ABSTRACT

During the last decade, the applications of PMN-PT spread significantly. Unlike PZT, the appropriate microtechnologies for PMN-PT Piezo-MEMS aren't fully documented in the literature. This paper deals with the PMN-PT etching by inductively coupled plasma (ICP) technique, also known as DRIE. The paper quantitatively presents the etching parameters of PMN-PT by the Ar/C₄F₈ gas combination and reports some related useful experience.

INTRODUCTION

The ability to fabricate well-defined structures on the surface of the substrates, with near vertical sidewalls, a high aspect ratio, and a relatively low surface roughness, is a key factor for many applications, like MEMS, NEMS and integrated optical devices. High depth, high aspect ratios, good uniformity over the wafer, vertical wall profiles and reasonable etching selectivity, i.e. the ratio of the etch rates of the substrate and the mask are the actual challenges.

Plasma-based reactive ion etching (RIE) is a very controllable dry process exploiting both chemical and physical processes to remove solid material locally [1]. The plasma is generated with a powerful RF electromagnetic field under low pressure. Accelerating ions collide with the wafer surface and eventually react with it. The effect is a combination of chemical reaction and atomic sputtering, whose balance depends on the material and method (gas concentrations, powers, substrate temperature).

Deep reactive ion etching (DRIE) using inductively coupled plasma (ICP) RIE system has demonstrated its potential in batch fabrication of deep anisotropic microstructures in Silicon. The technology is also used for highly directional and precise micro-scale etching of materials including piezoelectric. The interest is in highly integrated piezoelectric and piezo-on-silicon microsystems (from resonators and transducers to actuators and energy harvesters) [2] where traditional methods fail (e.g. mechanical lapping and trenching ultrasonic etching).

Dry etching of piezoelectric materials is not new issue, researches being reported in quartz [3], AIN [4], LiNbO₃ and PZT ceramics [5] where etching is mainly obtained by a rather physical sputtering with insignificant chemical contribution. Other newer materials with outstanding piezoelectric properties such as PMN-PT and PZN-PT are not documented in the literature.

The present paper is related to the authors mainstream activities in piezoelectric micro-actuators and tweezers for micromanipulation/microassembly. More recently, integrated PMN-PT piezo-actuators raised our interest, given that simulations predict improved performance [10]. Unlike PZT, the appropriate micro-technologies for PMN-PT based Piezo-MEMS aren't fully documented in the literature, this paper attempts to fill a gap by quantitatively reporting the etching parameters of PMN-PT.

ETCHING EXPERIMENTS

Material samples

The material used for these experiments was TRS-X2C from TRS Technologies of 68% PMM and 32% PT.
concentration, whose cut and poling was performed in \text{<001>} direction for an optimised out-of-plane operation. This type of plate possesses a longitudinal piezoelectric coefficient \(d_{33}\) between 2300 and 3300 pC/N. The \(k_{33}\) coupling factors range from 0.90 to 0.97. The transverse coefficients are isotropic for this type of cut, varying from -700 to -1200 pC/N according to several intrinsic or external parameters such as material concentration, crystallographic defects and operating temperature.

A number of ~30 samples of roughly 5 x 10 x 0.2 mm\(^3\) were initially prepared, of which 18 were successfully tested under different conditions. The DRIE mask was of a regular type: Nickel on a thin Chrome buffer. Nickel is known as performing well under intensive etching energies. Other materials such as Cr, Al or Cu were studied for etching masks but were dismissed due to low selectivity, etching chamber contamination or limited deposition thickness.

**Figure 1.** a) PMN-PT 5x10 mm initial samples, b) Ni electroformed mask sample.

Finally, Ni sample masks were realised using three different technologies: sputtering, evaporation and electroplating. The mask features (Fig 1 b) were developed using lift-off for the sputtering-deposited samples, wet etching for evaporated ones and electroforming for the latter.

**Figure 2.** Feature on an electroplated sample.

**Mask deposition and dry etching facilities**

The sputter deposition machine was a Plassys MP500 model while the evaporation one an Alliance concept Eva 450. Provided that the nickel is known for inducing residual stress during deposition, its thickness must be limited. For the sputtering technique the maximum layer should be under 0.7 \(\mu m\). The maximum limit for evaporated Ni on PMN-PT is larger, of around 1.5 \(\mu m\). Finally, electrodeposited layers can be much greater, like 15 \(\mu m\). Under special conditions we reached an electroplated 25 \(\mu m\) layer, but the sample became too constrained. On the other hand, as will be seen, etching time for such a layer would take too many hours for a realistic process. A related graphical representation is provided in the figure 4.

The ionic etching was carried out using a commercial multiplex AOE MPO 562 reactor from STS with an ICP RF generator of 3 kW and a RIE generator of 1.5 kW. The maximum size of the wafer is 6 inches, and the gas available are SF6, CF4, C4F8, He, O2 and Ar.

The temperature of the substrate holder was varied between -20 and 60\(^\circ\)C. The gas mixture we selected was a combination Ar/C4F8 (64sccm /5sccm). The PMN-PT samples were fixed on Si carriers with thermal grease for an optimal cooling of the sample. Step heights in \(\mu m\) were obtained progressively with a Tencor Alpha-step profilometer. Final profiles were also measured with a scanning electron microscope (SEM) and with a MSA-500 MEMS analyzer from Polytec. This specific tool based on Michelson interferometry may offer nanometer-scale resolution in out-of-plane direction.

**Figure 3.** 3D topography picture (measurement software TMS 3.1 installed on MSA-500 analyzer)

**Experimental design**

Several combinations of etching parameters were chosen in the attempt of assessing as much data as possible from the 18 samples. Input parameters were:

- RF source power (500, 1200 W),
- bias power (100, 300, 400, 500 W),
- temperature (-20, 0, 60 \(^\circ\)C) and
- internal pressure (2, 5, 10, 15 mTorr).

Etching times varied from 30 minutes to 280 minutes.

**EXPERIMENTAL RESULTS**

**Mask Type dependence**

One of the predominant challenges in PMN-PT DRIE is the mask sufficiency, which is limited by the etching selectivity between PMN-PT and the mask and by the thickness of the mask. Ni masks can be used as mask materials because of their reasonably high growth rate, typically 17\(\mu m/h\) for electroplated Ni. However, as the thickness of the mask is increased to several micrometers, some practical challenges or disadvantages are encountered. Nickel does not react with fluorine compounds to form volatile products. In addition to the micro-masking caused by re-deposition of the non-volatiles on the area to be etched due to mechanical erosion, electroplated metals are often non-uniform in thickness. Also, thicker hard masks may introduce severe stress on the PMN-PT wafer leading to possible breakage of the mask and the PMN-PT substrate during processing. The etch mask selectivity was studied for electroplated, evaporated Ni and sputtered masks at 500W powers. It was shown that sputtered Ni gives better selectivity (12:1 compared to 8,3:1 for electroplated Ni). But the limiting factor of Ni sputtered mask was the difficulty to deposit layers thicker than 1.5 \(\mu m\) using the lift-off.
Bias power dependence

The etch rate decreased with the drop of bias power, from 0.14 μm/min for 500W to 0.06 μm/min for 100 W and conversely the selectivity raised from 7.85:1 to 9:1 (Fig. 5, Ni evaporated mask).

Microtrenches and nanometer slits

For the electroplated Ni, some micro-trenches at the bottom edge of the sidewall appeared and was attributed to a higher electron density at the edges during etching, leading to higher etching speed (Fig. 6,7,9). This phenomenon was already observed for Quartz by Abe et al. [11] and was attributed to a bias voltage too high. Dahm et al. have also reported this effect [12] and interpreted this to a high flow of precursor gas. The main contribution for the appearance of this phenomenon is the bias voltage value.

Nanometer slits were also observed at the interface between very close structures. The phenomenon was also reported in the case of PZT [13] and is not fully understood, being attributed to material ferroelectric properties.

Pressure dependence

After several tries, we have found that the lowest achievable pressure (2 mTorr) of the DRIE STS machine gave improved results in terms of etching speed (by 10%). The associated selectivity is however noticed to decrease quite significantly (from 10:1 to 8:1) at lower pressure values (Fig.10).
Temperature Dependence

As noticed from Fig.11 there seems no linear correlation between the etching speed and the process temperature, but the selectivity increase by several percents with the increase of the substrate holder temperature. This must be the result of a small release of the stress in the mask layer. However, due to the low Curie temperature of PMN-PT material we don't recommend high temperatures etching because of the loss of piezoelectric properties.

The etching anisotropy in terms of sidewalls angles is affected mainly by lateral mask shrinking (see Fig 6 and 9) with lateral speeds slightly superior to the vertical ones. Because of the difficulty to asses reliable results for shallow etched surfaces, data for only electroplated mask profiles were reliable. As noticed from the figures lateral erosion increase with the bias power (18 nm/min at 300W and 22 nm/min at 500W).

Lateral mask etching

The etching anisotropy in terms of sidewalls angles is affected mainly by lateral mask shrinking (see Fig 6 and 9) with lateral speeds slightly superior to the vertical ones. Because of the difficulty to assess reliable results for shallow etched surfaces, data for only electroplated mask profiles were reliable. As noticed from the figures lateral erosion increase with the bias power (18 nm/min at 300W and 22 nm/min at 500W).

CONCLUSIONS

As most piezoelectric materials, the reactive component of PMN-PT etching represents an insignificant part of the process, which mainly relies on the physical sputtering of the surface atoms due to energetic ions collisions. Therefore, we used an Ar composition, knowing that the inert gases sputter yield is higher than that of other elements or molecules (Cl2, C2H6 etc.). An experience plan was set-up in the attempt to test various parametric conditions. The material was PMN-PT [001] lapped at 200μm thickness. The Nickel shadowing masks were electroformed at ~5.5μm or sputtered and evaporated at 0.3-0.7μm thickness.

Preliminary experience indicated the gas combination Ar(92%) + CF4(8%). We used an STS ICP machine, a couple dozens charts were obtained by varying different parameters (gas pressure, RF source and bias powers and the substrate temperature).

Best achieved etching rate was 0.19 μm/min with a selectivity ratio of 8:1 for 1200W source and 300W bias powers at 2 mTorr pressure. Sidewalls angles lie at ~70°, mainly due to erosion of the Ni mask in lateral (horizontal) direction (Fig. 6, 9 b, 9 d). Lateral mask shrinking increased with the raise of the bias power. Expected micro-trenches at the bottom edge of the sidewall were noticed and quantified, being attributed to high local ion density at the edges during etching. Nanometer slits were also observed at the edges between structures. Compared to PZTs [5][13], (selectivity ratios of up to 35:1, etching speeds of 0.14 – 0.4 μm/min, and profile angles of ~75°), we conclude that PMN-PT is slightly more resilient to dry etching than PZT. However, according to our experience, profiles of ~100 μm are achievable, with the cost of extended etching times.
