Abstract: Abstract

Purpose. *Staphylococcus epidermidis* is a significant pathogen in neonatal sepsis and other nosocomial infections. For further investigations of the colonisation patterns and invasive pathways typing methods that are applicable on large populations of bacterial isolates are warranted.

Methods. In the present study a genotyping method based on polymerase chain reaction (PCR) for the repeat regions of four genes (*sdrG*, *sdrF*, *aap* and *sesE*) that encode for bacterial surface proteins was developed and applied to a sample of well-characterised neonatal blood isolates of *S. epidermidis* (n = 49). The PCR products were visualised on agarose gel (*sdrG*, *sdrF* and *sesE*) or by fragment analysis (*aap*). The discriminatory index (D-index) for genotyping of the different genes was compared to genotyping by pulsed-field gel electrophoresis.

Results. The highest D-index for the PCR-based typing methods was found for the combination of *sdrF*, *sdrG*, and *aap* (D-index 0.94), whereas the optimal two-gene combination (*sdrF* and *aap*) resulted in a D-index of 0.92.

Conclusions. We conclude that the described method can be used for genotyping of large populations of *S. epidermidis* isolates with a sufficient discriminatory capacity, and we suggest that the combination of *sdrF* and *aap* is most suitable to use.

Running title: PCR-based typing of neonatal *Staphylococcus epidermidis*

Key words: *Staphylococcus epidermidis*, genotype, PCR, human

Abstract

Purpose. *Staphylococcus epidermidis* is a significant pathogen in neonatal sepsis and other nosocomial infections. For further investigations of the colonisation patterns and invasive pathways typing methods that are applicable on large populations of bacterial isolates are warranted.

Methods. In the present study a genotyping method based on polymerase chain reaction (PCR) for the repeat regions of four genes (*sdrG*, *sdrF*, *aap* and *sesE*) that encode for bacterial surface proteins was developed and applied to a sample of well-characterised neonatal blood isolates of *S. epidermidis* (n = 49). The PCR products were visualised on agarose gel (*sdrG*, *sdrF* and *sesE*) or by fragment analysis (*aap*). The discriminatory index (D-index) for genotyping of the different genes was compared to genotyping by pulsed-field gel electrophoresis.

Results. The highest D-index for the PCR-based typing methods was found for the combination of *sdrF*, *sdrG*, and *aap* (D-index 0.94), whereas the optimal two-gene combination (*sdrF* and *aap*) resulted in a D-index of 0.92.

Conclusions. We conclude that the described method can be used for genotyping of large populations of *S. epidermidis* isolates with a sufficient discriminatory capacity, and we suggest that the combination of *sdrF* and *aap* is most suitable to use.

Introduction

Neonatal sepsis is a common complication in neonatal intensive care. Premature birth, low birth weight, and long hospital stay are significant risk factors for this condition [1]. In parallel with the survival of more premature and vulnerable infants, *S. epidermidis*, which is known as a commensal, has emerged as the most common cause of neonatal sepsis [2]. These

infections are often caused by multiresistant strains that can persist in neonatal intensive care units (NICUs) for long periods [3-9].

To prevent the spreading of these strains, additional knowledge of the factors that influence the colonisation of newborns, the invasive routes, and other pathogenetic factors of *S. epidermidis* is warranted. These issues cannot be investigated without manageable typing methods requiring an acceptable workload that can fingerprint the large numbers of *S. epidermidis* isolates.

In the search for typing tools applicable to large samples of bacterial isolates, sequencing of the repeat regions in the genes encoding *S. epidermidis* surface proteins, such as *aap* and *sdrG*, has been suggested as a novel typing method [10]. The aim of the present study was to develop a method that combines the diversity in the serine-aspartate dipeptide repeats with an easy-to-use detection approach, and to apply this method to a well-characterised collection of neonatal blood isolates, thus enabling comparison with pulsed-field gel electrophoresis (PFGE).

Materials and Methods

Bacterial isolates

Fifty clinical isolates of *S. epidermidis* previously determined to species level by Staph-zym (Rosco Diagnostica, Taastrup, Denmark), obtained from blood cultures of neonates and collected from 1990 to 1997 at the Neonatal Intensive Care Unit, Örebro University Hospital, were included in this study. After subcultivation, one of the bacterial isolates was identified as a *S. hominis* by sequencing of the *rpoB* gene [11] and was hence excluded, leaving the remaining 49 *S. epidermidis* isolates for further analysis. These isolates have previously been characterised phenotypically and genotypically, including PFGE [4]. According to the clinical and laboratory criteria applied in the former study, 11 isolates were classified as representing

1 true neonatal sepsis and 38 isolates were considered as contaminants. All isolates were stored
2 at -70°C pending analysis and were subcultured on blood agar plates (4.25% Columbia II
3 Agar, BBL, Becton Dickinson, MD, USA; 0.3% Agar No. 2, Lab M Ltd., Bury, UK; 5%
4 bovine blood) and checked for purity prior to DNA preparation.

24 *DNA preparation*

25 A QIAamp DNA Mini Kit was used to isolate DNA from the strains (Protocol D, QIAGEN,
26 Hilden, Germany) with the following modifications; Bacteria obtained from the blood agar
27 plate were dissolved in sterile saline and pelleted, dissolved in 180 µL ATL buffer (QIAGEN)
28 with 10 µL mutanolysin 10 U/µL (Sigma, St. Louis, MO, USA) added and incubated at 37°C
29 for 30 min. The mix was treated with proteinase K and AL buffer (QIAGEN) at 56°C for 30
30 min and DNA-purified according to the tissue protocol, using ethanol and wash buffers
31 supplied in the kit, and finally eluted in 50 µL AE buffer (QIAGEN) and stored at 4°C.

sequences on BLAST (Table 1). To facilitate fragment analysis of the products one primer in each pair was purchased labelled with VIC and 6-FAM, respectively.

The *sdrF*, *sdrG*, and *sesE* amplicons (6 µL) were treated with restriction enzymes for 2 hours. *SdrG* was treated with HpyCH4III (New England Biolabs Inc. (NEB), Ipswich, MA, USA) 5 U at 37°C, *sdrF* with BtsCI (NEB) 10 U at 50°C, and *sesE* with BstYI (NEB) 5 U at 60°C, respectively, and *aap* was analysed without any enzyme treatment. Enzymes were selected using the NEB cutter computer program.

The PCR products and restriction fragments were separated and visualised on a 1.5% agarose gel (Agarose 1000, 1 × TBE, 100 V, 60 min) stained with ethidium bromide. The stained bands were compared to a size marker on each gel (100 bp DNA ladder, Gibco BRL, Carlsbad, CA, USA).

The product sizes of all *aap* PCR products and the enzyme-treated fragments from *sdrF*, *sdrG*, and *sesE* that yielded similar visual results were confirmed by fragment analysis, using ABI 310 or ABI 3130xl, and compared to LIZ-1200 (GeneScan 1200 LIZ, ABI, Foster City, CA, USA) size standard in Peakscanner 1.0/GeneMapper 4.0 (ABI).

Statistical methods

To evaluate discriminatory capacity of different PCR methods, a discrimination index (D-index) for each included gene and for combinations of the studied genes was calculated [13]. Briefly, the D-index represents the likelihood that two randomly picked strains from the sample are separated by the method and recognised as two different strains. This means that a high D-index (close to one) divides the sample into many small groups, whereas, a low D-index (close to zero) indicates that the sample is only divided into a few large groups. Confidence intervals of 95% were calculated, as described by Grundmann et al. [14].

Results

The *sdrG*, *sdrF*, and *sesE* repeats were present in all 49 isolates, whereas *aap* was detected in 38/49 isolates. When the primary PCR products of *sdrG*, *sdrF*, and *sesE* were visualised on the agarose gels, all genes had a single predominating genotype, *sdrG*, 35 isolates; *sdrF*, 36 isolates; and *sesE*, 44 isolates, respectively, with amplicons so similar in size that they were indistinguishable on the gel. To further enhance the discrimination between these genotypes, the PCR products were treated with restriction enzymes, and the subtypes of isolates with similar band patterns were confirmed by fragment analysis.

For *aap* the primary PCR products of all bacterial isolates that carried the *aap* gene were of similar size and thus difficult to separate on the agarose gel. Since no suitable restriction enzyme for the product could be identified, the sizes of these amplicons were instead determined by fragment analysis.

sdrG

After treatment with HpyCH4III restriction enzyme, the *sdrG* samples showed 2–4 distinct bands of a size ranging from 100 to 300 base pairs (bp), representing 13 different genotypes (Table 2). The most common genotype included 25 isolates, which all had identical band patterns. Four genotypes comprised 6, 5, 3, and 2 isolates, respectively, and the final 8 genotypes were only represented by single isolates.

sdrF

After treatment with BtsCI restriction enzyme, the *sdrF* samples showed 1–3 clear distinct bands in the size range of 250–1,000 bp that were used for typing and corresponded to 17 different genotypes. The most common genotype consisted of 19 isolates with identical band

patterns (Table 2). Five genotypes included 7, 5, 3, 3, and 2 isolates, respectively, and 11 genotypes were only represented by single isolates.

sesE

After treatment with BstYI restriction enzyme, the *sesE* samples showed 1–5 distinct bands in the size range of 100–700 bp. These were used for typing and resulted in 8 different genotypes (Table 2). Twenty-four isolates constituted the most common genotype, and the others had 12, 4, 3, and 3 strains, respectively. Three genotypes were represented by single isolates.

aap

Since the *aap* repeat was found in 38/49 isolates, one genotype consisted of 11 isolates without *aap*. The remaining 38 isolates were analysed with fragment analysis showing a size range of 414–514 bp and 7 genotypes with 13, 11, 8, 2, 2, 1, and 1 strains respectively.

PFGE

Six isolates were indistinguishable by PFGE, and 17 were classified as single isolates. The remaining isolates were assigned to various genotypes with 2 or 3 isolates. The 6 indistinguishable isolates were also indistinguishable when analysing *sdrG*, *aap* and *sesE*. Regarding *sdrF*, 5 isolates showed an identical result, whereas, one isolate had a different genotype. The 17 single isolates were subdivided into 11 groups with *sdrG* and *sdrF*, 7 groups with *aap*, and 6 groups with *sesE*.

Discriminatory index

All the calculated D-indices are presented in Table 2. The highest D-index for a single gene was found for *sdrF* (0.82), followed by *aap*, *sdrG*, and *sesE*, respectively. By combining two

genes, the highest D-index was found in *aap/sdrF* (0.92), followed by *aap/sdrG*. When a third gene was added, the D-index was only marginally enhanced (*aap/sdrG/sdrF*, *D-index* 0.94). The corresponding figure for PFGE was 0.98.

Correlation between PFGE and surface protein PCR results

When comparing results of PFGE and the PCR genotyping method, we found concordance in the vast majority of isolates. According to PFGE three clusters including 9, 5 and 5 closely related isolates respectively were identified; the remaining 30 were divided into 5 pairs and 20 single isolates. Using all four of the investigated genes the repeat region PCR characterized the three clusters in exactly the same way as PFGE with the exception of 2 isolates in the largest cluster, where the result for *sdrF* diverted. One of the clusters including five isolates showed exactly the same genotypes as 2 other isolates that were grouped into one pair and one single isolate according to PFGE.

Discussion

In this study we present a novel typing method for *S. epidermidis* based on PCR and the use of restriction enzymes. The method combines feasibility and low cost with a high discriminatory capacity. We used a gel-based detection in combination with fragment analysis to evaluate the replicates, which enables the method to be applicable to large collections of samples.

S. epidermidis constitutes the predominant bacterial species of the normal skin flora and is represented by numerous isolates per individual but is also a significant nosocomial pathogen in predisposed patients. Nosocomial strains of *S. epidermidis* regularly display multiple antibiotic resistance, but the emergence of resistance also to glycopeptides during the recent years further impose the importance of epidemiological surveillance[15,16]. Thus there is an urgent demand for swift, easy-to-use typing methods for *S. epidermidis* not only for research purposes but also for clinical use, for instance in case of an out-break of multi-resistant bacterial strains in a hospital setting. It is our opinion that PCR of repeat regions can become such a tool that can be applied in a situation when an epidemiological survey has collected hundreds of isolates, and there is need to quickly and easily trim down the number of interesting isolates that qualify for further analysis.

In 2007 Monk and Archer [10] suggested sequencing of repeat regions in *aap* and *sdrG* as a typing system for *S. epidermidis* and showed that there was sufficient variation in these genes to make them suitable candidates for gene-based typing. Sequencing of the repeat regions gives detailed information and facilitates interlaboratory comparisons, but on the other hand, it is complicated, expensive, and time-consuming, which limits its use to small samples.

Therefore we instead suggest a gel-based approach to minimize costs and, thus, make the

1 method more suitable for epidemiological studies. Presumably because of these protocol
2 differences, our D-indices for *aap* and *sdrG* seem to be lower than those published by Monk
3 and Archer. To counteract this loss of information when sequencing is replaced by a gel-based
4 approach, two additional genes were studied, and by combining these genes, we can now
5 present a gel-based typing method with a discriminatory power that is comparable to the
6 sequence-based method that Monk and Archer described.

7 In the present study PFGE was used as a reference method. PFGE or multilocus sequence
8 typing (MLST) are widely used for detailed genotyping of *S. epidermidis*, but are too
9 laborious to be applicable to large samples of bacterial strains [3,6,10,17,18] . The high
10 correlation between PFGE and repeat region PCR found in this study might indicate that the
11 methods share a common biological background. On the basis of our data we suggest that the
12 PCR-based typing method presented in this article can be used as an alternative to PFGE or
13 MLST, when high speed and low costs are a higher priority than maximum discriminatory
14 capacity.

15 We targeted repeat regions in four genes encoding different cell-wall-anchored proteins.

16 These proteins have been suggested as important factors in the attachment and interaction
17 between bacteria and human cells. There are additional data supporting the view that some of
18 these proteins are expressed during clinical infections with *S. epidermidis* [12,19]. It has been
19 suggested that repeats are a way to form coil-like structures that enable the protein to span the
20 cell wall (SD-repeats), or to project the A region of the protein away from the cell wall [12].

21 Our choice of genes was based on the fact that they had repeat regions with a high rate of
22 variation, as well as a proven stability when recultured [10]. The genes have also been
23 reported to have a high prevalence in sepsis strains, contaminants and skin flora [12,20,21]. In
24 our material 78% of the isolates were positive for *aap* and 100% for the other genes.

We evaluated four different genes and, as presented in Table 2, no single repeat analysis had a satisfactory discriminatory power. Therefore, we also studied combinations of genes and, in our opinion, two genes were sufficient in this sample to achieve what we consider to be an acceptable discriminatory capacity. Adding a third gene only marginally increased the discriminatory capacity. We, therefore, suggest the combination of *aap* and *sdrF* as suitable for genotypic typing of neonatal *S. epidermidis* isolates, but before the generalisation of these results can be stated, other series of *S. epidermidis* strains with a more heterogeneous origin should be evaluated.

Conclusion

We present a novel gel-based typing method for *S. epidermidis* based on PCR of four genes encoding cell-wall proteins and the use of restriction enzymes. The method combines feasibility and low cost with a high discriminatory capacity, comparable to that of PFGE and sequence-based methods. In our study a combination of two genes, *aap* and *sdrF*, was found to be optimal, but other combinations of the four studied genes could be more suitable when applied to another material of *S. epidermidis* isolates. Our proposed method could be used for epidemiological investigations, for example in case of outbreaks of multiresistant strains or exploring the dynamics of the colonization pattern of newborns. In addition, it enables pathogenic studies of, for example, tracking invasive routes of clinical isolates as well as identification/recognition of virulent clones.
