ABSTRACT: The permeance of carbon dioxide, oxygen, nitrogen, and air through commercial polymers based on polyethylene (PE), biaxially oriented polypropylene (BOPP), and polyamide (PA) used for food packaging is reported. The influence of temperature (from 10 to 60°C) and crease stress cycles (30, 50, 70, and 110) on gas permeance is also analyzed. Generally, the highest changes in gas permeance changes with increased stress cycles are observed with films having a metallized layer in the structure, namely BOPPcoex/BOPPcoex.met and, to a lesser extent, BOPPcoex.met/PE laminate. The lowest crease stress influence on barrier properties is obtained for PE film. In this case, the highest activation energy for the permeability coefficient (P) is obtained. Normal progressions of activation energies for P are: $N_2 = \text{Air} > \text{CO}_2 > \text{O}_2$.

KEY WORDS: Crease strains, gas permeance, laminates, films, flex tests.

INTRODUCTION

THE USE OF different polymers, such as polyethylene (PE), polypropylene (PP), and polyamide (PA) in the foodstuffs packaging industry depends on the properties of the final product.

Manufacturing, handling, and packaging procedures can greatly affect the barrier properties of flexible packaging materials.

The gas transport coefficients (permeability, the diffusion and the solubility coefficients) vary generally with parameters which can be intrinsic to the polymer, such as the degree of crystallinity, the nature of the polymer, or even the thermal and mechanical histories of samples [1]. The kind of gases used, characterized by its molecule size and nature as well as its conditions of temperature and pressure, are also factors influencing barrier properties. Molecular orientation which usually develops in processing is known to have a major effect on the mechanical properties of both glassy and crystalline polymers. The resistance to repeated flexure or creasing is important in use. Some films are highly resistant [2] whereas others will fail by pinholing or total fracture after bending only a few times. Even if failure does not occur, certain properties of the film may be seriously impaired. For example, permeability to gases or water vapor, tensile or optical properties may be seriously affected [3,4]. Additives to a plastic material to modify its properties generally increase the permeability. This increase is further affected with increased crease stress on polymers [4,5].

Orientation of polymer materials reduces gas diffusivity. In a study of permeability of carbon dioxide (CO_2) through ultradrawn polystyrene, Wang and Porter [6] pointed out that the solubility remains nearly constant while the diffusion coefficient decreases with draw.

Today's polyolefin packaging can have a range of functional requirements, among them high flexibility, optical clarity, low water loss, sealability, extended shelf life, slow permeability to oxygen (O_2) and CO_2 , lack of leachables, dimensional stability during sterilization, flex resistance, biocompatibility and environmental compatibility, and low cost. PE was the first commodity plastic used for food packaging. PE films are often laminated with other polymers for applications in which PE is used for heat sealing and/or as a barrier to water vapor. Biaxially oriented polypropylene film (BOPP) is also a widely used transparent packaging material. Its advantageous properties include low density, no toxicity, good moisture resistance, good mechanical strength, and dimensional stability and printability. Commercial BOPP films have special inner structures obtained by the stretching of the thick, extruded sheets at high temperatures in the machine direction and in the transverse direction [7]. Polyamide has frequent use as a component in these multilayer film structures [8] due to its unique combination of mechanical strength, puncture resistance, transparency, thermal stability, O_2 and aroma barrier, and thermoformability. A number of papers report on the effect of drawing on polymers permeability [6,9–11].

The present study focuses on the crease action influence on gas (CO₂, O₂, nitrogen (N₂), and air) permeance changes through commercial mono- and di-layer films (PE, PA, BOPP, and metallized BOPP), used for food packaging.

EXPERIMENTAL DETAILS

The investigated test films are listed and specified in Table 1. Films were obtained, without graphics, directly from the producer, Aluflexpack d.o.o., Umag, Croatia.

Permeance Measurement

Gas permeance determination [12,13] was performed by a manometric method using a permeance testing appliance, Brugger type GDP-E [14].

Table 1. Materials used in the experiments.

	Polymer	Abbreviation	Thickness (μm)	Comments
1	Polyethylene	PE	75	Polyethylene low density, PE-LD
2	Polyamide	PA	15	Polyamide 6; Density (23°C) = 1.15 g cm ⁻³
3	Bioriented coextruded polypropylene	BOPP coex	20	
4	Bioriented coextruded metallized polypropylene	BOPP coex.met	20	Vacuum deposited aluminum
5	Polyamide/Polyethylene	PA/PE	15/75	2.2–2.7 g m ⁻² polyurethane solvent based adhesive
6	Polypropylene bioriented coextruded/Polyethylene	BOPPcoex./PE	20/75	2.5–3.0 g m ⁻² polyurethane solvent based adhesive
7	Polypropylene bioriented coextruded metallized/ Polyethylene	BOPPcoex.met./PE	20/75	2.5–3.0 g m ⁻² polyurethane solvent based adhesive
8	Polypropylene bioriented coextruded/Polypropylene bioriented coextruded metallized	BOPPcoex./ BOPPcoex.met	20/20	2.0–2.5 g m ⁻² solventless adhesive
9	Polypropylene bioriented coextruded/Polypropylene bioriented coextruded	BOPPcoex./ BOPPcoex	20/20	2.0–2.5 g m ⁻² solventless adhesive

Permeance calculation for the samples, using the manometric operating method B (only the bottom sample surface is evacuated), was determined from Equation (1).

$$q = k_1 \frac{V}{N \cdot T} \quad (1)$$

where

$$k_1 = 3.42 \times 10^7$$

q = permeance unit ($\text{cm}^3 \text{m}^{-2} \text{d}^{-1} \text{bar}^{-1}$)

V = measurement volume (mL)

N = slope of the measurement curve (s)

T = temperature (K).

The permeability coefficient of the gas in film was calculated according to the following equations:

Permeability Coefficient

$$P = k_2 q l \quad (2)$$

where:

$$k_2 = 1.16 \times 10^{-9}$$

l = polymer thickness (cm)

Activation Energy for Permeability Coefficient

$$P = P_o \exp\left(\frac{-E_p}{RT}\right) \quad (3)$$

where:

P_o = the pre-exponential factor

R = the gas constant ($\text{J mol}^{-1} \text{K}^{-1}$)

T = the temperature (K)

Permeance characteristics changes were checked after the samples were submitted to 30, 50, 70, and 110 full flex cycles at 23°C on a Crease Resistance Tester, Type KFT, Brugger Feinmechanik GmbH. The flexing action consists of a twisting motion followed by a horizontal motion, thus, repeatedly twisting and crushing the film [15]. The frequency is at a rate of 45 cpm (cycle per minute).

Permeance experiments were performed three times and the mean values are reported with the standard deviation, average value, and coefficients of variability (%) for permeability coefficient (P) value for the analyzed polymers in Table 2.

Table 2. Permeability coefficient of films and laminates.

Polymers	Standard deviation	Average	Coefficient of variability (%)
PE	2.3×10^{-11}	2.2×10^{-9}	1
PA	6.1×10^{-12}	2.8×10^{-10}	2
BOPPcoex	4.83×10^{-12}	6.98×10^{-10}	1
BOPPcoex.met.	6.14×10^{-12}	3.7×10^{-10}	2
PA/PE	3.4×10^{-11}	2.1×10^{-9}	2
BOPPcoex/PE	2.8×10^{-11}	2.8×10^{-9}	1
BOPPcoex.met/PE	1.8×10^{-11}	2.64×10^{-9}	1
BOPPcoex./BOPPcoex.met	7.1×10^{-12}	1.12×10^{-9}	1
BOPPcoex/BOPPcoex.	7.09×10^{-12}	1.07×10^{-9}	1

DSC Experiments

The DSC analysis was carried out on a Netzsch DSC 200 differential scanning calorimeter operating in the temperature range between -100 and 500°C at a heating rate of $10^\circ\text{C min}^{-1}$ in a nitrogen atmosphere. Calibrations for both the temperature and the enthalpy were achieved from measurements of melting temperature and enthalpy of indium. From DSC thermograms, the heat of fusion ΔH_f and the degree of crystallinity X_c were determined according to the equation:

$$X_c = \frac{\Delta H_f}{\Delta H_{f,th}}, \quad (4)$$

The theoretical heat of fusion $\Delta H_{f,th}$ of 100% crystalline polymer was assumed to be 293 J g^{-1} for PE and 190 J g^{-1} for PP and PA [16].

RESULTS AND DISCUSSION

Thermal Properties

Figure 1 shows the results of DSC measurements on as-received films. The curves exhibit one or two endothermic peaks that correspond to the

Figure 1. DSC thermograms of as-received films obtained at heating rate of $10^{\circ}\text{C min}^{-1}$.

melting of crystalline phases of semi-crystalline polymers. All parameters obtained from DSC measurements on the investigated specimens are summarized in Table 3, where T_{onset} and T_{end} refer to the temperature of the onset and end of the melting process and T_{m} is the melting temperature (DSC peak temperature).

For PA/PE laminate, it was difficult to estimate PA heat of fusion due to the overlapping of PA melting with the onset of PE oxidation. On the assumption that polymers in laminates have the same degree of crystallinity, the approximate content of polymers and tie-layers (or adhesive coatings) can be calculated. In PA/PE and BOPP/PE laminates, a minor peak appears in the DSC thermograms at about 101°C while the main peak is around 104°C . These findings indicate that the crystalline structure did change during the production of multilayer films, probably because of the tempering at a temperature of about 100°C . During tempering, crystal segregation occurs. Amorphous domains of highest order in the molecular structure can form crystallites with melting points higher than the temperature where the tempering was done. Complete melting deletes any thermal history as shown previously [17].

Figure 2 and Table 3 show that the crystallization behavior of PE was not seriously affected by mechanical stress.

Table 3. Parameters of investigated films obtained from DSC measurements.

Sample	T_{onset} (°C)	T_{end} (°C)	T_m (°C)	ΔH_f (J g ⁻¹)	X_c (%)
PE	42	110	103	92	31
PE stressed (110 cycles)	40	112	108	105	36

Figure 2. DSC thermograms of as-received (solid line) and stressed (110 crease stress cycles, dotted line) PE films obtained at heating rate of 10°C min⁻¹.

Permeance Properties

The effect of mechanical stress is presented for 50 and 110 stress cycles as very similar data were obtained for gas permeance in the lower (from 30 to 50) and higher (from 70 to 110) stress cycle range applied.

In the case of PE (Figure 3), the highest permeance values ($2100\text{--}7500\text{ cm}^3\text{ m}^{-2}\text{ d}^{-1}\text{ bar}^{-1}$), for all gases investigated, are obtained at higher temperatures ($50\text{--}60^\circ\text{C}$). It is generally assumed that the free volume in a polymer is increased by raising the temperature [18].

As shown in Figure 2 and Table 3, the crystallization behavior of PE was not seriously affected by the flex test – the minor changes could be due to the inhomogeneity of the sample. As identical trends and similar values were obtained for all gases, with some exceptions which will be commented on later, the O_2 permeability data were used as representative for both monofilms (Figure 3) and laminates (Figure 4).

Although there is no great difference between the sizes of N_2 , O_2 , and CO_2 molecules, according to literature data the permeability of polymers to CO_2 is at least 4 times that of O_2 [18,19]; however, this was not the case for the samples in this series as will be discussed later.

PA film showed the highest increase of O_2 permeability with increased stress cycles (Figure 3), while a negligible effect of stress cycles from 30 to 70 was observed in the case of N_2 and air permeability. High permeability changes due to mechanical stress were also observed for BOPPcoex.met where O_2 permeability (Figure 3) increased with stress cycle increase (≥ 50 cycles) in the entire temperature range investigated. In the case of CO_2 , significant permeability increase was obtained (above 40°C) for 110 cycles applied, and for N_2 when 70 and 110 cycles were applied, at temperature $>20^\circ\text{C}$.

The results of G'Sell et al. [20] showed that structural damage takes place as the plastic deformation proceeds in tension, while only little damage is recorded in shear.

Another important feature, according to the same authors [20], is the progressive damage suffered by the semicrystalline structure at large strains. The evidence of this phenomenon, for both PE and PP, is the decrease of density probably due to progressive fragmentation of crystallites and micro-cavitations at stress concentrated zones.

The effect of mechanical stress on gas permeance of BOPPcoex/PE laminate was observed at 50 cycles applied and did not change with further cycles (Figure 4). For BOPPcoex.met/PE a slight increase in permeance was observed even at 30 cycles for all gases investigated, while with further stress cycles a negligible effect on permeance was observed.

Generally the highest changes in gas permeance with increased stress cycles were observed with films having a metallized layer in the structure, namely BOPPcoex/BOPPcoex.met and, to a lesser extent, BOPPcoex.met/PE laminates. Similar observation was reported by Oliveira et al. [3]. Although the barrier properties of metallized

Figure 3. Influence of temperature (10–60°C) and crease stress (0, 50, and 110 cycles) on O₂ permeability in monofilms.

Figure 4. Influence of temperature (10–60°C) and crease stress (0, 50, and 110 cycles) on O_2 permeability in laminates.

polymers are improved they are susceptible to roughening of the surface during growth, and to the incorporation of voids and pinholes during the deposition of the film [21]. For SiO_x , Al, and AlO_x coated films the O_2 permeance rate was shown to be related to surface roughness of the barrier film, indicating that pinhole defects are not the only source of permeation through barrier films [22].

The analyzed samples were checked for cracks and/or pinhole presence. No such evidence was found by backlighting the samples and/or by applying alcoholic solution of rhodamine on the samples placed on a sheet of filter paper. The BOPPcoex/BOPPcoex.met laminate even showed decreases in gas permeance with increased stress cycles when measured at higher temperatures ($>40^\circ\text{C}$). A similar observation was obtained for O_2 permeance only in BOPPcoex/BOPPcoex laminate (Figure 4), while there was negligible influence of stress cycles on N_2 , CO_2 , and air permeance.

As for the PA/PE laminate, the effect of mechanical stress was more pronounced at 70 and 110 cycles applied, in the case of CO_2 (Figure 5) and air permeance when measured above 40°C . On the contrary, O_2 (Figure 4) and N_2 permeance are the highest, at $t \geq 40^\circ\text{C}$, for the unstressed PA/PE.

Among the investigated monofilms the highest O_2/CO_2 permselectivity (Figure 6) was obtained for BOPPcoex at $10\text{--}30^\circ\text{C}$. In this case the O_2/CO_2 selectivity decreases with increased stress cycles at $t \geq 40^\circ\text{C}$. As previously reported [17] BOPPcoex showed the highest O_2 solubility and the lowest O_2 diffusivity.

Figure 5. Influence of temperature ($1/T$) and crease stress cycles (0–110) on CO_2 transmission rate through PA/PE laminate.

Figure 6. Effect of temperature (10–60°C) and stress cycles (0, 50, 110) on O_2/CO_2 permselectivity of some polymers.

As for the laminates, the highest O_2/CO_2 selectivity was shown by BOPPcoex/PE, with remarkable increase at $t > 40^\circ C$. For this laminate, the diffusivity and solubility for both O_2 and CO_2 increased at $t > 40^\circ C$ [17]. With increased mechanical stress on BOPPcoex/PE the O_2/CO_2 selectivity also increased at 10–50°C.

The permselectivity, as reported by Zimmerman and Koros [23], increases because the matrix has a great ability to selectively distinguish between molecules of similar size: kinetic diameters for O_2 and CO_2 are $3.46 \times 10^{-8} \text{ cm}$ and $3.30 \times 10^{-8} \text{ cm}$, respectively [24]. Only PE film showed no influence of mechanical stress on O_2/CO_2 selectivity changes (Figure 6).

An increased O_2/CO_2 permselectivity is obtained for the following films exposed to stress cycles:

PA (10–60°C)
 BOPPcoex.met (10–40°C);
 BOPPcoex/PE (10–50°C);
 BOPPcoex.met/PE (10–40°C);
 BOPPcoex/BOPPcoex.met (10–40°C)

A decreased O_2/CO_2 permselectivity is obtained for the following films exposed to stress cycles:

BOPPcoex (40–60°C);
 PA/PE ($t > 30^\circ C$);
 BOPPcoex/BOPPcoex ($t \geq 40^\circ C$)

Figure 7. The effect of crease stress (0, 50, and 110 cycles) on activation energy for the gas permeability coefficient through the polymers.

This loss in selectivity is generally interpreted as plasticization: a weakening effect on the polymer introduced by the strongly sorbing CO_2 [25].

Permeability increase with temperature is mostly due to enhanced motion of the polymer segments and increased energy level of permeating molecules [18]. Furthermore, high temperature causes larger gaps in the polymer matrix. Activation energy for the gas permeability coefficient (P) was the highest for PE film (Figure 7). Normal progressions of activation energies for P are: $\text{N}_2 = \text{Air} > \text{CO}_2 > \text{O}_2$.

According to Mano et al. [26] the curvature observed in the Arrhenius plots for PE, which also agrees well with the data [17], can be explained by two approaches. In the first case, two separate processes were assumed to contribute to the α -relaxation, with activation energies of 150–170 and 180–210 kJ mol^{-1} , respectively (dynamic data). The activation energies obtained from creep are lower than those obtained from dynamic mechanical experiments, reflecting a dependence of activation energy, a microscopic property, on the selected experimental technique [26]. Matsuo et al. [27] also concluded that a decrease in the activation energies was observed in PE films with increasing drawing levels, i.e., with increasing orientation within the crystalline phase.

Korsukov et al. [28], for example, have reported that aldehyde groups are produced in PE and PP at an increased rate when stress is applied. The reason applied stress leads to a more rapid rate of reaction is that

mechanical tension contributes to chemical bond scission. The thermal energy of activation is lowered by the potential energy of the stress. If the mechanism of the reaction at higher or lower temperatures should differ, this too would alter the slope of the curve. Numerous examples of non-linear Arrhenius plots, the consequence of a change in mechanism, can be found in the literature [29–32].

Laminates with metallized layer (BOPPcoex.met/PE and BOPPcoex/BOPPcoex.met) show much lower activation energy, due to metallic layer damage by flexing, in comparison to laminates without a metallized layer (BOPPcoex/PE and BOPPcoex/BOPPcoex). As regards activation energy value (Figure 7), the presence of PE layer in laminates (PA/PE; BOPPcoex/PE) enables material to preserve better barrier properties to O_2 and air than to CO_2 and N_2 .

The lowest activation energy is obtained for O_2 permeation through BOPPcoex/BOPPcoex laminate, while much higher values are obtained for N_2 , air, and CO_2 permeability. Excellent correlation (from $r = 0.584$ to $r = 0.995$) between activation energy and molecular diameter of permeates is obtained for the samples exposed to 50 stress cycles. Poor correlation exists in the case of three materials (PE, BOPPcoex, and PA/PE) exposed to 110 stress cycles.

CONCLUSIONS

Generally, the highest variation in gas permeance changes with increased stress cycles, observed with films having a metallized layer in the structure, namely BOPPcoex/BOPPcoex.met and, to a lesser extent, BOPPcoex.met/PE laminate.

The lowest effect of mechanical stress on gas permeance was noticed for PE; BOPPcoex/PE, and BOPPcoex/BOPPcoex films. Similar behavior was noticed for BOPPcoex with the exception of CO_2 permeance which significantly increased at $60^\circ C$ and 110 stress cycles applied.

An increased O_2/CO_2 permselectivity for metallized films (BOPPcoex.met; BOPPcoex.met/PE; BOPPcoex/BOPPcoex.met) was obtained at the lower temperature range ($10\text{--}40^\circ C$) in comparison with non-metallized films (BOPPcoex/PE and PA). Generally, a decrease in O_2/CO_2 permselectivity at temperature $>30^\circ C$ was obtained with increased flexing for BOPPcoex, PA/PE, and BOPPcoex/BOPPcoex.

Thus, it is highly recommended to apply mechanical stresses at 50 full flex cycles before measuring the permeability at different temperatures to determine their influence on barrier characteristics of flexible materials used for food packaging.

BIOGRAPHIES

Saša Mrkić

Saša Mrkić obtained his BS Food Technology at the University of Zagreb. After working in the bakery industry for a few years he attended the University of Zagreb, Faculty of Food Technology and Biotechnology where he did research work in food packaging materials while he obtained his PhD in food technology. Mrkić is now employed in the confectionary industry.

Kata Galić

Kata Galić received her BS Biotechnology from the University of Zagreb and then obtained her MSc and PhD degrees from the University of Zagreb, Faculty of Food Technology and Biotechnology. Her research interests have included permeability characteristics of polymeric materials and factors affecting barrier changes of polymers. She has received several fellowships during her career and presented 32 scientific and 20 professional papers. Galić has been on the faculty of the University of Zagreb for 24 years. She is now a professor at the University of Zagreb, Faculty of Food Technology and Biotechnology

where she was vice-dean for international scientific cooperation. Galić is a member of the Institute for Packaging in Croatia.

Marica Ivanković

Marica Ivanković obtained her BS in Chemical Technology and her MS in engineering chemistry from the University of Zagreb before spending three years at the Department of Materials and Production Engineering at the University of Naples, Italy. She returned to the University of Zagreb where she obtained her PhD in chemical engineering from the Faculty of Chemical Engineering and Technology. She has performed research in thermodynamics of polymer solutions as well as the synthesis and characterization of organic-inorganic hybrids and nanocomposites. Ivanković has published 40 papers and has been active in several engineering organizations. She is a professor at the University of Zagreb, Faculty of Chemical Engineering and Technology, where she has been a member of the faculty for 22 years.
