HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
This is a preliminary PDF of the author-produced manuscript that has been peer-reviewed and accepted for publication. Since it is being posted so soon after acceptance, it has not yet been copyedited, formatted, or processed by AMS Publications. This preliminary version of the manuscript may be downloaded, distributed, and cited, but please be aware that there will be visual differences and possibly some content differences between this version and the final published version.

The DOI for this manuscript is doi: 10.1175/2008JTECHA1218.1

The final published version of this manuscript will replace the preliminary version at the above DOI once it is available.
A microdrop generator for the calibration of a water vapor isotope ratio spectrometer

Abstract

A microdrop generator is described to produce water vapor with a known isotopic composition and volume mixing ratio for the calibration of a near-infrared diode laser water isotope ratio spectrometer. The spectrometer is designed to measure in-situ the water vapor deuterium and oxygen ($^{17}$O and $^{18}$O) isotope ratios from the low troposphere up to the lower stratosphere with a high temporal resolution, and is based on ultra-sensitive optical-feedback cavity enhanced absorption spectroscopy.

To calibrate the spectrometer, a commercial microdrop generator (Microdrop GmbH) is used to inject water droplets of known size at a preset repetition frequency into a stream of dry nitrogen or synthetic air. Complete evaporation of the small droplets assures that there is no isotopic fractionation between the liquid phase and the generated moist “air”. The water mixing ratio of the synthetic air is controlled by the repetition rate and gas flow. The current system spans a water mixing ratio range from about 10 to 5,000 ppmv, representing the range of conditions expected in the low to upper troposphere. Both lower and higher mixing ratios can be produced after small modifications to the injector operating conditions or the system design.
1. Introduction

Water vapor is a key element in the global climate, as it is the most active greenhouse gas. In the troposphere, water is responsible for the global movement of latent heat and it affects cloud cover, which controls radiation and cooling rates. In the stratosphere, water vapor affects ozone levels through its involvement in the production of odd-hydrogen and the formation of stratospheric clouds (Kirk-Davidoff et al., 1999; Forster and Shine, 2002). In-situ measurements of isotope ratios in atmospheric moisture are believed to be vital to the study of these phenomena. (Moyer et al., 1996; Keith, 2000; Schmidt et al., 2005; Toon et al., 2003).

Lower in the troposphere the study of the hydrological cycle provides important contributions to our understanding of the global carbon budget, as the hydrological and carbon cycles are linked through the exchange of oxygen atoms in the ecosystem (Yakir and da S.L. Sternberg, 2000; Wang and Yakir, 2000). Isotope measurements directly on the vapor compartment of the hydrological cycle represent also the missing link in the validation of global circulation modeling efforts. Currently such models are not able to correctly describe the isotopic composition of precipitation in polar regions, and in fact do not agree with each other (Hoffmann et al., 2000; Werner and Heimann, 2002; Helsen et al., 2004). Still, such models are supposed to put the use of ice-core isotope data as a temperature proxy on a firm physical basis.

The usefulness of water isotopologues stems from the fact that the isotopologues of a molecule such as $\text{H}_2\text{O}$ exhibit small differences in their physical and chemical behavior, resulting in isotope fractionation during physical, chemical and biological processes. Thus, abundance ratios of the stable water isotopologues provide an additional mass-balance
equation and give information on the history of an air parcel, which may, for example, be used to help understand the transport of water from the troposphere to the stratosphere. In ecological studies, the strong feedback of vegetation to the atmosphere results in considerable differences in isotopic composition between the highly depleted soil and enriched leaf water. These large differences are the basis for separating the two ecosystem water flux components of transpiration and evaporation (Yepez et al., 2003; Williams et al., 2004).

The isotopic composition is reported in the “δ” notation, giving the enrichment (most commonly expressed in per mil, denoted by ‰) relative to a reference material:

$$\delta = \left( \frac{R_{sample}}{R_{reference}} - 1 \right)$$  \hspace{1cm} (1)

Here, $R$ represents the ratio of the rare to the abundant isotope in the sample or the reference material. The international standard reference material used for the measurements of $^2$H and $^{18}$O in water is VSMOW (Vienna Standard Mean Ocean Water), which therefore by definition has $\delta^2$H, $\delta^{17}$O, and $\delta^{18}$O values equal to zero. If $\delta$ is positive the sample is "enriched", whereas if $\delta$ is negative the sample is said to be "depleted" relative to the standard.

Unfortunately, atmospheric water vapor and its isotopic composition are extremely difficult to measure for a variety of reasons, including:

i. Water vapor in the atmosphere is characterized by the fact that its concentration spans a range of over four orders of magnitude. Water vapor levels decrease from around 20,000 ppm at ground level to about 5 ppm at high altitudes (in the lower stratosphere).
ii. The high affinity of water for instrument surfaces: water vapor adsorbs on nearly all surfaces with an associated isotopic fractionation. This serious problem can potentially cause significant systematic errors in the determination of the water vapor isotope ratios, as well as concentration, especially at very low concentration.

iii. The high variability on short spatial and temporal scales. The temporal and spatial distribution of water vapor is complex and local because its spatial distribution is often strongly related to temperature (Pielke, 2001).

iv. In addition, carrying out measurements in the higher troposphere and lower stratosphere means working in a harsh environment where temperature and pressure are low with obvious consequences for the thermal design of the instrument (with the balloon or aircraft platform presenting its own specific difficulties).

Isotope measurements are usually carried out by Isotope Ratio Mass Spectrometry (IRMS). The IRMS technology has achieved high levels of precision. The main drawback, however, is that IRMS is incompatible with condensable gases, and in particular with a sticky molecule like water. Sample preparation in this case is complicated, requiring that the isotope ratios of interest be transferred to another molecule, for example, by reduction of water to H\(_2\) for the determination of \(\delta^2H\) and equilibration of water and carbon dioxide for the determination of \(\delta^{18}O\) (Kerstel, 2004; Kerstel and Meijer, 2005). But in this case, a direct measurement of the \(\delta^{17}O\) isotope ratio is difficult due to mass overlap with \(^{13}\text{CO}_2\). An alternative mass spectrometric technique, in which water is reacted with cobalt fluoride to produce molecular oxygen gas, was described by Baker et al. (2002).

Moreover, IRMS instruments are voluminous and heavy, and for this reason alone not suitable for in-situ measurements. A possible solution would be the use of a cryogenic sampling device to collect samples, in combination with a laboratory based isotope analysis
by IRMS (or a laser-based technique). For tropospheric and ecological measurements such an
approach has been used by Helliker et al. (2002) and West et al. (2006), respectively.
Franz and Röckmann (2004) have shown that this approach can be successful, if executed
with extreme care, even for studies at very low water mixing ratio, such as encountered high
in the troposphere and in the lower stratosphere. They modified a continuous flow IRMS
system to be able to analyze liquid water samples as small as 120 nL. The precision reported
is 7‰, 0.7‰, and 1.3‰ for δ²H, δ¹⁷O, and δ¹⁸O, respectively. This system was subsequently
used to analyze lower stratospheric air samples collected in small (~150 mL) cryogenic traps
for δ¹⁷O and δ¹⁸O (Franz and Röckmann, 2005). Although the precision on the oxygen
measurements is 3-4‰, the errors of the individual samples are correlated, resulting in
measurement errors as low as 0.3‰ for the Δ¹⁷O-anomaly (=δ¹⁸O-0.528⋅δ¹⁷O). Still, such an
approach is complex and carries a high risk of failure, and, more principally, offers a poor
temporal and spatial resolution.

Recent advantages in the laser field have improved in-situ measurements of atmospheric trace
gases, as alternative to more conventional methods. Semiconductor lasers enable the
development of compact, stable and reliable spectrometers. Diode-laser spectrometry offers
several advantages over mass spectroscopy for precise in-situ measurements at low
concentrations. The measurements are simple, direct, and do not require appropriate sample
preparations, although calibration with standard gases remains necessary.

In 2003, we developed a compact diode-laser spectrometer, named Groningen-Grenoble
Water Isotope Spectrometer (G2WIS), for in-situ measurement of stratospheric water isotope
ratios. The technique used is Optical Feedback Cavity Enhanced Absorption Spectroscopy
(OF-CEAS) (Morville et al., 2004, 2005; Kerstel et al., 2006), which is in essence a variation
on the technique of Cavity Ring Down Spectroscopy (CRDS) (for a review see: Berden et al., 2000 or Mazurenka et al., 2005), enabling the realization of very long effective absorption path lengths (~6 km) with a very compact optical arrangement.

In May 2004, this device participated in an engineering test flight on board of the NASA DC-8 research aircraft, in Dryden, California. Data was collected at altitudes from 300 m above ground up to 12.5 km. The device performed well during these flights, showing precision levels of 9‰, 3‰, and 1‰, for $\delta^2\text{H}$, $\delta^{17}\text{O}$, and $\delta^{18}\text{O}$, respectively, for 10-sec averaged data obtained during level flight, where the measured water mixing ratio was of the order of 1000 ppmv.

A new version of the spectrometer was built for integration on the M55 Geophysica stratospheric airplane. The device is compact and power efficient (50 kg and 150 W, respectively, including pump and all electronics). This version of the spectrometer was named IRIS (water Isotope Ratio Infrared Spectrometer), and participated in the European AMMA (African Monsoon Multidisciplinary Analysis) campaign out of Ouagadougou, Burkina Faso, in the summer of 2006 (Iannone et al., 2009).

The great interest in the application of the water vapor stable isotopes $^2\text{H}$ and $^{18}\text{O}$ has also led to the development of laser-based isotope ratio spectrometers by a number of other academic groups, as well as commercial developments by different companies.

Recently, in-situ measurements of the isotopic content of water vapor in the upper troposphere and lower stratosphere onboard the NASA WB-57 aircraft platform were performed by Hanisco and colleagues (2007). Their mid-IR spectrometer is based on the technique of Off-Axis Cavity Enhanced Absorption Spectroscopy (OA-CEAS), better known
as Off-Axis Integrated Cavity Output Spectroscopy (OA-ICOS), and uses a cryogenically cooled mid-infrared quantum cascade laser (QCL). The size and volume alone would make this spectrometer not suitable for more wide-spread application to tropospheric measurements.

Lee et al. (2005) carried out ground-based continuous measurements of δ¹⁸O in atmospheric water vapor, in New Haven, Connecticut (USA), using a commercial tunable diode laser gas analyzer (Campbell Scientific) based on direct absorption spectroscopy with a cryogenically cooled lead-salt diode laser.

Two other companies developed water vapor isotope analyzers, both using a high-finesse optical cavity to increase the sensitivity, while using a near-infrared laser source that operates in the spectral region near 1.39 μm, as used in our instrument (Picarro 2008; Los Gatos 2008).

All water vapor isotope ratio analyzers mentioned here above require an accurately performed calibration, irrespective of the exact methodology used. Gas analyzers need, in fact, to be periodically calibrated to ensure system integrity and sensor accuracy. In case of concentration only measurements, span calibration can be performed, which involves the measurement of a gas mixture at a number of known concentration levels (Werle et al., 2005), whereas for isotope ratio determination, it is necessary to use a series of samples with different, but well-known, isotopic composition (Kerstel, 2004; Kerstel and Gianfrani, 2008, and references therein). It may be necessary to repeat this procedure at different water mixing ratios, if the spectrometer is to be used over an extended range of mixing ratios, as it can in general not be taken for granted that the spectrometer calibration is independent of the water concentration. This is, for example, demonstrated in the work on liquid water samples by Kerstel et al. (1999) and Lis et al., (2008). In both cases, this behavior is principally due to unequal sample mass, and thus unequal total pressure, in the gas cell(s) during the sample and
Iannone et al., A microdrop generator for the calibration of...

the reference measurement, in combination with a data analysis procedure that fails (in fact, was not designed) to retrieve the true area of the spectral absorption profile, and therewith the isotopologue number density. Kerstel et al. (1999) showed that the differential pressure induced apparent isotope shift could be adequately modeled by taking the details of their data analysis procedure into account. However, the measurements on atmospheric moisture by Lee et al. (2005) were carried out at constant pressure, but still show a dependence of the isotope determination on the water mixing ratio. In this case, the most likely explanation is a non-linear response of the detector, an improper accounting for the detector dark-current, or systematic errors made in the determination of the spectral background. The problem was addressed by dynamically adjusting the volume mixing ratio of the reference vapor stream to bring the absorption signals on the reference measurement at the same level as those of the sample (i.e., outside atmospheric air) measurement (Lee et al., 2005).

Up to now, the standard method to calibrate a water vapor isotope or concentration analyzer relied on the production, by means of a dew point generator, of a moist air stream whose vapor content is determined by thermodynamic equilibrium conditions, and for which the isotope ratios are assumed to follow the Rayleigh distillation model. This method is described by Franz and Röckmann (2005) and by Lee et al. (2005), who both used a (commercial) dew point generator as a Rayleigh distillation device. The dew point generator is able to produce a stable water vapor mixing ratio by saturating dry nitrogen or air at a well-known and stable temperature and pressure. The dew point generator reservoir is first flushed several times, and then filled with water of known isotopic composition. Dry air is bubbled through the temperature stabilized reservoir of the dew point generator, and the moist stream coming out of the device is sent to the spectrometer. The isotopic composition of the vapor is related to that of the liquid in the reservoir through generally well-known, but
temperature dependent, isotope fractionation factors. Since the liquid water in the reservoir of
the dew point generator becomes progressively enriched in the heavier isotopes, the vapor
will not show a constant isotopic composition over time, but will also become increasingly
heavier. This approach, therefore, requires knowledge of the thermodynamic equilibrium and
known isotope fractionation factors, as well as a determination of the (change in) isotopic
composition of the water in the reservoir. Using a dew point generator, it is not practically
feasible to rapidly change between standard waters of different isotopic compositions, and, in
view of the relatively large quantities of water involved, using water samples with different
isotopic compositions can become expensive, and is in any case not practical for field
applications.

Therefore, Lee et al. (2005) also used a dripper device, in order to generate a reference stream
with known isotopic composition. In this case the vapor was generated using a syringe pump,
which was programmed to dispense the liquid at a precise rate into a flask flushed with dry
air. As long as the water released evaporates completely, there will be no isotopic
fractionation between the supplied liquid phase and the generated moist stream.

Both methods described above, the dew point generator and the dripper device, have in
common that they can produce air streams with high water mixing ratios typical of
tropospheric conditions, but require mixing of the air stream with a secondary dry air stream
to reach the low mixing ratios typical of the upper troposphere and lower stratosphere. The
lowest water mixing ratio achieved by Lee et al., using the dew point generator without
subsequent mixing with dry air, was ~2,500 ppm, whereas the dripper device was able to
produce water mixing ratios from 800 ppm up to 30,000 ppm (Lee et al., 2005).
The aim of this paper is to describe a novel approach to produce a moist air stream with a calibrated water mixing ratio and of known isotopic composition that spans practically the entire range encountered in the upper and lower troposphere.

A similar approach has been employed by St. Clair (2008) to calibrate the measurements of H$_2$O and HDO in the upper troposphere and lower stratosphere, using Hoxotope, an instrument based on a combination of photolysis and laser induced fluorescence (LIF). Unlike our instrument, Hoxotope has been exposed to a very small span of mixing ratios (200 ppmv).

To demonstrate the device, we report the results of the laboratory characterization of an OF-CEAS spectrometer (G2WIS), developed in our laboratories for the airborne measurement of water vapor isotopes in the lower atmosphere.

2 Experimental

Our approach consists of using a commercial, piezoelectric droplet generator, hereafter referred to as microdrop generator or, even shorter, injector, to inject water droplets of predetermined (sub-nanoliter) volume at a preset repetition frequency into a stream of dry nitrogen or dry synthetic air. The injector’s micro-dispenser technology is based on the same principle as inkjet printer nozzle technology (de Gans and Schubert, 2003; Meinhart and Zhang, 2000). The ejected fluid volume in these devices depends mainly on the geometrical dimensions of the nozzle and is influenced by liquid properties like surface tension and viscosity, as we will see later. The water volume mixing ratio of the generated moist air stream is most easily controlled by changing the repetition frequency of the injector. The range of mixing ratios that can be reached is further determined by the mass flow rate of the carrier gas. Here we use the injector to produce water mixing ratios over almost three orders of magnitude, from 12 to 7,600 ppm. The water isotopic composition of the moist stream is
equal to that of the liquid sample supplied to the injector, since the small size of the droplets assures their complete evaporation. This is a major advantage, especially compared to the case of the dew point generator.

2.1 The microdrop generator

The injector (Microdrop GmbH, model MD-K-130) consists of a glass capillary, with a 30 µm diameter nozzle at the end, surrounded by a piezo ceramic tube. A voltage pulse applied to the piezoelectric element produces a shockwave in the fluid contained inside the glass capillary, forcing single droplets to be ejected from the nozzle with a well reproducible volume (< 1% variation under constant operating conditions (Lee 2002)) and with a velocity of approximately 2 m/s. In order to observe the droplets, an external CCD camera and a light emitting diode (LED) are used. When the stroboscopic light pulses, emitted by the LED, are in resonance with the injector driving frequency, the falling droplet can be “frozen” on the CCD camera screen.

Figure 1 shows four sequences in the water droplet formation and ejection from the nozzle. In the first frame, the fluid is propelled towards the orifice. Subsequently, the fluid is pulled-back. Break-up of the fluid column generates a small micro-drop that is ejected from the nozzle. The droplet formation is viewed at different times using a variable delay between the driving pulse and the strobe flash. As the delay is increased, the effect is to produce a slow-motion picture of the formation of the droplet.

The injector’s glass capillary is connected to the water reservoir through a polytetrafluorethylene (PFTE) tube. The micro dispenser injector is located in a small aluminum housing, 40 mm wide and 40 mm height. The droplets can travel up to 5 mm from the injector nozzle before hitting the bottom of the housing.
In order to generate the droplet, the liquid column inside the glass capillary of the injector must gain sufficient inertia momentum to surmount the effects due to the surface tension and viscous forces. The Reynolds number is the relevant parameter here, giving the ratio of the inertial drag force to the viscous drag force. In our case, with water as the working fluid, and assuming a temperature of 20°C, a velocity of 2 m/s, dynamic viscosity $\eta$ of $10^{-3}$ kg $\cdot$ m$^{-1}$$\cdot$s$^{-1}$ ($=1$ mPa $\cdot$ s), density of 998 kg/m$^3$, and finally a nozzle diameter of 30 μm, the Reynolds number is about 60. This is sufficiently low that the flow inside the injector nozzle is laminar (Squires and Quake, 2005). Under these conditions the droplet size is determined principally by the nozzle size, but may vary with the liquid viscosity, the exact details of the pulse train applied to the piezoelectric actuator, and the pressure differential over the injector capillary and nozzle (E. R. Lee, 2002). For a detailed description of the physics of the microdrop generator we refer to Lee (2002).

A droplet mass of 49.6±0.2 ng (corresponding to a volume of 49.7 pL) was determined experimentally by collecting the amount of water produced by the injector over a 3-hour period when driven at 400 Hz in a small flask. The droplet mass is then determined by dividing the difference of final and initial mass of the flask by the product of repetition frequency and measurement time.

This result compares well to the 48 pL specified by the manufacturer, based on a measured diameter of 45 μm and the assumption of a spherical droplet.

A limitation of the injector system, in its present configuration, is that, at a flow rate of 150 mL/min, the generated water mixing ratio should not exceed ~3,500 ppmv by much. Above this value, the droplets no longer evaporate completely before hitting the bottom of the injector housing. Permanent wetting of the inside of the injection chamber now occurs, which
was verified by observing the bottom of the injection chamber with the CCD camera. This is
accompanied by isotope fractionation of the water sample and a slow time-response.

Figure 2 represents a diagram of the gas handling system used to perform the measurements
of the water vapor isotopes, generated by the injector. A high-pressure tank of dry nitrogen is
equipped with a standard pressure regulator, which brings the pressure down to about 3 bars.
Although the certified amount of water is < 5 ppm, the actual concentration is more likely less
than ~1 ppm (see below, paragraph 3.1). Therefore, no effort was made to further dry the
nitrogen. For high-precision isotope measurements at the lowest water concentrations, further
drying of the nitrogen gas is recommended. Subsequently, a pressure controller (Combo, model PR50A15Z1) regulates the pressure in the gas line to approximately 30 mbar above
ambient pressure, in order to avoid water leaking from the injector nozzle. Control of the
differential pressure is also important in assuring a constant performance of the injector in
terms of droplet size (E.R. Lee, 2002). The dry air stream then enters into and out of the
injection chamber through 4.5 mm inner diameter tubes. The injection chamber itself
measures ca. 12 mm in diameter and 6 mm in height. With this height the droplets can travel
~5 mm before hitting the bottom.

The CCD camera axis of view is perpendicular to the plane of the drawing. The moist air
stream, passing a flow meter, is led to the infrared water isotope spectrometer. The gas lines
are made of hydrophobically coated (Restek Corp.) stainless steel tubing.

Measurements with the injector were performed on three local water standards, GS-22, GS-48
and GS-50, whose isotopic compositions are very well known through repeated IRMS
analyses at our institute. The GS-48 standard has an isotopic composition of (-43.3±0.3)‰ for
$\delta^2$H and (-6.52±0.03)‰ for $\delta^{18}$O, while the GS-50 standard has a value of (-276.7±0.3)‰ and
(-35.01±0.03)‰ for $\delta^2$H and $\delta^{18}$O, respectively. At (-113.5±0.3)‰ and (-15.29±0.03)‰ for
δ²H and δ¹⁸O, respectively, the isotopic composition of GS-22 is between those of GS-48 and GS-50. All values are with respect to the international VSMOW-SLAP scale (Gonfiantini, 1984). For all three local water standards, the ¹⁷O isotope ratio was independently measured and found to follow mass dependent fractionation within the measurement uncertainty (Meijer and Li, 1998).

Two microdroplet generators were employed, one for GS-48, the other for GS-22 and GS-50, enabling a more rapid switching between the reference materials.

2.2 Infrared laser spectrometric water vapor measurements

The moist air streams produced with the microdrop generator were analyzed for their water isotopic composition using the G2WIS infrared laser based spectrometer. The absorption technique exploited here is based on a high-finesse optical cavity in which the light intensity transmitted at the cavity resonances is measured, as a narrowband laser is swept across them. A distinguishing feature of the technique is the use of optical feedback to a semiconductor laser (hence OF-CEAS), in order to significantly improve the intensity and stability of the transmitted light (Morville et al., 2005). From time to time (at least once per spectral scan in an automated procedure) the decay rate of photons inside the cavity is measured in order to normalize the absorption scale (Kerstel et al., 2006). This periodic determination of the cavity ring down time, in combination with an equidistant frequency scale determined by the cavity free spectral range, assures a highly accurate measurement of the absorption coefficients used to evaluate the volume mixing ratio and the isotope ratios.

The laser spectrometer scans between selected H₂¹⁶O, ²H¹⁶O¹H, H₂¹⁷O, and H₂¹⁸O absorption lines to provide nearly simultaneous detection of their absorption coefficients. Data are acquired at a rate of ~10 spectra per second, but usually averaged over longer periods to improve the signal-to-noise ratio. Dicke-narrowed Voigt line shapes, using the Rautian hard-
collision model (Rautian and Sobel’man, 1967), were fit to all spectral features to retrieve the
areas associated with the individual spectral lines, and thus indirectly the isotopologue
number densities.

The principle of laser spectroscopy depends on the fact that the amount of light absorbed by a
sample is related to the concentration of the gas species present in the sample. The Lambert-
Beer law relates the incident light intensity $I_0$ to the transmitted light intensity $I$:

$$I = I_0 e^{-\alpha(\lambda)l}$$

(2)

where $\alpha$ is the absorption coefficient of the sample at the wavelength $\lambda$, and $l$ is absorption
path length. The wavelength dependent absorption coefficient $\alpha$ can be written as:

$$\alpha(\nu) = n(p,T) \cdot g(p,T, \nu - \nu_0) \cdot S(T)$$

(3)

Where $n$ is the number density of the absorbing species, $g$ is the normalized line shape
function, $\nu_0$ is the center frequency of the absorption feature, $S$ is the corresponding line
strength, and $p$ and $T$ are the total pressure and the temperature of the sample, respectively.

Evaluation of Eq. (3) requires quantitative knowledge of the exact line shape function. Since
the line shape function is normalized to unity, integration of the absorption feature removes
the dependence on the pressure of the line shape function $g$ (Eq. 3). The line strengths for the
rotational-vibrational transitions used by our spectrometer are taken from the HITRAN (High
Resolution TRANsmission) database (Rothman et al., 2005). It should be noted that the line
strengths reported by HITRAN for the isotopic species take their natural abundance already
into account.
The number density of the absorbing molecules is then related to the total pressure of the sample inside the spectrometer, assuming an ideal gas, in the following way:

\[ n = \nu \frac{p}{kT} \]  

where \( k \) is the Boltzmann constant and \( \nu \) the volume mixing ratio. The latter is thus determined by a measurement of the absorption coefficient at known pressure and temperature.

The isotope ratio ("delta-value") instead is given by the super-ratio of the absorption coefficients of the rare and abundant isotopologues in the sample and a reference material. For example, in the case of oxygen-18 (Kerstel, 2004):

\[ \delta^{18}O = \left( \frac{\alpha^{18}_{\text{sample}} / \alpha^{18}_{\text{reference}}}{\alpha^{16}_{\text{sample}} / \alpha^{16}_{\text{reference}}} \right) - 1 \]  

In practice, the absorption coefficients of the rare and abundant isotopic species are determined almost simultaneously in the same gas, and thus also at the same temperature. However, there may be a small temperature difference between the sample and the reference spectral recordings. It is then easy to show that the isotope ratio of Eq. (5) is independent of the absolute temperature, but sensitive to the temperature differential between the sample and reference recordings (Kerstel, 2004). For this reason, the spectrometer is actively temperature controlled.

---

1 The laser spectroscopic method determines molecular isotope ratios. It can be shown that these are practically equal to the more usual atomic isotope ratios, also for the case of \( \delta^2\text{H} \) (see Appendix I in Kerstel, 2004).
stabilized to about 32 °C to within about 0.2 °C. Considering the temperature coefficients of
the absorption lines in question (Kerstel et al., 2002), this reduces any temperature related
isotope ratio error to less than 0.2‰ for δ^{18}O and 1.6‰ for δ^{2}H.

The pressure controller at the entrance of the spectrometer actively stabilizes the pressure
inside the spectrometer gas cell to a set value in the range of 0 to 200 mbar. A needle valve at
the exit of the gas cell controls the flow rate. Data presented here have been obtained at three
different pressure settings of 40, 100, and 160 mbar and three different flow rates of 150, 300,
and 600 mL/min at standard temperature and pressure (STP).

3 Experimental results

3.1 Microdrop generator linearity of response

The linearity of the instrument was evaluated by exposing the optical spectrometer to several
water mixing ratio levels, starting from low humidity conditions and then stepping the
concentration up through a series of fixed levels, by increasing the droplet repetition
frequency, as shown in Figure 3a. The measurements were carried out with a flow of 150 STP
mL/min. The time resolution in the figure is 1 s (i.e., circa 10 spectral scans were averaged to
produce one data point in the figure). Each concentration level was maintained for at least half
an hour before stepping to the next.

Figure 3b shows, instead, two transitions where the water vapor mixing ratio decreases from
1,400 to ~335 ppm, and subsequently further down to 60 ppm. From these measurements the
(single) exponential time constants were determined to be 5.4 (±0.3) sec and 5.7 (±0.2) sec,
respectively. These time constants are not very different from those determined previously for
the spectrometer only (~3 s) (Kerstel et al., 2006), and correspond approximately to the time
needed to exchange the gas in the spectrometer cavity, the injector assembly, and the tubing
between them (total volume ~20 mL), at the current low flow through the cell (150 mL/min STP).

The last 15 minutes of data belonging to Figure 3a at each water vapor concentration level were used to determine an averaged mixing ratio value. These averaged instrument readings are shown in Figure 4 versus the output of the microdrop water vapor system as calculated from the drop size and repetition frequency, and the flow conditions in the injector. The microdrop generator performed very well, showing a high stability and reproducibility. However, above a concentration of about 3,500 ppm, the evaporation of the water droplets is not complete and steady-state wetting of the bottom of the injection chamber is observed. This is most evident from the increasing time needed to reach the next stable water concentration level (Figure 3a). But it is also observable in Figure 4, where the data point at a calculated injector mixing ratio of 7,600 ppm, shows that the measured mixing ratio is more than 20% too low. The solid line represents a linear fit to the lower volume mixing ratio data, excluding the data with \( \nu > 4,000 \) ppm. The slope is 1.038 (±0.007), indicating that the spectrometer overestimates the water concentration. The slope, however, falls practically within the limits posed by the combined uncertainty on the droplet size (±0.4%), the flow measurement (±3%), the pressure controller reading as specified by the manufacturer (±0.5 % of full scale), and the frequency determination (up to 0.5%), which together determine the volume mixing ratio of the moist air stream produced by the injector.

Since an exact cancellation of device non-linearities between injector and spectrometer to the level demonstrated in the figure is highly unlikely, we may conclude that the volume mixing ratio produced by the injector is indeed linearly dependent on the repetition frequency and that the response of the G2WIS device too is clearly highly linear over two orders of magnitude (correlation coefficient ≥ 0.9999). The linear fit in Figure 4 yields, however, a small non-zero intercept of 39±6 ppm. For a given configuration and operating parameters,
this offset is very stable and indicates the existence of an extra source of water with a constant mixing ratio. Possible origins of this source are the background level of water vapor contributed by out-gassing of the inner parts of the injector or the optical cell, or a small leak present in the vacuum system, or even residual water present in the “dry-N₂” cylinder. We have noted that the offset depends to some extent on the time the system is purged with dry nitrogen before the first amount of water is injected. The offset is, however, particularly sensitive to the flow rate. Figure 5a shows that at a flow rate of 600 mL/min STP the offset has essentially disappeared (the intercept is now -1.8±1.7 ppm). This is a strong indication that the origin of this water source is not the compressed nitrogen (which appears to contain no measurable amount of water), but that outgassing is to blame. In addition to release of water molecules adsorbed on the inner walls, trapping of moist air in dead space in the injector, optical cavity, or gas connections, is a possibility. In fact, no attempt was made to design an injector geometry that avoids stagnation points in the flow pattern. Also, whereas the spectrometer is made from internally polished stainless steel, the injector is machined from a solid aluminum block, with no special surface treatment. Most importantly, no provision was made to heat (part of) the injector assembly.

In Figure 5a, the measured volume mixing ratios are shown as a function of the injector repetition frequency at three different flow rates (150, 300 and 600 mL/min). The combination of repetition frequencies and flow rates in this case covers a volume mixing range from 12 to 3,500 ppm. Flow rate and mixing ratio should be inversely proportional. This is indeed approximately true: with a doubling of the flow rate the slope of the straight line fit to the data decreases first by a factor of 2.09 (from 150 mL/min to 300 mL/min), then by a factor of 2.03 (from 300 mL/min to 600 mL/min). The first is slightly outside the error margin of 3% of the flow meter reading. However, it cannot be excluded that the injector operating conditions have changed to produce a somewhat smaller drop size in this case.
In a final test of the instrument linearity, Figure 5b shows measurements at varying droplet repetition frequency and a fixed flow rate of 150 mL/min, but with the pressure controller of the infrared spectrometer set to three different gas cell pressures between 40 and 160 mbar. As expected, the measurements show no systematic dependence on the cavity pressure, demonstrating that the data (spectral) analysis correctly accounts for pressure broadening of the spectral absorption features. This also is an indication that spectrometer saturation is not the cause of lower measured mixing ratios at high water concentrations.

3.2 Isotope ratio measurements

In order to calibrate the instrument, a series of measurements were performed, in which the local water standards GS-22, GS-48, and GS-50, were alternatingly introduced in the spectrometer. Since only two micro dispenser injectors were available, one of them was used to inject two different local water standards. In order to avoid possible memory effects, a clean dispenser reservoir was used for each water standard, whereas the injector capillary and PFTE tube were cleaned before re-using the injector with the new water source. The water mixing ratio was about 2,000 ppm, while the flow rate was set to 150 mL/min. The data points in the figure are the average of the results of about 200 spectra, yielding a time resolution of 20 s. The average of the means of the two GS-48 measurement series and the mean of the one GS-50 series were used to scale the raw measurements in the same manner as the VSMOW-SLAP scale correction recommended by the IAEA (Gonfiantini 1984, Hut 1987). Figure 6 shows the time series of the $\delta^{2}$H and $\delta^{18}$O measurements. The $\delta^{17}$O measurements are not considered here as they are not expected to yield information beyond that provided by $\delta^{18}$O, due to the very tight relation between $\delta^{17}$O and $\delta^{18}$O observed in all
tropospheric water (see, e.g., Meijer and Li, 1998). The figure also shows the mean value and
the standard deviation for each measurement series. The GS-22 δ²H measurements deviate by
4.5‰ and -3.5‰ from the accepted value, whereas the δ¹⁸O measurements are about 1.4‰
too high. These numbers should be compared to the combination of the measurement error on
GS-22 and the accuracy with which the VSMOW-SLAP calibration curve is known at the
position of GS-22. In the following error analysis we use the standard deviation of the five
local reference water measurements, as opposed to the standard error on the mean, since the
measurements were calibrated on a time scale of 1 to 3 hours, long compared to the stability
time of the spectrometer (and caused by the necessity to thoroughly clean the injector between
its usage for GS-22 and GS-50). The latter was determined to be of the order of 20 s., based
on an Allan variance analysis (Werle et al., 1993). This treatment is, however, beyond the
scope of this paper and will be published elsewhere. Spectrometer drift on the time scale of
hours means that the use of the standard error is likely to seriously underestimate the true
uncertainty in the measurements. The major contribution to drift of the spectrometer on these
time scales is expected to come from the temperature dependence of the line strengths. As
stated previously in section 2.2, the expected temperature-induced uncertainty on the isotope
ratio measurements is about 1.6‰ and 0.2‰ for δ²H and δ¹⁸O, respectively. These
uncertainties are smaller than the standard deviation of the respective spectrometer
measurements, such that the use of the standard deviation in the error budget is likely a
conservative choice. The standard deviations of the GS-48 and GS-50 isotope ratio
measurements translate into an uncertainty of 2.5‰ for δ²H and 0.25‰ for δ¹⁸O on the
accuracy with which we can know the isotope ratio values of GS-22. We have not considered
the uncertainties in the IRMS determinations of the isotope ratios, given that these are about
one order of magnitude smaller than the standard deviations of the laser spectrometer results.
Combining the standard deviations of the GS-22 determinations with the calibration uncertainty, we conclude that the \( \delta^2 \text{H} \) determinations are within 1 to 1.5 times the 1-sigma measurement uncertainty of the accepted value. The \( \delta^{18} \text{O} \) determinations are approximately 3.5 times the 1-sigma uncertainty removed from the accepted value for GS-22. This deviation is larger than expected and may indicate that we have slightly underestimated the (temperature) stability of the spectrometer in our error budget. Fractionation, due to, e.g., condensation in the system, can be excluded as it should have affected the deuterium measurement too.

Finally, the injector is used to investigate the dependence of the precision of the isotope ratio measurements on the water volume mixing ratio. The level of precision is directly determined by the signal-to-noise ratio of the spectral features of the rare and abundant isotopologues, and thus can be expected to deteriorate at exceedingly small signal levels. The results are reported in Figure 7, which shows the 1-sigma standard deviation determined for 2-second averaged isotope ratio determinations for water mixing ratios from 32 to 7,600 ppm. It is clear that, starting at a water vapor mixing ratio of ~2,000 ppm the standard deviation of the oxygen isotope ratios remains essentially constant with increasing mixing ratio. Only the deuterium precision continues to improve, which is easily understood if one realizes that the deuterium line in the spectrum is almost one order of magnitude weaker than the \( \text{H}^{18} \text{OH} \) line.

By co-adding spectra, the precision continues to improve up to a total averaging time of about 20 s. The best precisions obtained are then 1.3‰, 0.4‰, and 0.15‰ for \( \delta^2 \text{H} \), \( \delta^{17} \text{O} \), and \( \delta^{18} \text{O} \) respectively.

4 Conclusion
In this paper, we demonstrate that a microdrop generator system provides a simple and efficient method for calibrating an optical isotope ratio spectrometer for the on-line measurement of isotope abundance ratios of atmospheric moisture. The accuracy of the volume mixing ratio was dominated by the limited accuracy (3%) of the mass flow meter. The stability of the mixing ratio is almost one order of magnitude better. For a good reproducibility of the mixing ratio care should be taken to stabilize the differential pressure over the nozzle. The device was demonstrated at mixing ratios from 12 to over 5,000 ppm. Lower mixing ratios can be produced, but the flow rate should then be sufficiently high (~1 L/min or higher). At lower flow rates, the droplet frequency would need to be very low (< 1 Hz), leading to a periodically oscillating mixing ratio and flow stagnation points in the injection chamber may contribute to a background moisture level. Higher mixing ratios can be obtained if condensation (and thus isotope fractionation) in the injector can be avoided, for example by increasing the path the droplets can travel before hitting the wall of the injection chamber, and by heating the latter. For a rapid change-over between different isotope standards it is, however, necessary to use one injector for each standard material used.

The microdrop generator was used to investigate the linearity of response and the accuracy and precision of a sensitive infrared laser based spectrometer for on-line water vapor isotope measurements. The $\delta^{17}$O and $\delta^{18}$O precisions reach their minimum values at around 1,000 ppm and remain essentially constant at higher mixing ratios. The level of precision improved with averaging over 20 seconds, reaching values of 1.3‰, 0.4‰, and 0.15‰, for $\delta^2$H, $\delta^{17}$O, and $\delta^{18}$O, respectively.
The microdrop generator is able to reach much lower water vapor mixing ratios than the direct, non diluted output of a dew-point generator or bubbler device, and is characterized by the absence of isotope fractionation between the supplied liquid phase water and the produced moist air stream. It is also compact and requires a minimum amount of water, making it ideal to calibrate an atmospheric moisture isotope spectrometer, also in field situations.

Figure 1: Four photographs of the CCD camera screen taken at different stroboscope delay times. Part of the glass capillary of the droplet generator can be seen, in addition to the droplet formation. The third frame shows the ejection of the droplet, which is followed by the retraction of the water column back into the capillary.

Figure 2: Schematic diagram of the experimental arrangement. Water droplets, generated by the micro dispenser, are injected directly into a flow of high-purity nitrogen. A pressure controller keeps the pressure in the gas line to ~30 mbar above ambient pressure in order to avoid liquid leaking from the injector. The flow rate through the optical cavity is controlled by a pressure controller before the cavity, in combination with a needle valve after the cavity.

Figure 3: (a) Response of the laser spectrometer to step-wise changes of the water mixing ratio of a moist air flow of only 150 mL/min. The water concentration was increased by increasing the droplet frequency of the nozzle injector. The pressure inside the optical cavity of the spectrometer was kept at 100 mbar. (b) Response of the spectrometer to two subsequent step-downs in the water concentration. The time constants are 5.4(3) sec and 5.7(2) sec for the transitions from 1,400 to 335 ppm, and from 335 to 60 ppm, respectively (the exponential fits are shown as a solid lines). The slow onset of the first transition is due to the manual, gradual change in injector frequency.

Figure 4: Response of the laser spectrometer as a function of the calculated volume mixing ratio of the injector system. A highly linear relationship is observed between the laser spectrometer signal strength and the nozzle injector water concentration over almost three
orders of magnitude. Above about 3,500 ppm, the droplets no longer evaporate completely and liquid formation is observed in the injector chamber.

Figure 5: Laser spectrometer response as a function of the injector mixing ratio with (a) the pressure inside the optical cavity set to 100 mbar and flow rates of 150 (□), 300 (∆), and 600 mL/min (◊), and (b) a constant flow of 150 mL/min, but different cavity pressures of 40 (○), 100 (◊), and 160 mbar (□). The results show that, as expected, the mixing ratio is essentially inversely proportional to the flow rate and that there is no systematic dependence on the cavity pressure.

Figure 6: δ²H and δ¹⁸O measurements of three local reference waters, GS-22, GS-48, and GS-50, with well-known isotope ratios. The GS-48 and GS-50 reference materials were used to perform a VSMOW-SLAP style calibration. The isotope ratios of GS-22 are recovered to within 1.5 and 3.5 times the 1-sigma uncertainty level for δ²H and δ¹⁸O, respectively. The water volume mixing ratio is roughly 2,000 ppm.
