Series Plus Gas Chromatography coupled to a 5973 mass spectrometer. Twenty three individual PAH analytes were quantified with a detection limit of 10 ng/g for each analyte. Metals (V, Cr, Mn, Ni, Cu, Zn, As, Se, Ag, Cd, Pb) in sediment pore water samples were determined by ICP-MS (Fison Plasma Quad II Plus) equipped with a nebulizer. To determine reproductive parameters, 20 juvenile grass shrimp were added to aquaria contain 700 g of test sediment and 40 l of seawater. Three aquaria were used for each station or experiment (n=3). Salinity of the water was 28 ppt and temperature was maintained at 27°C. Shrimp were fed *Artemia* and kept under 12 h light/12 h dark regime. Every 5 days the following parameters were determined: (a) mortality; (b) number of females with mature ovaries; (c) number of females with attached embryos. Grass shrimp were exposed to test sediments for 60 days with no change of seawater. Embryo hatching rates were determined after transferring 25 stage 8 embryos to polystyrene plates with each well containing 1.2 ml of estuarine water and 1 embryo. For pore water bioassays, 0.1 ml of sediment pore water was added to 1.1ml of filtered estuarine water in a polystyrene plate with each well containing one stage 8 embryo (25 embryos per test) and hatching rates determined. For assessment of DNA strand breaks, the comet assay was carried out on stage 7 embryos exposed to sediment pore water (diluted 1:10 with filtered estuarine water) for 24 h. The comet assay followed the procedures described by Singh et al., (1988) with modifications described

by Lee and Kim (2002). A computerized image-analysis system (Komet Version 4.01, Kinetic Imaging Ltd.) was used to determine % DNA in tail of fifty randomly selected cells per slide.

At different distances from the highway storm drain, total PAH concentrations (sum of 24 analytes) were 29, 1.5 and 0.1 $\mu\text{g/g}$ sediment for stations A, B, and C, respectively (Table 1). Concentrations of the different PAH analytes in these stations were previously reported (Lee et al., 2004). In the coal fly ash experiment, the concentrations of vanadium and selenium in sediment pore water are reported (Table 1) since the concentrations of these metals in coal fly ash sediment pore water (V: 129-278 $\mu\text{g/l}$; Se: 115-256 $\mu\text{g/l}$) was much higher than their concentrations in reference sediment pore water (V: 1-2 $\mu\text{g/l}$; Se: 0.04-0.1 $\mu\text{g/l}$). High selenium concentrations were found in sediment pore water near a coal-fired power station (Jung and Batley, 2004). Grass shrimp exposed to coal combustion residues has increased DNA strand breaks and had accumulated selenium (Kuzmick et al., 2007). Embryos exposed to pore water from sediment close to a highway storm drain (station A) showed significant ($p < 0.05$) difference with respect DNA strand breaks (38% DNA in tail) and reduction in embryo hatching (35%) when compared with embryos exposed to sediments distant from the storm drain (Stations B and C) (Table 1). Embryos exposed to sediment with coal fly ash had reduced hatching (25-35%) and increased DNA strand breaks (38-41% DNA in tail) compared to controls. Zoea that emerged died within a few hours. Female grass shrimp exposed to highway runoff sediment and coal fly ash sediment, showed significant reduction in embryo production and embryo hatching (Table 2) compared to females exposed to reference sediment.
