Abstract

Tumor necrosis factor (TNF)-α, a pleiotropic cytokine that exerts a variety of effects, such as growth promotion, growth inhibition, angiogenesis, cytotoxicity, inflammation, and immunomodulation, has been implicated in several inflammatory conditions. It plays a significant role in many inflammatory diseases of lung. Given that there is significant literature supporting the pathobiologic role of TNF-α in asthma, mainly in severe refractory asthma, and COPD, TNF-α inhibitors (infliximab, golimumab and etanercept) are now regarded as potential new medications in asthma and COPD management. The studies reported in literature indicate that TNF-α inhibitors are effective in a relatively small subgroup of patients with severe asthma, possibly defined by an increased TNF axis, but they seem to be ineffective in COPD, although an observational study demonstrated that TNF-α inhibitors were associated with a reduction in the rate of COPD hospitalisation among patients with COPD receiving these agents to treat their rheumatoid arthritis. These findings require a smart approach because there is still good reason to target TNF-α, perhaps in a more carefully selected patient group. TNF-α treatment should therefore not be thrown out, or abandoned. Indeed, since severe asthma and COPD are heterogeneous diseases that have characteristics that occur with different phenotypes remained poorly characterized and little known about the underlying pathobiology contributing to them, it is likely that definition of these phenotypes and choice of the right outcome measure will allow us to understand which kind of patients can benefit from TNF-α inhibitors.
Introduction

Tumor necrosis factor (TNF)-α, a pleiotropic cytokine that exerts a variety of effects, such as growth promotion, growth inhibition, angiogenesis, cytotoxicity, inflammation, and immunomodulation [1], has been implicated in several inflammatory conditions [2-6].

This cytokine is produced predominantly by activated macrophages but also by other immune (lymphocytes, natural killer cells, mast cells) as well as stromal (endothelial cells, fibroblasts, microglial cells) cells. TNF is synthesized as a monomeric type-2 transmembrane protein (tmTNF) that is inserted into the membrane as a homotrimer and cleaved by the matrix metalloprotease TNF-α converting enzyme (TACE; ADAM17) to a soluble circulating trimer (solTNF); both tmTNF and solTNF are biologically active [7, 8]. The balance between tmTNF and solTNF signaling is influenced by cell type, activation status of the cell, the stimulus eliciting TNF production, TACE activity, and expression of endogenous TACE inhibitors leading to divergent TNF-mediated effects on cellular viability [9, 10].

TNF-α receptors and signaling

The actions of TNF-α are mediated as well as regulated by its ubiquitously expressed TNF receptors 1 (TNF-R1, Tnfrsf1a) and 2 (TNF-R2, Tnfrsf1b), which are membrane glycoprotein receptors that specifically bind TNF and homotrimers of lymphotoxin A, but the two receptors differ in their expression profiles, ligand affinity, cytoplasmic tail structure, and downstream signaling pathway activation [11]. TNF-R1 is expressed in most cell types, and can be activated by binding of either solTNF or tmTNF, with a preference for solTNF; whereas TNF-R2 is expressed primarily by cells of the immune system and by endothelial cells, and is preferentially activated by tmTNF [12]. The cytoplasmic domains of these receptors are unrelated and are linked to different intracellular signalling pathways.

TNF-R1 and TNF-R2 are assumed to use different intracellular signaling pathways and may thus mediate different functions Multiple experimental
approaches have shown that TNF-R1 initiates the majority of biological functions of TNF-α [13, 14]. The binding of TNF to TNF-R1 leads to the recruitment of TRADD (TNF-R1-associated death domain protein) into the receptor complex. TRADD subsequently recruits other effector proteins into the complex. FADD/MORT1 (FAS-associated death domain protein), TRAF2 (TNF receptor associated factor 2), and the death domain kinase RIP (receptor interacting protein) have been shown to interact directly with TRADD. While FADD/MORT1 is essential for TNF-induced apoptosis through activating a caspase cascade, RIP and TRAF2 are critical in the activation of nuclear factor-κB (NF-κB) and activator protein 1 (AP-1), which regulate the expression of numerous immune and inflammatory response genes. Both transcription factors are activated through protein kinase cascades culminating in the phosphorylation of yet-to-be-identified IκB kinases and the molecularly characterized c-jun N-terminal kinases (JNK), respectively. In addition, it has been reported that RIP mediates TNF-induced necrotic cell death. For TNF-R2 signaling, it is known that the occupancy of TNF-R2 by TNF leads to the recruitment of TRAF1 and TRAF2 as well as inhibitors of apoptosis protein 1 and 2 (cIAP1 and cIAP2). However, because most of the research effort from many laboratories is devoted to the study of TNF-R1 signaling, it is less clear how these molecules correlate to transduce the diverse TNF signals through TNF-R2.

Until recently, the prevailing theory was that the majority of the biological effects mediated by TNF-α are achieved through its interaction with TNF-R1 where the TNF-R2 plays a minor role in binding and redistributing the ligand to TNF-R1 in a process coined “ligand passing” [15]. However, there is accumulating evidence that signaling through the TNF-R2 influences a number of pro-inflammatory responses, including the activation of T cells [16-18], myofibroblasts [19], inhibition of angiogenesis and tumor suppression [20]. The proteinase TACE can also cleave TNF-R1 and TNF-R2 to yield soluble TNF receptors (sTNF-R) that act as competitive non-signalling agonists for TNF. sTNF-Rs show a higher degree of affinity for the cytokine than the corresponding bound forms. When TNF is bound to these soluble receptors, it
can no longer interact with the membrane forms and, therefore, it has been speculated that the presence of the soluble forms may constitute a way of regulating TNF actions [21].

TNF and its receptors may have a number of physiological and pathological roles. TNF-α acts as an endogenous mediator of pro-inflammatory cytokine stimulation and other cellular responses, including lymphocyte activation and migration, and cell proliferation, differentiation and apoptosis [22-24]. Moreover, TNF-α can induce reactive oxygen species (ROS) [24, 25] and stimulate the induction of various genes involved in inflammation [26-28] including interleukin-8 (IL-8). TNF-α also depletes cellular glutathione (GSH), a cellular antioxidant [29].

**Role of TNF-α in asthma and COPD**

TNF-α plays a significant role in many inflammatory diseases of lung. Of the various pulmonary diseases, it is implicated in asthma, chronic bronchitis, chronic obstructive pulmonary disease (COPD), acute lung injury and acute respiratory distress syndrome [30]. Figure 1 illustrates the putative role of TNF-α in the pathogenesis of asthma and COPD.

TNF-α is expressed in asthmatic airways and may play a key role in amplifying asthmatic inflammation through the activation of NF-κB, AP-1 and other transcription factors [31]. Elevated levels of TNF-α have been observed in induced sputum and in bronchoalveolar lavage fluid (BALF) from asthmatic patients and up-regulated TNF expression has been detected in alveolar macrophages, mast cells, and bronchial epithelial cells [32-39]. TNF-α induces the expression of multiple airway epithelial cell genes, including cytokines (IL-5, IL-6, IL-8, G-CSF, GM-CSF), chemokines (eotaxin, MCP-1, RANTES), adhesion molecules (ICAM-1), extracellular matrix glycoproteins (tenascin), neuropeptides (endothelin-1), mucins (MUC-1, MUC-2, MUC-5AC), and cytosolic phospholipase A2 [40-51]. TNF-α increases the adhesion of activated eosinophils to respiratory epithelial cell cultures and promotes neutrophil chemotaxis, adherence, and transendothelial and transepithelial migration [52–54]. IgE receptor activation induces TNF-α release from human lung tissue.
and upregulates eosinophil TNF mRNA levels [55]. TNF-α causes transient bronchial hyperresponsiveness (BHR) [56] likely because it decreases M₂ muscarinic receptor expression and promotes recruitment of eosinophils, containing major basic protein, an M₂ antagonist [57]. It is widely accepted that airway hyperreactivity can be caused by dysfunction of neuronal M₂ muscarinic receptors that normally limit acetylcholine release from parasympathetic nerves [58]. Nonetheless, genetic polymorphism of the TNF-α gene on chromosome 6 is associated with asthma, asthma severity and BHR [59].

TNF-α is also believed to play a central role in the pathophysiology of COPD [60]. It is produced by alveolar macrophages, neutrophils, T cells, mast cells and epithelial cells following contact with different pollutants including cigarette smoke [61]. TNF-α has been shown in animal models to induce pathological features associated with COPD, such as an inflammatory cell infiltrate into the lungs, pulmonary fibrosis and emphysema [62, 63]. It enhances neutrophil chemotaxis and migration by inducing the expression of chemokine interleukin 8 (IL-8) and upregulating endothelial adhesion molecules [64, 65]. In vivo, elevated levels of TNF-α have been demonstrated in peripheral blood, bronchial biopsies, induced sputum and BALF of patients with stable COPD compared with control subjects [66-70]. TNF-α has been shown to correlate with body mass index (BMI) and cigarette smoke exposure [71, 72] and other inflammatory mediators [73] in COPD. A polymorphism of the promoter region of the TNF-α gene has been implicated in the occurrence, severity, and mortality risk of COPD [74-76]. Intriguingly, TNF-α levels in sputum increase significantly during acute exacerbations of COPD [77, 78]. TNF-α together with IL-1β has been identified as key cytokine that is able to initiate inflammatory cascades during exacerbations of severe asthma [79] and COPD [80]. In particular, it has been reported that TNF-α is the initial and predictive cytokine released in the cascade following lipopolysaccharide (LPS) exposure [80].
Given the role of TNF in the pathogenesis of asthma and COPD, it is obvious to assume that TNF-α and/or its soluble receptor may be a target for reducing asthma and COPD inflammation.

**TNF-α inhibitors**

The therapeutic goal when administering TNF-α inhibitors is to eliminate the surplus of TNF-α in the blood and from sites of inflammation. Reduction should be made such that TNF-α levels do not fall below levels that may comprise an individual's immuno-competency. Once a TNF-α inhibitor is administrated and absorbed from the site of administration, a number of interactions occur between tissue/fluids and blood. Upon reaching the target site the TNF inhibitors bind to soluble TNFs and TNF expressed on the surface of various cells triggering the pharmacologic mechanism of action. There are three commercially available biologic agents that inhibit TNF-α – etanercept, infliximab, and adalimumab. In addition, two other TNF inhibitors, certolizumab pegol and golimumab, are in development. Some recent review articles offer a thorough description of these drugs [81, 82].

Etanercept is a fully human dimeric fusion protein composed of a TNF-α type II receptor and the Fc portion of IgG1. It is administered as a subcutaneous injection. Etanercept is a receptor blocker that binds to free-floating and cell-bound TNF. Once bound to TNF, it prevents TNF actions at its usual receptor sites on T cells as well as other cells. Etanercept does not activate complement mediated cell lysis.

Infliximab is a chimeric monoclonal antibody (mAb) composed of the constant region of human immunoglobulin and two murine variable regions targeted to TNF-α. It has a chimeric binding site, which means that a portion of the protein is mouse derived and is recognized as foreign protein by the human immune system. This increases the potential for antibodies directed against infliximab, which might neutralize its effect. Indeed, chimeric antibodies are designed to minimize the human antimouse antibody (HAMA) antigenic response triggered by the antigenic part of the mouse component, while retaining a high specificity. However, although the immunogenicity profile is reduced, chimeric
antibodies such as infliximab can still trigger a human anti-chimeric antibodies (HACA) response [83]. This is similar to the HAMA response and reduces the antibody's efficacy. Infliximab, once bound to TNF-α, may activate complement mediated cell-lysis. Complement mediated cell lysis is believed to be responsible for the effectiveness in granulomatous diseases such as Crohn’s disease and sarcoidosis.

Adalimumab is a recombinant human IgG1 mAb that is specific for human TNF. It was developed using phage display technology resulting in an antibody with human-derived heavy and light chain variable regions and human immunoglobulin G constant regions. Adalimumab is administered as a subcutaneous injection. The mechanism of action of adalimumab is the same as that of infliximab in that it binds to free floating and cell-bound TNF and may also induce complement mediated cell lysis.

The primary difference between the three TNF-α inhibitors is that the receptor blocker etanercept does not induce complement and has one binding site for TNF-α. The mAbs are “classic” immunoglobulins with a Fc portion and two arms each with a binding site for TNF-α and both induce the complement cascade upon binding to TNF-α.

Certolizumab is a Fab1 fragment of an IgG1 mAb and lacks effector functions because it has no Fc region. Golimumab is IgG1 antibody, which is capable of complement fixation and Fc-receptor binding. It is fully human mAbs.

**Safety of TNF-α inhibitors**

Given their mechanisms of action, it is possible that use of TNF-α inhibitors may predispose patients to an increased risk of serious and life-threatening infection, recrudescence of tuberculosis (TB), and reactivation of hepatitis B.

The anti-TNF-α therapies have subtly different side-effect profiles. Patients taking infliximab appear to have a higher risk of infection from histoplasmosis, coccidiomycosis or reactivation TB [84, 85]. Cases of TB were also reported in the studies of adalimumab, particularly at doses higher than those that were subsequently licensed, suggesting a dose–response effect. The reasons for this
remain unclear, but it is possible that, by virtue of their ability to fix complement, the monoclonal anti-TNF-α antibodies interfere with granuloma formation in a manner that is beneficial in Crohn's disease but detrimental in the reactivation of TB, whereas etanercept has neither of these effects. In any case, suppression of defense against infections also occurs with etanercept treatment, particularly against intracellular growing pathogens. Individual cases of a TB reactivation have also been described with the use of etanercept. Animal studies have suggested that partial rather than complete TNF blockade may allow preservation of the beneficial and anti-inflammatory functions of this cytokine in TB immunity [86].

The TNF-α inhibitors are contraindicated in patients with unstable congestive heart failure (CHF) and should be used only after other agents have failed in patients with a past history of CHF who are stable [87]. In particular, there have been reports of etanercept-induced CHF [88]. This event appears to be very rare, but therapy with etanercept for patients with unstable cardiac disease might be best avoided. This is a problem in COPD patients because the prevalence of CHF in patients with COPD is known to range from 20% to 32% [88].

The oncogenic potential of etanercept, particularly for lymphoma, is a much-debated issue. It may be dependent on the disease state that is being treated. Recent reports have suggested a slight (perhaps up to 3-fold) increase in the risk of lymphoma, particularly in patients with rheumatoid arthritis [89]. A recent meta-analysis involving infliximab and adalimumab demonstrated an increase risk of lymphoproliferative diseases and malignancies in patients treated with these agents [90].

Several patients treated with TNF antagonists have developed multiple sclerosis [91]. Others with multiple sclerosis have had exacerbations of their disease when treated with these agents.

At least 2 cases in which the use of infliximab has been associated with hepatotoxicity in the absence of other factors have been published [87]. No
similar reports of hepatotoxicity caused by etanercept or adalimumab have been published [87].

**TNF-α inhibitors and asthma**

Considering the critical role of TNF-α in the pathogenesis of asthma and the need for alternative treatments for those asthmatic patients with severe disease who are particularly resistant to conventional therapy, molecules targeted at blocking the effects of TNF-α are likely to constitute a considerable advance in the management of these difficult patients. Indeed, some trials have explored the possibility of using TNF-α inhibitors in asthmatic patients (table 1).

An uncontrolled study of etanercept 25 mg administered subcutaneously twice weekly for 12 weeks in 15 patients with severe asthma documented a significant (2.5 doubling concentration) improvement in methacholine BHR, a 240-mL improvement in Forced Expiratory Volume in 1 Second (FEV₁), and an improvement in asthma quality of life [92]. These findings were confirmed in a study that measured markers of TNF-α activity on peripheral-blood monocytes in 10 patients with refractory asthma, 10 patients with mild-to-moderate asthma, and 10 control subjects and also investigated the effects of treatment with etanercept (25 mg twice weekly) in the patients with refractory asthma. Antagonism of TNF-α with 10 weeks of etanercept therapy significantly reduced the expression of membrane-bound TNF-α by peripheral-blood monocytes and improved the provocative concentration of methacholine causing a 20% fall in FEV₁ (PC₂₀), the asthma-related quality of life, FEV₁, and symptom scores, as compared with placebo [93]. The baseline expression of membrane-bound TNF-α by peripheral-blood monocytes and the extent to which it was reduced by etanercept treatment were independently associated with the net improvement in both primary outcome measures.

Although these interesting data indicate a role for etanercept in the treatment of asthma, the results of other studies deny such a role. The administration of etanercept for 2 weeks to subjects with mild-to-moderate allergic asthma did not prevent pulmonary eosinophilia during the late phase response to
bronchoscopic segmental allergen challenge and, furthermore, TNF antagonism increased pulmonary IL-4 levels [94]. Data from a different study of etanercept administered once weekly for 12 weeks in 39 patients with severe corticosteroid refractory asthma demonstrated only a small but significant improvement in asthma control and systemic inflammation, as measured by serum albumin and CRP, with no improvements in the secondary endpoints of lung function, Peak Expiratory Flow (PEF) or BHR, supporting the view that if anti–TNF-α is to be effective in asthma, it will only be on a relatively small subgroup of patients, possibly defined by an increased TNF axis [95]. Minor adverse events, including injection site pain and skin rashes, were more frequent with etanercept than with placebo.

Only one study evaluated the effectiveness of infliximab. This mAb reduced diurnal PEF variability and, interestingly, the number of mild exacerbations encountered, but not morning PEF, in a trial of symptomatic patients with moderate asthma despite receiving inhaled corticosteroid (ICS) therapy [96]. There were no serious adverse events related to the study agent.

A trial that assessed the safety and efficacy of golimumab (50, 100, or 200 mg) through week 52 in a large population of patients with uncontrolled, severe persistent asthma was unable to demonstrate significant differences were observed for the change in percent-predicted FEV₁ or severe exacerbations through week 24 [97]. Unfortunately, an unfavourable risk/benefit profile led to early discontinuation of therapy with golimumab. 30.3% of patients treated with golimumab experienced serious adverse events, with serious infections occurring frequently. Moreover, one death and eight malignancies occurred in the golimumab groups. Nonetheless, careful examination of 53 nucleotide polymorphisms in 144 severe asthmatic subjects demonstrated a positive association between pharmacologic effect of golimumab and a common single nucleotide polymorphism (SNP) in 2 TNF receptor genes. Polymorphisms in TNF-α or ADAM17 did not associate with a positive effect of golimumab [98].

**TNF-α inhibitors and COPD**
In view of the similarities between chronic severe asthma and COPD, it has been suggested that blocking the biological effects of TNF-α may be beneficial in the treatment of COPD. Although randomised controlled trials to evaluate the effectiveness of TNF-α inhibitors in patients with COPD have been few, the results of the first studies seem to indicate that they are not really effective in this disease (table 2).

An exploratory study of infliximab treatment in patients with COPD did not show a short-term improvement in clinical or inflammatory parameters from infliximab treatment in patients with mild-to-moderate COPD, although patients so treated did demonstrate an increase in exhaled nitric oxide (eNO) [99]. Increased cough was reported by eight patients in the infliximab group.

In a larger dose-finding study, subjects with moderate to severe COPD received infliximab 3 mg/kg or 5 mg/kg or placebo at Weeks 0, 2, 6, 12, 18, and 24 and efficacy, health status, and safety were assessed through Week 44. No therapeutic benefit was observed in the primary outcome variable: health status as assessed by the Chronic Respiratory Questionnaire (CRQ) [100]. Similarly, no therapeutic benefit was noted in lung function, dyspnea, or in the incidence of moderate to severe COPD exacerbations. A modest trend toward improved 6-minute walk test (6-MWT) was demonstrated in the infliximab treatment groups, although this did not reach statistical or clinical significance. Higher proportions of infliximab-treated subjects discontinued the study agent due to adverse events (20–27%) than did placebo-treated subjects (9%). The most frequently reported adverse events in the combined infliximab treatment groups were COPD exacerbation, upper respiratory tract infection, sinusitis, pain, back pain, headache, and diarrhea. The Authors observed no opportunistic infections and no differences in the occurrence of infections requiring antibiotics, but they did find a higher incidence of pneumonia in infliximab-treated subjects and, although not statistically significant, more cases of cancer.

A recent small study population in cachectic patients with COPD revealed no change in levels of inflammatory markers in exhaled breath condensate (EBC) and minor effects on systemic inflammatory markers following treatment with
infliximab (5 mg/kg) administered to patients at weeks 0, 2 and 6 and evaluated at weeks 8 and 12, and followed through week 26 [101].

Nonetheless, an observational study conducted to evaluate the effectiveness of TNF-α antagonists in preventing COPD hospitalisations in a cohort of patients diagnosed with both rheumatoid arthritis and COPD identified from a health claims database, demonstrated that TNF-α inhibitors were associated with a reduction in the rate of COPD hospitalisation among patients with COPD receiving these agents to treat their rheumatoid arthritis [102]. This effect, however, was due exclusively to a reduction of 50% in the rate of COPD hospitalisation with etanercept. The other TNF-α inhibitor under study, namely infliximab, did not reduce the risk of COPD hospitalisation.

What can we learn from trials

The studies reported in literature indicate that TNF-α inhibitors are effective in a relatively small subgroup of patients with severe asthma, possibly defined by an increased TNF axis [103], but they seem to be ineffective in COPD, although in the study of Rennard et al. [100], the 6-MWT post hoc analyses suggested that cachectic individuals, as well as younger individuals, derived relatively greater benefit from treatment with infliximab. The discrepancy in the results obtained in two inflammatory diseases such as asthma and COPD have not been entirely unexpected. In fact, targeting of TNF-α is extremely effective in some inflammatory conditions (such as rheumatoid arthritis, inflammatory bowel disease and psoriasis), but has proved to be a less useful target in other conditions in which efficacy was expected, such as vasculitis, but even within rheumatoid arthritis, about one-third of patients show little response to this treatment for reasons that are still poorly understood.

Barnes has suggested that the failure of anti-TNF therapy is more likely a result of the fact that COPD is a highly complex inflammatory disease in which many other cytokines and mediators are involved, and that blocking a single cytokine does not have any effect, as other cytokines such as interleukin (IL)-1β and IL-6 may play a similar role [104]. In the recent study of Sapey et al. [105] that aimed to know the relationships between this cytokine and its
antagonists in disease compared with healthy controls, TNF-α, sTNF-R1, and sTNF-R2 concentrations were not raised and TNF-α did not correlate with markers of disease suggesting that TNF-α is unlikely to be highly active in stable COPD. Nonetheless, it remains possible that TNF-α is quiescent when COPD is stable and only becomes biologically active (with increased concentrations) during exacerbations [106]. Indeed, the substantial increase in TNF-α production following LPS exposure and in vivo exacerbation studies suggests that the role of TNF-α may be more predominant in acute inflammatory episodes rather than in the chronic disease process [80]. Therefore, we completely agree with the opinion future studies may be better focused on the roles of anti-TNF therapies in preventing or modifying the severity of acute exacerbations. In any case, it must be mentioned that there is evidence of a subset of patients with polymorphisms of the TNF-α gene (that influence gene expression) who have an increased severity of COPD [107] or a mucus producing phenotype [108].

Although there have been no head-to-head trials, the literature seems to indicate that etanercept might be more effective than infliximab in asthma and COPD. Intriguingly, infliximab demonstrates clinical benefit in Crohn's disease whereas etanercept is ineffective. It is also interesting to note that infliximab appears to be less efficacious in smokers compared to non-smokers who suffer from Crohn's disease [109]. One might, therefore, speculate that, while the two drugs share a common therapeutic target, they might also differ in some aspects of their mode of action.

Although both infliximab and etanercept are potent neutralizers of TNF bioactivity, there are fundamental differences in their molecular structures, their binding specificities, and the manner in which they neutralize TNF. Infliximab, by virtue of being IgGI antibodies, can activate complement and bind Fc receptor and it also can bind both monomeric and trimeric sotNF and tmTNF, whereas etanercept only binds TNF trimers and interacts with tmTNF with reduced avidity, compared with that of infliximab [82, 110-112].

Furthermore, infliximab forms stable complexes with soluble TNF-α, whereas etanercept tends to form relatively unstable complexes, allowing dissociation of
TNF-α and the potential to form a reservoir for binding TNF [110]. Infliximab, therefore, completely neutralizes TNF bioactivity, whereas freely diffusing etanercept might be considered to redistribute bioavailable TNF from sites of production to sites of lower concentration.

Another difference between etanercept and infliximab is the ability of etanercept to neutralize lymphotoxin, a property that is shared by its parent receptor TNF-R2 [110, 113]. Lymphotoxin A is involved in the normal development of lymphoid tissue and also acts as an inducer of the inflammatory response [114]. A further important consequence of the structural differences between these drugs is the fact that infliximab, but not etanercept, fixes complement, and therefore can lyse cells that express TNF-α on their surface [115]. Since TNF-α is initially expressed on the cell surface before being cleaved off by TACE, a wide range of cells, including T cells, may be susceptible. Indeed, preliminary reports appear to confirm this in vivo, with a decrease in absolute numbers of peripheral blood CD4+ T cells (which express interferon γ and TNF-α) in patients with ankylosing spondylitis treated with infliximab and a reciprocal increase with etanercept [116, 117]. All these substantial differences might explain why etanercept is more effective than infliximab in asthma and COPD.

Nonetheless Barnes believes that it is unlikely that any different results would be obtained with a different anti-TNF approach using etanercept, as the effects of blocking antibodies and soluble receptors are usually similar in terms of clinical efficacy in other inflammatory diseases [104]. Unquestionably this interpretation is correct. Nonetheless, we are convinced that although the overall results of published studies are perhaps disappointing, there is still good reason to target TNF-α, perhaps in a more carefully selected patient group. TNF-α treatment should therefore not be thrown out, or abandoned.

The true problem is that patients enrolled in the different trials have been considered as subjects of a general population with always the same characteristics since we consider severe asthma and also COPD as homogeneous diseases, and recruited using arbitrary clinical and physiological criteria. On the contrary, severe asthma and COPD are heterogeneous diseases
that have features that occur with different phenotypes remained poorly characterized and little known about the underlying pathobiology contributing to them [118, 119]. Considerable thought should be put into recruitment criteria with the emphasis more on identifying and including the at need population [120]. It is likely that definition of these phenotypes will allow us to study the correct patient population. If we will also be able to choose the right outcome measure we understand which kind of patients can benefit from TNF-α inhibitors.

We believe that the findings present in the literature require such an approach. Otherwise we could not consider a therapeutic option that in a well-identified group of patients would meet therapeutic needs not otherwise met. In other words, we could risk to throw the baby out with the bath water.

<td>Improvement ACQ, FEV₁, FVC, morning and evening PEF, and BHR</td>
</tr>
<tr>
<td>Berry et al. [93]</td>
<td>10 patients with refractory asthma, and 10 patients with mild-to-moderate asthma</td>
<td>Randomized placebo controlled crossover</td>
<td>Etanercept 10 wk</td>
<td>1° BHR and AQLQ, 2° FEV₁, eNO, sputum cell counts</td>
<td>Improvement AQLQ, FEV₁, BHR ↓ sputum histamine</td>
</tr>
<tr>
<td>Morjaria et al. [95]</td>
<td>39 patients with severe corticosteroid refractory asthma</td>
<td>Randomized placebo controlled parallel group</td>
<td>Etanercept 12 wk</td>
<td>1° AQLQ, 2° ACQ, FEV₁, PEF, BHR, exacerbations</td>
<td>No benefit compared with placebo</td>
</tr>
<tr>
<td>Rouhani et al. [94]</td>
<td>26 patients with mild-to-moderate allergic asthma/inhaled β₂-agonists only</td>
<td>Segmental allergen challenge</td>
<td>Etanercept 2 wk</td>
<td>Markers of inflammation BHR</td>
<td>Increased TNF-R2 in BAL, no change in BHR</td>
</tr>
<tr>
<td>Erin et al. [96]</td>
<td>38 patients with moderate asthma/inhaled corticosteroids only</td>
<td>Randomized placebo controlled parallel group</td>
<td>Infliximab 6 wk</td>
<td>1° morning PEF, 2° FEV₁, exacerbations, sputum markers</td>
<td>No change in morning PEF ↓ PEF variability ↓ exacerbations</td>
</tr>
<tr>
<td>Wenzel et al. [97]</td>
<td>231 patients with severe and uncontrolled asthma/high-dose inhaled corticosteroids and long-acting β₂-agonists</td>
<td>Randomized, double-blind, placebo-controlled</td>
<td>Golimumab 52 wk</td>
<td>1° FEV₁, exacerbations, 2° AQLQ, rescue medication</td>
<td>No benefit compared with placebo</td>
</tr>
</tbody>
</table>

ACQ, Asthma Control Questionnaire; AQLQ, Asthma Quality of Life Questionnaire; BHR, bronchial hyperresponsiveness; eNO, exhaled nitric oxide; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; PEF, peak expiratory flow.
Table 2 - Summary of studies of TNF-α inhibitors in COPD
