ABSTRACT

In the context of polarized sources localization using a cocentered orthogonal loop and dipole array, direction-of-arrival estimation performance in terms of mean square error are investigated. In order to evaluate these performance for both asymptotic and non-asymptotic scenarios (low number of snapshot and/or low signal to noise ratio) we derive closed-form expressions of the Weiss-Weinstein bound. The analysis is performed under both conditional and unconditional source signal models. We show the good ability of the proposed bound to predict the well known threshold effect. We also show the influence of the polarization parameters.

Index Terms— DOA and polarization estimation, Weiss-Weinstein bound, COLD array

1. INTRODUCTION

In array processing, the use of an antenna able to handle the source polarization is of importance for a large class of application (see [1] and references therein). One of such antenna is the so-called COLD (cocentered orthogonal loop and dipole) array. Several papers related to the COLD array can be cited: in [1], the authors have introduced an efficient Direction-Of-Arrival (DOA) and polarization estimation technique and the COLD array was shown to improve both the DOA and the polarization estimation performance compared to the cocentered crossed-dipole array. Another example concerning asymptotic performance is given in [2] where the statistical resolution limit, under the conditional observation model (i.e., when the source signals are assumed to be deterministic) was investigated. The authors have introduced an approach based on the Cramér-Rao bound (CRB), and again, under some conditions, the COLD array was shown to provide better performance than a conventional array.

In this paper, we are interested by the ultimate performance of such an array in non-asymptotic scenarios, i.e., when the Signal to Noise Ratio (SNR) and/or the number of snapshots are low. Indeed, it is well known that such an array processing problem is a non-linear estimation problem for which a threshold phenomenon (i.e., when a drastic increase of the DOA estimator mean square error appears) [3]. Unfortunately, the CRB cannot capture this threshold effect [4]. Therefore, we are herein interested to investigate a more relevant bound for the COLD array observation model: the so-called Weiss-Weinstein bound (WWB) [5]. Moreover, since the WWB is a Bayesian bound, it takes into account the support of the parameter via the prior distribution of the parameters. Consequently, the WWB provides a powerful tool to predict the global MSE behavior in both asymptotic and non-asymptotic regions.

Due to its complexity (in comparison with the CRB), there are few publications related to the WWB in the literature. Some of previous works, such as [6], have evaluated the WWB only by way of simulations (i.e., without closed-form expressions). The bound has been compared to the MSE of the MUSIC algorithm and classical Beamforming using an $8 \times 8$ element array antenna. In [7], the authors have introduced a numerical comparison between the Bayesian CRB, the Ziv-Zakai bound and the WWB for DOA estimation. In [8], numerical simulations of the WWB to optimize sensor positions for non-uniform linear arrays have been presented. In [9], by considering the matched-field estimation problem, the authors have derived a semi closed-form expression of the WWB in the so-called unconditional observation model (i.e. when the source signals are assumed to be Gaussian). Concerning the aforementioned context of the conditional observation model a closed-form expression of the WWB is given in the simple case of spectral analysis in [10]. Recently, the closed-form expressions of the WWB for DOA estimation with a classical planar array were derived in [11], and were applied for the array geometry design. Note that all these works have been performed in the context where arrays are not able to handle the polarization of the source signals.

In this paper, we consider the WWB performance bound on the DOA and the SNR threshold analysis of a polarized source with a COLD array. The closed-form expressions of the WWB are given under both conditional and unconditional observation models for which we present simulation results.

2. MODEL SETUP

We consider the context of DOA estimation of a single polarized source using a linear (possibly non-uniform) array of $N$ COLD sensors. The source signal is assumed to be narrow-band and to be located in the far-field area. The sensor positions with respect to a reference axis are characterized by the vector $d = [d_1 \ldots d_N]$. As in [1, 12] we assume that the source is coplanar with the array. Therefore, the DOA of the source signal depends only on the azimuth angle, denoted $\phi$. We assume that the source polarization is known or previously estimated. Let us set $u = \left[ \frac{\pi \rho L_{sd}}{\lambda} \cos \rho - L_{sd} \sin \rho e^{i \psi} \right]^T$, the polarization vector, with polarization angles $\rho \in [0, \pi/2]$ and $\psi \in [-\pi, \pi]$, $\lambda$ denotes the wavelength, and $A_{sl}$, $L_{sd}$ denote the dipole lengths and the loop perimeters, respectively, with the assumption that $A_{sl} < 3\lambda/10$, and $L_{sd} < \lambda/10$. The output at the $i^{th}$ sensor and for the $t^{th}$ snapshot is a two components vector given by [4]:

$$
\begin{align*}
\begin{bmatrix}
\hat{y}_{i}(t) \\
\hat{y}_{i}(t)
\end{bmatrix}
= [a(\phi)]^t g_{i}(t) u + n_i(t), \quad t = 1, \ldots, T,
\end{align*}
$$

This project is funded by both the Digiteo Research Park and the Region Ile-de-France.
where \( s(t) \) denotes the source signal, where \( [a(\phi)]_j = e^{j(\phi \cdot t, \sin \phi)} \) denotes the \( j^{th} \) element of the steering vector \( a(\phi) \) and where \( n_i(t) \) is an additive noise. This noise is assumed to be complex, circular, uncorrelated (spatially, temporally and between the loop and the dipole of each sensors) Gaussian with zero mean and the variance \( \sigma^2 \). We will use the two classical alternative hypothesis about the source signal

- \( \mathcal{H}_1 \): the source signal is assumed to be deterministic and known. This is the so-called conditional signal model [13].
- \( \mathcal{H}_2 \): the source signal is assumed to be a complex circular random Gaussian, independent of the noise, with zero mean and known covariance matrix \( \sigma^2 \mathbf{I} \). This is the so-called unconditional signal model [13].

For mathematical convenience, we consider the estimation of \( \omega = \sin \phi \), and we assume that \( \omega \) follows a uniform distribution \( \omega \sim U[-1,1] \), i.e.

\[
p(\omega) = \begin{cases} 
\frac{1}{2} & \text{if } -1 \leq \omega \leq 1, \\
0 & \text{otherwise.} 
\end{cases} \tag{2}
\]

The output signal for the \( t^{th} \) snapshot of the whole array can be then expressed as:

\[
y(t) = \left[ \frac{\hat{y}(t)}{\hat{y}(t)} \right] = b(\omega)s(t) + n(t), \tag{3}
\]

where \( b(\omega) = u \otimes a(\omega) \), with \( \otimes \) denotes the Kronecker product, where \( \hat{y}(t) = [\hat{y}_1(t) \ldots \hat{y}_N(t)]^T \), and where \( \hat{y}(t) = [\hat{y}_1(t) \ldots \hat{y}_N(t)]^T \).

With the aforementioned assumptions, under \( \mathcal{H}_1 \), the full observation vector \( \{y(t)\} \) follows a Gaussian distribution with parameterized mean, i.e., \( y|\omega \sim \mathcal{CN}(\mathbf{1}_T \otimes b(\omega)s, \sigma^2 \mathbf{I}_{2NT}) \), with \( s = [s(1) \ldots s(T)]^T \). And, under \( \mathcal{H}_2 \), \( y(t) \) follows a Gaussian distribution with parameterized covariance matrix, i.e., \( y|\omega \sim \mathcal{CN}(\mathbf{0}, \mathbf{I}_T \otimes \mathbf{R}(\omega)) \), where \( \mathbf{R}(\omega) = \sigma^2 b(\omega)b(\omega)^H + \sigma^2 \mathbf{I}_{2N} \). Consequently, the likelihood function under \( \mathcal{H}_1 \) can be expressed as:

\[
p(y|\omega) = \frac{1}{(\pi \sigma^2)^{2NT}} \exp \left( -\frac{1}{\sigma^2} \sum_{t=1}^{T} \|y(t) - b(\omega)s(t)\|^2 \right), \tag{4}
\]

and the likelihood function under \( \mathcal{H}_2 \) is given by

\[
p(y|\omega) = \frac{1}{(2\pi \sigma^2)^{NT}} |\mathbf{R}(\omega)|^{-\frac{1}{2}} \exp \left( -\frac{1}{\sigma^2} (y|H \mathbf{R}(\omega)^{-1} y(t) \right), \tag{5}
\]

where \( |\cdot| \) denotes the matrix determinant and \( \|\cdot\|^2 \) denotes the norm operator. The Weiss-Weinstein bound will be derived under both models \( \mathcal{H}_1 \) and \( \mathcal{H}_2 \).

3. WEISS-WEINSTEIN BOUNDS FOR THE COLD ARRAY

The Weiss-Weinstein bound is a lower bound on the mean square error well known to accurately predict the SNR threshold effect which appears in non-linear estimation problems [5]. The WWB is generally obtained by taking the supremum of a function over a set of test point and over a set of parameter \( s \in [0,1] \). Concerning the parameter \( s \), one often set \( s = 1/2 \), see [9–11], although there are no proof that \( s = 1/2 \) could leads to the tightest WWB. The WWB for \( s = 1/2 \) is given by:

\[
WWB = \sup_h \frac{h^2 \eta(h,0)\eta(h,0)}{2(\eta(h,h) - \eta(h,-h))} \tag{6}
\]

where \( h \) is the difference between the parameter of interest and a test-point and where the function \( \eta \) is defined as

\[
\eta(\alpha, \beta) = \int \frac{1}{(\pi \sigma^2)^{2NT}} \exp \left( -\frac{1}{\sigma^2} \|y - b(\alpha + \beta)\|^2 \right) dy, \tag{7}
\]

by denoting \( \zeta(\alpha, \beta) = \int \frac{1}{(\pi \sigma^2)^{2NT}} \exp \left( -\frac{1}{\sigma^2} \|y - b(\alpha)\|^2 \right) dy \). \( \Omega \) and \( \Theta \) are the observation space and the parameter space, respectively. \( p(y, \cdot) \) and \( p(\cdot) \) denote the joint distribution of the full observation vector and the parameter (possibly a test point) and the \textit{a priori} distribution of the parameter (possibly a test point). Note that one has to respect \( \omega + h \in \Theta \).

3.1. Conditional observation model

From (4), the expression of \( \zeta(\alpha, \beta) \) is given by:

\[
\zeta(\alpha, \beta) = \int \frac{1}{(\pi \sigma^2)^{2NT}} \exp \left( -\frac{1}{\sigma^2} \|\mathbf{x} - b(\alpha + \beta)\|^2 \right) d\mathbf{x} = 1, \tag{8}
\]

one obtains

\[
\zeta(\alpha, \beta) = \exp \left( -\frac{1}{4 \sigma^2} \|b(\omega + \alpha) - b(\omega + \beta)\|^2 \right). \tag{9}
\]

Since \( b(\omega) = u \otimes a(\omega) \), and since \( u^H u = \frac{4\pi^2 A_2^2 \cos^2 \rho + L_{\text{tot}}^2 \sin^2 \rho} {4\pi^2 A_2^2 \cos^2 \rho + L_{\text{tot}}^2 \sin^2 \rho} \), the closed-form expression of \( \|b(\omega + \alpha) - b(\omega + \beta)\|^2 \) is obtained by noting that

\[
\|b(\omega + \alpha)\|^2 = N \left( \frac{4\pi^2 A_2^2 \cos^2 \rho + L_{\text{tot}}^2 \sin^2 \rho} {4\pi^2 A_2^2 \cos^2 \rho + L_{\text{tot}}^2 \sin^2 \rho} \right), \tag{10}
\]

\[
b(\omega + \alpha)^H b(\omega + \beta) = \sum_{i=1}^{N} e^{j \frac{\pi}{2} \Phi_i (\beta - \alpha)}, \tag{11}
\]

and that

\[
b(\omega + \beta)^H b(\omega + \alpha) = \sum_{i=1}^{N} e^{j \frac{\pi}{2} \Phi_i (\beta - \alpha)}. \tag{12}
\]
One observes that the functions $\zeta(\alpha, \beta)$ are no longer depending on the parameter $\omega$, consequently, $\eta(\alpha, \beta)$ can be rewritten as:

$$
\eta(\alpha, \beta) = \zeta(\alpha, \beta) \int_{\Omega} \sqrt{p(\omega + \alpha)p(\omega + \beta)} d\omega.
$$

(15)

Under the uniform distribution prior assumption, one obtains:

$$
\int_{\Omega} \sqrt{p(\omega + \alpha)p(\omega + \beta)} = 1 - \frac{[\alpha + [\beta]}{2}
$$

(16)

From (6), (12), (13), (14), (15) and (16), one obtains the closed-expression of WWB as (17) (shown on the top of next page). Note that the bound is independent of the parameter $\psi$.

### 3.2. Unconditional observation model

From (5), the expression of $\zeta(\alpha, \beta)$ can be expressed as:

$$
\zeta(\alpha, \beta) = \frac{1}{\pi^{2N^2}} \left| R(\omega + \alpha)\right|^{T/2} \left| R(\omega + \beta)\right|^{T/2} 
\times \exp \left( -\frac{1}{\sigma^2} \sum_{i=1}^{N} y(t)^H \Gamma^{-1} y(t) \right)
$$

(18)

By setting $\Gamma^{-1} = \frac{R(\omega + \alpha)^{-1} R(\omega + \beta)^{-1}}{R(\omega + \alpha)^{-1} + R(\omega + \beta)^{-1}}$, one obtains, $\Gamma = \frac{R(\omega + \alpha)^{-1} R(\omega + \beta)^{-1}}{R(\omega + \alpha)^{-1} + R(\omega + \beta)^{-1}}$, which leads to

$$
\zeta(\alpha, \beta) = \frac{1}{\pi^{2N^2}} \left| R(\omega + \alpha)\right|^{T/2} \left| R(\omega + \beta)\right|^{T/2} 
\times \exp \left( -\frac{1}{\sigma^2} \sum_{i=1}^{N} y(t)^H \Gamma^{-1} y(t) \right)
$$

(19)

Since $\int_{\Omega} \frac{1}{\pi^{2N^2}} \left| R(\omega + \alpha)\right|^{T/2} \left| R(\omega + \beta)\right|^{T/2} dy = 1$, one obtains

$$
\zeta(\alpha, \beta) = \frac{1}{\pi^{2N^2}} \left| R(\omega + \alpha)\right|^{T/2} \left| R(\omega + \beta)\right|^{T/2}
$$

(20)

Due to the special structure of $R(\omega + \delta) = \sigma^2 b(\omega + \delta) b(\omega + \delta)^H + \sigma^2 I_{2N}$, one easily gets

$$
||R(\omega + \delta)|| = \sigma^4 \left( 1 + \frac{\sigma^2}{\sigma^4} \right)
$$

(21)

Furthermore, thanks to Woodbury identity, one gets

$$
R(\omega + \delta)^{-1} = \frac{1}{\sigma^2} \left( I_{2N} - \sigma^2 b(\omega + \delta) b(\omega + \delta)^H \right)
$$

(22)

Thus

$$
R(\omega + \alpha)^{-1} + R(\omega + \beta)^{-1} = \frac{1}{\sigma^2} \left( 2I_{2N} - \sigma^2 b(\omega + \alpha)b(\omega + \alpha)^H - \sigma^2 b(\omega + \beta)b(\omega + \beta)^H \right)
$$

(23)

The matrix determinant of $R(\omega + \alpha)^{-1} + R(\omega + \beta)^{-1}$ equals to the product of their eigenvalues. Particularly, there are $2N - 2$ eigenvalues equal to $2/\sigma^2$, and the eigenvectors corresponding to the two remaining eigenvalues is a linear combination of the form $b(\omega + \alpha) + \rho b(\omega + \beta)$. Furthermore, the two above eigenvalues $\nu$ are the solution of the following equation

$$
(\nu^2 - 2\nu + 1) ||b(\omega + \alpha)||^2
$$

Thus

$$
(\nu^2 - 2\nu + 1) ||b(\omega + \alpha)||^2
$$

(24)

which reduces to

$$
\nu^2 \sigma^4 + \nu \sigma^2 \left( 2 - A||b(\omega + \alpha)||^2 - 2 + 2B||b(\omega + \beta)||^2 \right)
$$

(25)

where $A = \frac{\sigma^2}{\sigma^4} ||b(\omega + \alpha)||^2 + \sigma^2$, $B = \frac{\sigma^2}{\sigma^4} ||b(\omega + \beta)||^2 + \sigma^2$, and $C = ||b(\omega + \alpha)||^2 ||b(\omega + \beta)||^2 + \sigma^2$. Since $b(\omega + \alpha)$ and $b(\omega + \beta)$ are nonlinear, thus, their coefficients are equal to $0$. Solving the first coefficient for $\nu$ and substituting $\nu$ to the second coefficient one obtains the equation

$$
\nu^2 \sigma^4 + \nu \sigma^2 \left( 2 - A||b(\omega + \alpha)||^2 - 2 + 2B||b(\omega + \beta)||^2 \right)
$$

(26)

Solving (26) for $\nu$, and since $||b(\omega + \alpha)||^2 = ||b(\omega + \beta)||^2 = ||b(\omega)||^2$, one obtains

$$
||R(\omega + \alpha)^{-1} + R(\omega + \beta)^{-1}|| = \frac{2N}{\nu_1}\nu_1
$$

(27)

Finally, substituting (21), (27) into (20), we have

$$
\zeta(\alpha, \beta) = \left( 1 + \frac{\sigma^2 ||b(\omega)||^2}{\sigma^4} - \frac{\sigma^2 ||b(\omega)||^2}{\sigma^4} \right)^{-1}
$$

(28)

From (12), (13), and (14), one observes that, as for the conditional case, $\zeta(\alpha, \beta)$ does not depends on the parameter $\omega$. Consequently, the closed-form expression of the WWB is given by (29) (shown on the top of next page). Note that the bound is independent of the parameter $\psi$.

### 4. SIMULATION RESULT

In a first simulation, we compare the MSE behavior of the maximum a posteriori estimator (MAP) versus the WWB. We use an uniform linear COLD array consisting of $N = 10$ sensors with the intersensors spacing equal to $\lambda/2$ and $T = 20$ snapshots. The polarization parameter is set to $\rho = \pi/4$, $\psi = \pi/3$, $A_{\omega} = 2\lambda/10$, and $L_{sd} = \lambda/10$. The empirical MSE of the MAP is obtained over 1000
In this paper, we have derived closed-expressions of the WWB in the context of source localization with a COLD array under both conditional and unconditional observation models. The WWB is shown to be a useful tool to capture the threshold effect. Furthermore, we showed that the polarization parameter $\rho$ has a strongly impact on the MSE behavior.

5. CONCLUSION

In this paper, we have derived closed-expressions of the WWB in the context of source localization with a COLD array under both conditional and unconditional observation models. The WWB is shown to be a useful tool to capture the threshold effect. Furthermore, we showed that the polarization parameter $\rho$ has a strongly impact on the MSE behavior.
