HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
A free-parameter theoretical model is developed in order to study the ultrafast dynamics in confined diluted magnetic semiconductors induced by laser. The hole-spin relaxation process is due to the Elliot-Yafet mechanism, which involves the scattering of the holes on the localized magnetic impurities. The role played by the quantum confinement and the band structure is analyzed. It is shown that the sample thickness and the background hole density strongly influences the phenomenon of demagnetization. Quantitative results are given for III-V ferromagnetic GaMnAs quantum wells of thickness 4 and 6 nm.

DOI: 10.1103/PhysRevB.81.155309 PACS number(s): 78.20.Ls, 78.30.Fs

I. INTRODUCTION

Ultrafast light-induced magnetization dynamics in ferromagnetic films and in diluted magnetic semiconductors (DMS) is today a very active area of research. Since the observation of the ultrafast dynamics of the spin magnetization in nickel films and the analogous processes in ferromagnetic semiconductors, special interest has been devoted to the development of dynamical models able to mimic the time evolution of the magnetization on both short- and long-time scales. In III-V ferromagnetic semiconductors such as GaMnAs and InMnAs, a small concentration of Mn ions is randomly substituted to cation sites, so that the Mn-Mn spin coupling is mediated by the hole-ion $p-d$ exchange interaction, allowing the generation of a ferromagnetic state with a Curie temperature of the order of 50 K. The magnetism can therefore be efficiently modified by controlling the hole density through doping or by excitation of electron-hole pairs with a laser pulse. In particular, unlike metals, total demagnetization can be achieved in a regime of strong laser excitation.

The time evolution of the total magnetization in wide DMS (layer thickness or the order of $w=70$ nm) excited by laser pulses was presented in Ref. 5. The authors treated the exchange interaction between the holes and the manganese ions in the first quantization formalism and their analysis was performed within a first-order Fermi golden rule (FGR) perturbative framework. In particular, the magnetic ion spin transition rate was evaluated microscopically by means of a balance equation (inverse Overhauser effect) and analogous processes which govern the hole-spin dynamics were taken into account phenomenologically through an equation describing transfer of angular momentum and spin relaxation. In this model, spin relaxation effects are thus included phenomenologically by means of a relaxation time which is considered as an adjustable parameter fixed by fitting the experimental measurements.

In the present work, we are interested in developing a parameter-free theoretical model able to describe the out-of-equilibrium dynamical evolution of the hole and magnetic-ion spins in a strongly confined DMS, i.e., ultrathin quantum wells of width smaller than 10 nm. Thus, we have extended the results derived in Ref. 6 by including the band structure of the semiconductor material and a microscopical explanation of the hole-spin relaxation based on the Elliot-Yafet mechanism. The latter involves the scattering of the holes on the localized magnetic impurities of the DMS.

The ultrafast spin relaxation phenomena observed in III-V semiconductors like GaAs, were interpreted by Elliot and Yafet in Ref. 7 as a consequence of a strong spin-orbit (SO) interaction, which is present in wide gap semiconductors. As another consequence of SO, the mixing between heavy and light-hole component of the wave function around the maximum of the hole band leads to an entanglement between the momenta and the spin degrees of freedom. Elliot and Yafet used these considerations to show that a relaxation phenomenon acting on the momentum of a particle such as the photon scattering by a charge carrier is able to also relax its spin. This mechanism has been studied in a rather general framework in Ref. 8. The study of the Elliot-Yafet mechanism applied to confined semiconductor structures was presented in Ref. 9 and showed that the relaxation time is very sensitive to the Fermi energy of the hole gas and can vary from ps to fs time scale. The same physical assumptions are used in Ref. 10 where an experimental study of the ultrafast demagnetization in Zn$_{1-x}$Mn$_x$Se/Zn$_{1-x}$Be$_x$Se has been performed. In particular, the authors observe a picosecond time evolution of the magnetization induced by an optical excitation. The experimental findings are interpreted in term of a multiple angular momentum transfer from each spin polarized hole populations to the system of the Mn magnetic ions without change of the hole-spin orientation. An estimate of the relaxation time is obtained within the framework of a first-order perturbation theory and is in agreement with the observed value. In particular, the authors assume that the magnetic ions may be considered in a quasiequilibrium state and the details of the miniband diagram have been discarded.

Let’s point out that the spin-orbit interaction plays a very important role in our model. Indeed, our discussion concerning the hole-spin relaxation is manly focused on the effect of this interaction on the spin thermalization. The role of the spin-orbit interaction is rather subtle since, even if it pro-
duces the dominant effect it does not enter explicitly in the calculation. The interpretation of the spin relaxation effect is based on the observation that when the parallel momentum of a hole \( \mathbf{k}_i \) is not strictly zero, the heavy and the light-hole band are mixed together to some extent and the spin projection ceases to be a good quantum number. This effect is taken into account through the \( kp \) formalism by using the Luttinger-Kohn matrix where the linear momentum appears explicitly and is out-of-diagonal. The physical origin for this band mixing (which is hidden in the \( kp \) approach) is the spin-orbit interaction which, for example, destroys the degeneracy at the \( \Gamma \) point and generates a coupling among different hole states.

Usually a distinction is done between: (i) normal processes for which the Kondo-like scattering between Mn magnetic impurities and holes involves a change in the hole sub-band (intersub-band process) and (ii) the processes for which initial and final hole states belong to the same sub-band (intraband process).

In our approach, both type of processes can qualitatively be explained in the same way: scattering processes that modify the momentum of a particle is able to also modify the spin state of a hole in the presence of a strong spin-orbit interaction. For this reason, in our work, we consider both cases (intraband- and intersub-band processes) as different manifestation of the E-Y mechanism.

The paper is organized as follows. In the next section, the theoretical models are described. In Sec. III, numerical results are presented and discussed. Finally, the paper is ended with concluding remarks.

II. THEORETICAL MODELS

A. Hole-spin relaxation time: Dynamical simulation

This section is devoted to the modeling of the coherent spin evolution of a hole state interacting with a single Mn impurity. The main contribution to the time evolution of the hole-spin expectation value is due to the exchange interaction

\[
V_{\text{ex}} = \gamma \mathbf{M}_{m,m'} \cdot \mathbf{S}_{m',z'} \cdot \delta(\mathbf{R}_m - \mathbf{r}).
\]

where \( \gamma \) is the exchange coupling constant and \( \mathbf{r} (\mathbf{S}) \), \( \mathbf{R}_m (\mathbf{M}) \) are, respectively, the position (spin matrix) of the hole and ion. Hereafter, the spin operators corresponding to the \( \mathbf{S} \) and \( \mathbf{M} \) matrices will be denoted by \( \mathbf{S} \) and \( \mathbf{M} \), respectively. The exchange interaction factors into two terms acting, respectively, on the spatial and the spin degrees of freedom. In particular, the term \( \mathbf{M}_{m,m'} \cdot \mathbf{S}_{m',z'} \) conserves the total spin of the system allowing for a transfer of spin angular momentum between the holes and the magnetic ions. The leak of ion spin polarization is compensated by an equal rising of the spin polarization of the hole gas. The term \( \delta(\mathbf{R}_m - \mathbf{r}) \) acts only on the spatial degrees of freedom and is responsible for the change of the linear momentum of the scattered particle. Elliot and Yafet have observed that, when the spin projection is not a good quantum number, as it is the case for a hole state in a semiconductor alloy, any interaction which scatters a particle from a linear momentum \( k \) to \( k' \) will also affect the hole spin with a consequent probability of modifying its spin direction. \(^7\) We conclude that, since the exchange interaction changes both the spin and the linear momentum of the hole, it can be responsible for the relaxation of the total hole spin in the same way as the phonon scattering process does.

We illustrate our conclusions with the following simple example. For the sake of simplicity, we here refer to the special case of a spherical symmetry of the band diagram. Our conclusions are independent on this approximation which will be not used in the next sections. The \( kp \) Hamiltonian \( \mathcal{H}_{kp} \) of a hole in a uniform semiconductor bulk structure is a \( n \times n \) matrix (where \( n \) is the total number of bands) parametrized by the quasi-momentum \( \mathbf{k} \) of the particle. As it is well known, for \( \mathbf{k} = 0 \), \( \mathcal{H}_{kp} \) is diagonal and therefore the band eigenstates are also spin eigenstates. For \( \mathbf{r} = \mathbf{r}_0 \) we consider a hole in a \( n \)-th \( \mathbf{k} = 0 \) eigenstate, and we denote its wave function by \( \xi_n(\mathbf{k},t_0) = \psi_n \delta(\mathbf{k}) \) with \( \mathcal{H}_{kp}(0) \psi_n = \epsilon_{k_n} \psi_n \) where \( \epsilon_{k_n} \) are the eigenvalues of \( \mathcal{H}_{kp}(\mathbf{k}) \). Under the action of the exchange interaction of Eq. (1) the particle is scattered from \( \mathbf{k} = 0 \) to a superposition of states with different momenta.

According to the Elliot-Yafet mechanism, when the states with \( \mathbf{k} \neq 0 \) start to be populated the hole spin starts to precess. For the sake of simplicity we consider a single scattering event where, for example, the hole spin is lowered by one unit of angular momentum thanks to the operator \( \mathcal{M}^+ \mathbf{S}^- \) and its momentum becomes \( \mathbf{k}_0 \) (the following considerations can be easily extended to a superposition of states). The spin component of the state \( \xi_n = \mathbf{S}^+ \xi_n \) is no more an eigenstate of \( \mathcal{H}_{kp}(\mathbf{k}_0) \) and its time evolution can be easily estimated by a projection over the spin eigenstates \( \xi_m(\mathbf{k}_0) \) of \( \mathcal{H}_{kp}(\mathbf{k}_0) \). In particular, the hole-spin expectation value with respect to a given direction \( \hat{\mathbf{n}} \) reads

\[
\langle \xi_m | \hat{\mathbf{n}} \cdot \mathbf{S} | \xi_n \rangle = \sum_{n_1,n_2} \langle \xi_{n_1}(\mathbf{k}_0) | \hat{\mathbf{n}} \cdot \mathbf{S} | \xi_{n_2}(\mathbf{k}_0) \rangle \langle \xi_{n_2}(\mathbf{k}_0) | \xi_m(\mathbf{k}_0) \rangle e^{i \mathbf{k}_0 \cdot \mathbf{r}_0}.
\]

A theoretical study shows that, in the spherical approximation of the band diagram, for any \( \mathbf{k}_0 \) it is always possible to find a direction \( \hat{\mathbf{n}}_{\mathbf{k}_0} \) for which the spin of the hole eigenvector \( \xi_m(\mathbf{k}_0) \) is oriented along \( \hat{\mathbf{n}}_{\mathbf{k}_0} \).\(^{11}\) It is immediate to verify that only the spin component of \( \xi_m' \) along \( \hat{n}_{\mathbf{k}_0} \neq \hat{z} \) is stationary while the perpendicular component oscillates with a frequency of the order of \( \omega_{\mathbf{k}} = (\epsilon_{k_{n_1}} - \epsilon_{k_{n_2}})/\hbar \). In a semiconductor device like a DMS, the quantum confinement of the hole gas can give rise to a strong splitting of the energy levels and consequently the oscillation frequencies \( \omega \) can induce a non-negligible relaxation of the \( z \) projection of the hole spin (some numerical simulations concerning the stationary states of a 4–6 nm DMS will be presented in Sec. III). In our discussion we have simplified the spin dynamics by assuming a single hole-ion scattering event (which is in the spirit of a first-order Dyson expansion). Generally, the linear momentum of the hole is continuously modified by the Dirac delta function and the previous approximation holds when the scattering frequency is lower than the rotation frequency \( \omega \).

These considerations can be verified with the following numerical model. We consider the time evolution of the hole wave function in the presence of the impurity magnetic field.
in the single-particle approximation. In particular we are interested in the study of the spin evolution in a strongly confined DMS (magnetic layer thickness of the order of a few nm). According to the kp theory the evolution equation for the hole envelope function is

\[ i\hbar \frac{\partial \tilde{\xi}_n(r,t)}{\partial t} = \sum_{n'} \left( H_{kp} \left( \frac{\partial}{\partial r}, \frac{\partial}{\partial z} \right) \right)_{n,n'} \tilde{\xi}_{n'}(r,t) + \gamma \sum_{n',\eta} M_{R_\eta} \cdot S_{n',\eta} \delta(r - R_\eta) \tilde{\xi}_{n'}(r,t). \]

By using \( \tilde{\xi}_n(k_i,z,t) = \int \tilde{\xi}_n(r,t) e^{-ik_i \cdot r} d\zeta, \) we obtain

\[ i\hbar \frac{\partial \tilde{\xi}_n(k_i,z,t)}{\partial t} = \sum_{n'} \left( H_{kp} \left( k_i, \frac{\partial}{\partial z} \right) \right)_{n,n'} \tilde{\xi}_{n'}(k_i,z,t) + \gamma \sum_{n',\eta} M_{R_\eta} \cdot S_{n',\eta} \int \tilde{\xi}_{n'}(k_i',z,t) d|k_i'|, \]

where the \( z \) axis is the quantization direction, \( M_{R_\eta} = \text{Tr}(M) = \sum_n |R_\eta,m| M(r) |R_\eta,m\rangle \) denotes the spin of the ion located in \( R_\eta \) with a magnetization directed along the \( z \) axis. Furthermore, we have used the following approximations: \( M_{R_\eta} = \sum_n |R_\eta,m| M(r) |R_\eta,m\rangle \) and the \( k_i \) dependence of \( M \) has been discarded. Due to the presence of the delta function in the above equation, we have \( R_\eta = z \) and \( M \) is the ion spin operator.

It is easy to show that if the Hamiltonian is axially symmetric with respect to the \( z \) axis and if the initial condition for \( \tilde{\xi}_n \) depends only on the modulus of \( k_i \), then the solution at any time will also only depend on \( |k_i| \), leading to

\[ i\hbar \frac{\partial \tilde{\xi}_n(k_i,z,t)}{\partial t} = \sum_{n'} \left( H_{kp} \left( k_i, \frac{\partial}{\partial z} \right) \right)_{n,n'} \tilde{\xi}_{n'}(k_i,z,t) + \gamma \sum_{n',\eta} M_{R_\eta} \cdot S_{n',\eta} \int \tilde{\xi}_{n'}(k_i',z,t) d|k_i'|. \]

In Fig. 1, the numerical solution of the above equation is shown by taking the initial condition \( \tilde{\xi}_0(k_i,z,t_0) = 4\pi^2 \delta(k_i) \varphi_{n_0}^{3/2}(z) \) where the functions \( \varphi_n \) are solutions of

\[ \sum_{n'} \left( H_{kp} \left( 0, \frac{\partial}{\partial z} \right) \right)_{n,n'} \varphi_{n'}^m = \varepsilon^m \varphi_n^m m = \pm 3/2; \pm 1/2. \]

In particular, the quantity \( \sigma = \sum_n \int |\tilde{\xi}_n(k_i,z,t)|^2 d\zeta \) for \( |k_i| = 0 \) [Fig. 1(a)] and for \( |k_i| > 0 \) [Fig. 1(b)] is depicted as a function of time. The numerical solution shows that, on a time scale of the order of 100 fs, as a consequence of the hole-ion local scattering, the component with non vanishing quasimomentum of the solution starts to be populated and the initial coherence of spin of the particle is lost. The expectation value the \( z \) component of the spin is thus mediated over the states with \( |k_i| > 0 \) where the expectation value is smaller than \( 1.5 \).

**B. Dynamical modeling of the exchange interaction**

This section is devoted to a deeper investigation of the hole-spin relaxation effects induced by the exchange interaction. We consider the simplest case of a two-particle system constituted of a single hole interacting with one Mn impurity. The effect of the other magnetic ions is modeled by an effective magnetic potential \( H_{\text{ex}} \) acting on the hole (mean-field approximation). The total Hamiltonian is therefore

\[ H = H_{kp} + H_{\text{ex}} + \mathcal{V}_{\text{ex}}, \]

where the Luttinger-Kohn Hamiltonian \( H_{kp} \) describes the effect of the lattice. The exchange interaction is

\[ \mathcal{V}_{\text{ex}} = \gamma M \cdot \tilde{S}(r - R_\eta), \]

where \( S \) and \( M \) are the spin operators acting on the Hilbert space of the holes and ions, respectively. The exchange interaction shows that the natural Hilbert space where to perform the theoretical study of the system is

\[ H^1 = H_h \otimes H_{\text{Mn}}, \]

where \( H_h \) and \( H_{\text{Mn}} \) are the Hilbert space of the holes and ions, respectively. The wave function of the system is

\[ \Psi(r,s;R_\eta,m) = \langle r,s | R_\eta,m | | h \rangle \otimes | \text{Mn} \rangle, \]

where \( |h \rangle (|\text{Mn} \rangle) \) is the component of the hole (ion) wave function in the Dirac formalism. \( r \) \( (R_\eta) \) and \( s \) \( (m) \) are the spatial coordinates and spin projections of the holes (ions). The Schrödinger equation for \( \Psi \) takes into account all the coherent correlations between holes and ions. The formulation of the problem in the Hilbert space \( H^1 \) requires a great numerical effort even for solving the simple two-particle problem. This is due to the complete mixing of the spatial degrees of freedom and those pertaining to the hole and ion spins (because generally the total wave function does not factor into a product of the holes and ions wave functions). The usual way to circumvent this difficulty is to project the solution in the Hilbert space

\[ H^2 = H_h \otimes H_{\text{Mn}}. \]
\[ \mathcal{P}^h \mathcal{O} = \text{Tr}_{\text{Mn}}\{ \mathcal{O} \}, \]

where \( \mathcal{O} \) is a generic operator acting on \( H^1 \) and \( \text{Tr}_{\text{Mn}} \) denotes the partial trace with respect to the ion spin degrees of freedom. In particular, we have

\[ \mathcal{P}^h \mathcal{V}_{\text{ex}} = \gamma (r - R_y)^2 \langle M \rangle \cdot S, \]

\[ \mathcal{P}^h \mathcal{V}_{\text{ex}} = \gamma (r - R_y)^2 \langle S \rangle \cdot \mathcal{M}, \]

where \( \langle M \rangle \) and \( \langle S \rangle \) are, respectively, the expectation value of the ion and hole spin.

We point out that the reduction in the dimensionality of the problem may cause a misleading interpretation of the spin dynamics induced by the exchange operator. We illustrate the limitations of this approximation procedure with the following example. For the sake of simplicity, we assume that the total spin of both the holes and the ions is \( S^M = \frac{1}{2} \) and we focus our attention on the spin degrees of freedom of \( \mathcal{V}_{\text{ex}} \). For the following discussion, we consider the simplified exchange interaction (we set \( \gamma = 1 \))

\[ \mathcal{V}_{\text{ex}} = \mathcal{M} \cdot S. \]

In \( H^1 \) the hole-ion system is defined by the density matrix

\[ \rho^2(t) = [\langle h(t) \rangle \otimes [Mn(t)]](h(t) \otimes [Mn(t)]), \]

where \( \langle M \rangle \) can be expressed in term of \( \rho^2_{\text{Mn}} \); \( \langle M \rangle = \text{Tr}(\mathcal{M} \rho^2_{\text{Mn}}) \). In this section for sake of simplicity we pose \( \hbar = 1 \). It is easy to see that Eqs. (13) and (14) are equivalent to

\[ \frac{\partial \langle S \rangle}{\partial t} = \langle S \rangle \land \langle M \rangle, \]

\[ \frac{\partial M}{\partial t} = \langle M \rangle \land \langle S \rangle. \]

It is not possible to derive Eq. (13) from the exact equation of motion of \( \rho^1 \) in \( H^1 \)

\[ i \frac{\partial \rho^1}{\partial t} = [\mathcal{H}_{\text{ex}}^1, \rho^1]. \]

In fact, if we apply the projection operator to the previous equation and identify \( \rho^2_{\text{Mn}} = \mathcal{P}^h \rho^1, \rho^2_{\text{Mn}} = \mathcal{P}^h \rho^1 \), in order to obtain Eq. (13) we need the following approximation:

\[ \mathcal{P}^h (\mathcal{V}_{\text{ex}}^1) = \mathcal{P}^h (\mathcal{V}_{\text{ex}}^1) \mathcal{P}^h (\rho^1). \]

If one solves Eqs. (15) and (16) using an initial condition where the hole spin is antiparallel to the ion spin (i.e.,

\[ \rho^2_{\text{Mn}}(t_0) = \frac{1}{2} \mathbbm{1} \] and \( \rho^2_{\text{Mn}}(t_0) = \frac{1}{2} \mathbbm{1} \) the z axis being the quantization direction) one obtains

\[ \langle M \rangle(t) = \langle M \rangle(t_0) = -\frac{1}{2} \mathbf{z}, \]

\[ \langle S \rangle(t) = \langle S \rangle(t_0) = \frac{1}{2} \mathbf{z}. \]

In contrast to what was expected, the exchange interaction in the reduced Hilbert space does not induce any spin rotation. On the other hand Eq. (17) leads to a non trivial dynamics. This can be seen by writing the exchange interaction in the canonical basis of \( H^1 \) where the wave vector is represented by

\[ \Psi = \begin{pmatrix} \psi(s = \uparrow, m = \uparrow) \\ \psi(s = \downarrow, m = \uparrow) \\ \psi(s = \uparrow, m = \downarrow) \\ \psi(s = \downarrow, m = \downarrow) \end{pmatrix} \]

\[ \mathcal{V}_{\text{ex}} = \begin{pmatrix} 1/4 & 0 & 0 & 0 \\ 0 & -1/4 & 1 & 0 \\ 0 & 1 & -1/4 & 0 \\ 0 & 0 & 0 & 1/4 \end{pmatrix}. \]

In Fig. 2, we present the expectation value of the ion spin given by \( \langle M \rangle = \text{Tr}_{\text{Mn}}(\mathcal{M} \mathcal{P}^h \rho^1) \) where \( \rho^1 \) is the numerical solution of Eq. (17). Let us note that, since to a pure-state solution in \( H^1 \) corresponds a mixed-state solution in the reduced Hilbert space \( H^2 \), the modulus of \( \langle M \rangle \) is no more constant. The aim of the above discussion was to reveal the modeling error that is made when the full dynamical correlation between hole and ion spins is discarded.

In Sec. II A, we estimated the hole-spin relaxation time by neglecting the exchange interaction. Indeed, this is due to the assumption that the hole-spin dispersion comes from (i) the Dirac delta function in the exchange Hamiltonian, and (ii) the spin-orbit interaction which entangles the linear momentum and the spin projection of the holes. When a hole is scattered by the hard-core potential represented by the Dirac delta function, all the values of the outgoing quasimomentum

\[ \sqrt{2} \langle \mathcal{O} \rangle \]

\[ \mathcal{P}^h \mathcal{O} = \text{Tr}_{\text{Mn}}\{ \mathcal{O} \}, \]

\[ \mathcal{P}^h \mathcal{V}_{\text{ex}} = \gamma (r - R_y)^2 \langle M \rangle \cdot S, \]

\[ \mathcal{P}^h \mathcal{V}_{\text{ex}} = \gamma (r - R_y)^2 \langle S \rangle \cdot \mathcal{M}, \]

\[ \langle M \rangle(t) = \langle M \rangle(t_0) = -\frac{1}{2} \mathbf{z}, \]

\[ \langle S \rangle(t) = \langle S \rangle(t_0) = \frac{1}{2} \mathbf{z}. \]
are excited and therefore a fast dispersion of the spin projection is expected even in the absence of an exchange of spin angular momentum between the holes and the ions. In presence of this scattering regime, the long-time correlation between the spin of the holes and that of the ions can be discarded and we can set the dynamics in the Hilbert space $\mathbb{H}$ where the spin correlation is averaged out by the projection procedure described in this section. Furthermore we remark that in Sec. II A we have discarded the fluctuations of the mean spin polarization of the ions induced by the presence of the hole. In particular, the terms $\mathcal{M}^z \mathcal{S}^z$ describe a two-particle interaction where both the hole spin and the ion spin are modified. They cannot be included in the single-particle approximation used to derive the equation of motion and a static concentration of the background ion spin can thus be assumed. The full interaction $\mathcal{M} \cdot \mathcal{S}$ is restored in the next paragraph where we have applied an approach based on the Fermi golden rule for describing the dynamics in a confined DMS including both the spin polarization flux and the hole-spin relaxation.

C. Time evolution of the total magnetization in confined DMS

We derive the time evolution equations for the hole and ion densities in the first quantization formalism and within the framework of the first-order FGR approximation. The exchange interaction $\mathcal{V}_{ex} = \gamma \mathcal{M} \cdot \mathcal{S} \delta(R_s - r)$ is treated as a perturbation. We define the normalized hole and ion densities $n_s$ and $n_m$ as,

$$n_s = \frac{1}{N^N} \sum_{k_i} n_{k_i,s},$$

$$n_m = \frac{1}{N^N} \sum_{\eta} n_{\eta,m},$$

where $n_{k_i,s}$, $n_{\eta,m}$ are, respectively, the hole and ion occupation probability and $k_i$ is the transverse momentum which lies in the plane of the quantum well. $N^N$ and $N^M$ are the total density of holes and ions, respectively, and $m$ denotes the $z$ projection of the ion spin, $s=(s,b)$ where $s$ and $b$ are, respectively, the band and sub-band index. The latter enumerates bound states in the $z$ direction (the periodicity of the total Hamiltonian is lost along the $z$ axis). For the light and heavy hole states $s=\pm 3/2, \pm 1/2$, each band is labeled with the corresponding spin at the $\Gamma$ point (which is still, for $k_i \neq 0$, the main contribution to the spin projection). The time evolution equations read

$$\frac{\partial n_s}{\partial t} = \frac{1}{N^N} \sum_{m} \mathcal{V}_{s,m},$$

$$\frac{\partial n_m}{\partial t} = \frac{1}{N^M} \sum_{s_i} \mathcal{V}_{s,m},$$

where

$$\mathcal{V}_{s,m} = N^d \frac{2 \pi}{\hbar} \sum_{k_i,k_i'} \sum_{m'} |\mathcal{V}_{i-i'}|^2 |n_{m} n_{k_i,s} (1 - n_{k_i',s}) - n_{m} n_{k_i,s} (1 - n_{k_i',s})| \delta(E_i - E_j),$$

(25)

We have applied the $kp$ theory for evaluating the scattering states $\psi_{k_i,s}(r)$ for a confined heterostructure. In a bulk semiconductor, the scattering states coincide with the Bloch wave functions $\psi_{k_i,s}(r)=e^{i \mathbf{k}_i \cdot r} \chi_{k_i,s}(r)$.

The $kp$ theory assumes that, when the lattice translational symmetry is broken along a given direction, as it is the case for a confined DMS, the periodic part of the Bloch function $u_{k,s}$ can be considered to be nearly the same for all the heterostructure, and the spatial variation of the band diagram can be modeled by introducing a smooth variation of the parameters characterizing the bulk structure in the $z$ direction. In the problem we are concerned with, the scattering wave functions $\psi_{k,s}(r)$ are the eigenstates of the DMS heterostructure

$$\left( - \frac{\hbar^2}{2m_0} + V_p(r) + V_m(r) + V_{Z}(r) \right) \psi_{k,s}(r) = \varepsilon_{k,s} \psi_{k,s}(r),$$

(26)

where $m_0$ is the electron mass, $V_p(r)$ is the periodic lattice potential and $V_m(r)$ is a nonperiodic external potential, which takes into account different effects like: (i) the bias voltage applied across the device; (ii) the contribution coming from the doping impurities; (iii) the self-consistent field produced by the mobile electronic charge carriers. $V_{Z}(r)$ is the Zeeman contribution which is calculated self-consistently from the hole-spin density as in the Zener model.  

Expansion of $\psi_{k,s}(r)$ on the basis of the Kane $kp$ functions reads

$$\psi_{k,s}(r) = \sum_{n} u_{k,n}(r) \varphi_{n,s}(r).$$

The envelope functions, $\varphi_{n,s}(r)$, are solutions of the Kane Hamiltonian system.
where \( \psi_{n}^{k_{s}}(k_{i}',z) = \frac{1}{\sqrt{V}} \int \tilde{\psi}_{n}^{k_{s}}(r) e^{-ik_{i}'r} dr \) and can be written as \( \phi_{n}^{k_{s}}(k_{i}',z) = \delta(k_{i}'-k_{1})\chi_{s}^{k_{s}}(z) \) where the functions \( \chi_{s}^{k_{s}}(z) \) are solutions of the system

\[
\sum_{n'} \left[ \mathcal{H}_{kp}(k_{i}', \frac{\partial}{\partial z'}) \right]_{n,n'} \psi_{n'}^{k_{s}}(k_{i}',z) = \epsilon_{n} \psi_{n}^{k_{s}}(k_{i}',z),
\]

where \( \psi_{n}^{k_{s}}(k_{i}',z) \) are solutions of the system \( \sum_{n'} \left[ \mathcal{H}_{kp}(k_{i}, \frac{\partial}{\partial z}) \right]_{n,n'} \chi_{n}(z) = \epsilon_{n} \chi_{n}(z) \). (27)

We note that care has to be taken to obtain a correct modeling of the boundary conditions in the envelope kp approach. Indeed, in the envelope function approximation, the inhomogeneity of the system is commonly taken into account by considering bulk band parameters which vary discontinuously at the interfaces. In this approach, microscopic effects due to the interfaces are neglected and, in particular, the periodic part of the Bloch’s function is considered nearly unaffected by their presence. Despite the fact that discontinuous band parameters go beyond the range of validity of the envelope function approximation, it has been observed that such an ansatz is capable of describing electron and hole states in quantum wells in a very good agreement with experiment (for a general discussion of this point see Refs. 11 or 15 for the case of “nasty” discontinuity). More specifically, in our model we have followed the same procedure as the one given in Ref. 16 or in Ref. 12. Since we restrict ourselves to the Luttinger-Kohn Hamiltonian, spurious solutions that could affect a general Kane model do not occur.11

If \( S \) is an operator acting on the hole-spin Hilbert space, we have

\[
S(0,n)^{P} = S(n)|\tilde{S}(n)^{P},
\]

where \( u_{n}^{\pm}(r) d^{2}r \). For example, for the heavy or light-hole band (where \( n = \pm 3/2; \pm 1/2 \)) the raising-lowering operator \( S^{\pm} \) gives

\[
S^{\pm}(0,n)^{P} = \sqrt{(\mathbb{S}^{h} \mp n)(\mathbb{S}^{h} \mp n + 1)}(0,n \pm 1)^{P},
\]

where \( \mathbb{S}^{h} \) is the total angular momentum of the hole and

\[
\langle r| S| n \rangle = \sum_{n'} S(n') \phi_{n}^{k_{s}}(r) u_{n}^{\mp}(0,r)^{P},
\]

where \( \langle r| n \rangle = \phi_{n}^{k_{s}}(r) \). The scattering matrix element becomes

\[
\mathcal{V}_{k_{1}s,1}^{\mp,m,m'} = \gamma(m)|\mathcal{M}^{m'}|\gamma(s) \mathcal{S}(r - \mathbf{R}_{g}) S^{\mp}|k_{1},s_{1}\rangle
\]

\[
= \gamma\mathcal{M}_{m,m'}^{\mp} \int \tilde{\psi}_{n}^{k_{s}}(r) \tilde{\psi}_{n}^{k_{s}}(r) \times u_{n}^{\mp}(0,r) d^{2}r.
\]

In order to perform the above integration, we have carefully considered the delta function, \( \delta(r - \mathbf{R}_{g}) \). To split the fast oscillating component of the integral with respect to the smooth one is represented by the envelope function, we have assumed that the original delta function is smeared out over the volume of the Wigner-Seitz (WS) cell. Thus, \( \delta(r - \mathbf{R}_{g}) \) is replaced by a quasismooth step function \( \delta_{g}(r - \mathbf{R}_{g}) \) which is nonvanishing only near the \( j^{2g} \) WS cell (this approximation is studied in detail in Ref. 17). This procedure is consistent with the physical picture underlying the exchange interaction in DMS for which the hole-ion coupling takes place only inside the ionic sites. The same argument was used in Ref. 18 where the exchange coupling is assumed to have a Gaussian shape and whose parameters were chosen to fit experimental measurements. By using the Fourier decomposition

\[
\tilde{\psi}_{n}^{k_{s}}(r) = \int \delta(k_{i} - k_{1}) \chi_{s}^{k_{s}}(k_{i}) e^{i(k_{i} + k_{i}' - k_{1})r} dr = \epsilon_{k_{i}} \chi_{s}^{k_{s}}(z),
\]

the expression (29) reads

\[
\mathcal{V}_{k_{1}s,1}^{\mp,m,m'}(\mathbf{R}_{g}) = \gamma\mathcal{M}_{m,m'}^{\mp} \int \left( \mathcal{R}_{m}^{\mp}(\mathbf{R}_{g}) \chi_{s}^{k_{s}}(k_{i}) e^{ik_{i}'r} \chi_{s}^{k_{s}}(k_{i}) \right) \times u_{n}^{\mp}(0,r) d^{2}r.
\]

Finally, the scattering kernel \( \mathcal{W} \) can be written as

\[
\mathcal{W}_{s,n} = \frac{2\pi}{h} |\mathcal{M}^{n}(s)|^{2} \sum_{m} |\mathcal{S}(0,n)\rangle \langle \tilde{S}(n)|^{P} d^{2}r.
\]

where \( \mathcal{S}(0,n)^{P} = S(n)|\tilde{S}(n)^{P} \) and \( \phi_{n}^{k_{s}}(r) \) are solutions of the system

\[
\sum_{n'} \left[ \mathcal{H}_{kp}(k_{i}, \frac{\partial}{\partial z}) \right]_{n,n'} \chi_{n}(z) = \epsilon_{n} \chi_{n}(z).
\]

In the above expressions, \( \mathcal{M}_{f}^{n} = S/2, f(E_{k}) \) is the Fermi-Dirac function for an energy \( E_{k} + E_{0} \) and \( \mu_{s} \) is an out-of-equilibrium chemical potential. The energy \( E_{m} \) of the \( m^{th}

PHYSICAL REVIEW B 81, 155309 (2010)
The ionic level is obtained by using the Zener mean-field interaction. In the axial approximation $[\mathcal{H}_A(p_0, z)]$ depends on $k_0$ only through $|k_0|^2\alpha^2$ where $\alpha$ is the angle between $k_0$ and the $x$ axis, and therefore, $\mathcal{E}(k_0, k')=\mathcal{E}(|k_0|^2|k'|^2)$ (this is true only up to the second order in $k$). Finally, for a two-dimensional system, we have

$$\mathcal{E}(k_x, k_y) = m^*_{e}\frac{2\pi\hbar^2}{\hbar^2} \int_{k_x, k_y} \mathcal{E}(k_x, k_y).$$

III. NUMERICAL RESULTS

Equations (23)–(25) have been solved in order to study the role played by the quantum confinement and the hole density on the dynamical evolution of the total magnetization after laser irradiation. We have considered a DMS sample composed of a Ga$_{0.925}$Mn$_{0.075}$As layer deposited on a GaAs buffer layer and a semi-insulating GaAs substrate. The initial hole and magnetic-ion distributions are calculated using the stationary mean-field Zener model. The laser pulse excitation is assumed to take place at $t=0$. Details and justifications based on physical grounds of the excited hole density used in the calculation are given in Refs. 5 and 6. In all simulations the thickness $w$ of the doped layer varies within the range 4–6 nm, $\gamma=0.09$ eV nm$^{-3}$ and $m^*_{e}=0.067 m^*_0$. In Figs. 3–5, the miniband diagrams calculated by using the Zener mean-field theory are depicted. In Fig. 3, a $w = 6$ nm DMS sample without Mn doping and having a background hole density $n^b=\sum n^h_{\ell}=10^{-4}$ nm$^{-3}$ is considered. In all the figures, the $z$ axis corresponds to the confinement direction of the hole gas coming from the abrupt junction between the DMS active Mn-doped region and the insulating layers. The $x–y$ plane represents the free parallel directions of motion for the holes. On the left panel of Figs. 3–5, the self-consistent hole band edge profile is represented (the Coulomb repulsion between the holes is taken into account by using the standard mean-field Hartree approximation). The horizontal line denotes the position of the hole chemical potential and the crosses represent the energies of the resonant levels (which correspond to the $k_z=0$ energy values of the various minibands). On the central panel, the steady state miniband diagram (here each miniband is twofold degenerated) for a temperature $T^b=10$ K is depicted. On the upper right panel, the expectation value of the hole total angular momentum $J_z$ is shown as a function of $|k_z|$. For $|k_z| 
eq 0$ the off-diagonal components of the $kp$ Hamiltonian mix the heavy- and light-hole components of the eigenstates and therefore the $z$ component of the hole-spin polarization is reduced. On the lower right panel, the occupation probability of the different bands is represented: the figure shows that, for a temperature of 10 K and a hole density of $10^{-4}$ nm$^{-3}$, only two (degenerate) minibands are populated. Furthermore, a comparison of $J_z$ reported on the upper right panel shows that the contribution of the hole with parallel momentum greater than 0.1 nm$^{-1}$ (where the heavy and hole com-

FIG. 3. (Color online) Band diagram of a 6 nm GaAs quantum well without Mn magnetic ions (see text for the meaning of the different panels). The density of holes is $n^h=10^{-4}$ nm$^{-3}$ and the temperature $T^b=10$ K.

FIG. 4. (Color online) Band diagram of a 6 nm Ga$_{0.925}$Mn$_{0.075}$As quantum well. The background hole density is: (a) $n^b=10^{-4}$ nm$^{-3}$, (b) $n^b=5\cdot10^{-4}$ nm$^{-3}$. The temperature is $T^b=10$ K.
ponents mix together) gives a non-negligible contribution to the total spin polarization of the hole gas. As a consequence, the smearing of the hole distribution around $|k_z|=0$ cannot be discarded and the hole-spin projection along the $z$ axis cannot be considered as a good quantum number.

In Fig. 4 and 5, we show, for different values of the hole density, the modification of the miniband diagrams when the Mn doping is included. The numerical results reveal that the band characteristics (minimum, shape, and expectation value of the spin eigenstates) are strongly affected by the hole concentration. Therefore, we also expect that the dynamical evolution of the total magnetization will be modified (may be characterized by different time scales) when the doping concentration and the layer thickness $w$ of the sample are varied.

In Fig. 6, we show the static magnetization as a function of temperature, obtained by using the mean-field Zener model. In particular, we represent the expectation value of the hole spin $\langle S_z \rangle$ (which lies in the interval $[-0.5, 0.5]$) which is typically preferred to the total angular momentum $J_z$ for representing the static magnetization curves (see, for example, Ref. 16). As already mentioned, the equilibrium values of the magnetization define the initial distributions that are used in the dynamical simulations. In particular, the equilibrium ion (panel a) and hole (panel b) magnetization for different hole background densities are represented.

In Fig. 7 and 8, the time evolution of the total magnetization for different sample thicknesses is presented. The laser excitation takes place at $t=0^+$ and according to the discussion of Ref. 6 its main effect is to raise instantaneously the initial temperature of the hole gas. In Fig. 7 and 8, the initial temperature is $T^h=10$ K and the corresponding temperature of the excited hole gas is $20$ K. Thus, we are considering a very weak laser excitation regime, which does not notably modify the self-consistent band structure calculated at equilibrium. Numerical results show that our model is able to reproduce the initial ultrafast lowering of the total magnetization of the sample and the subsequent recovery of the equilibrium state. In particular, the characteristic times of these processes are strongly affected both by the hole background density and the sample thickness. This is clearly illustrated in Fig. 9 where we have represented the time $t_m$ (panel a) corresponding to the minimum of the differential magnetization $\delta M(t)=M_m(t)-M_m(0)$, where $M_m=\langle M_z \rangle_{\text{NM}} + \langle S_z \rangle n^h$ and its maximum value, $\delta M_m=\delta M(t_m)$ (panel b) for different hole background densities. The results are represented in logarithmic scale and show, within the range of the hole concentration $10^{-4}-10^{-2}$ nm$^{-3}$ considered in this work, a nearly power-law decrease in the demagnetization time $t_m$ and a saturation of $\delta M_m$ as $n^h$ increases. In order to understand the above behavior a detailed analysis of the miniband characteristics and the scalar product of in and out scattering states would be required. As a general remark, we note that the rising of the hole density leads to the occupation of higher $|k_z|$ states where the $z$ component of the hole spin is not a good quantum number. Due to the coupling to the in-plane spin component, this higher energetic population accelerates the dissipation processes of the total spin. On the other hand, the increase in the hole concentration allows the access to a new miniband higher in energy where the minimum energy

Layer thickness $w=6$ nm (full lines) and $w=4$ nm (dashed lines).
states are around the $|k_i|=0$ point (which are, in the present model, stable against the spin Elliot-Yafet dispersion processes) and which can justify a partial saturation of the demagnetization processes. Moreover, during the demagnetization processes it is possible to define a time-dependent magnetization processes. Moreover, during the demagnetization processes it is possible to define a time-dependent magnetization processes.

The hypothesis of a quasiequilibrium Fermi distribution which force the spin of the holes to relax. As described in Sec. II A, hole-spin relaxation comes from the entanglement between the spin direction and the linear momentum of the hole, which gives rise to a mixing of the hole-spin components.

The hypothesis of a quasiequilibrium Fermi distribution for the momentum dispersion of the hole gas in presence of a complex band structure like those of Fig. 4 and 5 resolves in a fast thermalization of the initial spin configuration. The 6 nm sample with a background hole concentration of $10^{-3}$ nm$^{-3}$ provides a simple case for understanding the details of the spin relaxation processes.

\end{figure}

In fact, as can be clearly seen in Fig. 5(a), before the laser excitation only the first heavy hole band $3/2;-3/2$ is populated (the occupation probability for $T^h=10$ K is plotted on the bottom right panel). The first available higher energy band is the $3/2;-1/2$ light-hole miniband [for the band classification, see the upper right panel of the hole total angular momentum ($J$) in Fig. 5(a)]. Despite the fact that the direct transition $3/2;-3/2\rightarrow 3/2;-1/2$, which is a consequence of the hole-ion scattering process of type $m\rightarrow m+1$ is possible, the large energy gap (nearly 0.1 eV) between the two bands strongly reduces this process. The main hole-spin relaxation channel is therefore an intraband process. Indeed, for $|k_i|=0$ the envelope function $\chi^{(2)}(n_{xZ}, x; x; z)$ has a single component $n=s$ which corresponds to a spin-down state. For $|k_i|=k_F$, where $k_F$ denotes the Fermi momentum, the eigenstate becomes a mixture of spin-up and spin-down states. This can be seen in Fig. 10(a) where the $z$-integral of $|\chi^{(2)}_{xZ}|^{-3/2}$ with $n=1,\ldots,4$ and for different values of $|k_i|$ are depicted. The Fermi level is marked by a vertical line. In order to illustrate the spin transition, let us consider an ion spin transition from $m=i/2$ to $m'=i/2$. The numerical solution shows that the energy difference of the ionic levels is $\Delta m_i=1.3\times10^{-4}$ eV and corresponds to a momentum difference of the scattered holes of $\Delta|k_i|=0.02$ nm$^{-1}$ with a transition rate given by $\xi_{3/2,3/2}$. In particular, a hole-spin transition between the fourth component of the incoming hole $3/2;-3/2=1/2|X-iY;1\rangle$ and the second component of the outgoing particle $3/2;-1/2=-1/2|X-iY;1\rangle - \sqrt{2/3}|Z;1\rangle$ is allowed. As a consequence of this transition and according to the hypothesis of the hole gas thermalization, in an intraband Kondo-like process the spin of the system is not conserved. In fact, a spin lowering of the ions does not correspond to a net increase in the hole-spin gas. This is due to the fact that, in our model, the total spin polarization of each miniband is a function of the hole temperature and density which are both constant in such interband transitions. Our findings agree with the physical picture outlined in Ref. 10 where a confined Zn$_{1-x}$Mn$_x$Se/Zn$_{1-x}$Be$_x$Se structure has been considered. Due to the giant Zeeman splitting, in a low temperature regime, the initial and final states of the holes belong to the same spin sub-band and nonzero matrix elements of the hole-spin operator in the Luttinger Hamiltonian leads to a mixing between the heavy and light components of the hole states.
In this work, we have developed a dynamical model able to explain the observed time evolution of the magnetization in thin diluted magnetic semiconductor quantum wells and, in particular, the phenomenon of ultrafast demagnetization that takes places within a picosecond time scale. The microscopic mechanism underlying this effect is related to the hole-spin relaxation produced by the Elliot-Yafet mechanism and the mixing between heavy- and light-hole bands. We showed that the quantum confinement and the hole background density play an important role on the time evolution of the total magnetization. Besides the hole background density, the magnetic doping concentration would also affect the time evolution of the total magnetization. Theoretical predictions have been obtained for 4 and 6 nm GaMnAs samples. Finally, let us stress that our approach is free of any parameters and therefore goes well beyond previous works based on more phenomenological grounds.
