Running head: Psychopathology in parents of minors with CF

**Abstract**

**Objective** To assess the prevalence of symptoms of anxiety and depression and the extent of life satisfaction in parents caring for children with cystic fibrosis (CF) in Germany.

**Methods** The study included 650 caregivers of 564 children with CF ages 0 to 17, who completed the Hospital Anxiety Depression Scale (HADS), the Center for Epidemiologic Studies Depression Scale (CES-D) and the Questions on Life Satisfaction (FLZ<sup>M</sup>).

**Results** More than one-third (37.2%) of parents showed elevated levels of anxious symptoms, compared to 18.9% of a population sample ( $p \leq .001$ ) and significantly more parents reported elevated levels of depressive symptoms compared to a community sample (28% vs. 21%,  $p = .01$ ). Higher levels of anxious and depressive symptoms were associated with lower life satisfaction ( $p < .001$ ).

**Conclusions** High levels of anxious and depressive symptoms among parents of children with CF suggested that annual symptom screening is warranted. This will facilitate identification of those at risk and provide referrals and intervention for those who are in need of it.

**Keywords:** Anxiety; cystic fibrosis; depression; life satisfaction; parent caregivers.

## Introduction

Chronic medical conditions, such as cystic fibrosis (CF), have significant implications for the psychosocial well-being of the family system.<sup>1</sup> Parents of children with chronic illnesses must cope with uncertainty about progression of the disease, as well as challenges in everyday life, including adherence to complex treatment regimens, regular clinic visits, hospitalizations, financial stress due to costs of care, and disruptions in future plans.<sup>2</sup> As a consequence of these caregiving challenges, parents are at a high risk for the development of psychological symptoms and decreased quality of life.<sup>3</sup>

Advances in medical care and treatments over the past 20 years have led to an increase in life span of patients with CF, with a majority of children in developed countries now living into adulthood.<sup>4</sup> However, management of CF requires adherence to a complex and time-consuming treatment regimen, including inhaled and oral medications, airway clearance, and alterations in diet.<sup>5</sup> In general, poor adherence (50% or less) is reported in chronically ill pediatric populations<sup>6</sup>, and this was also shown for children with CF<sup>7</sup>. Adherence rates in children with CF vary depending on the specific treatment component, with adherence for chest physical therapy rated between 40-47%<sup>8</sup> and approximately 51% in a newer US study<sup>7</sup> and estimates being especially low for dietary recommendations<sup>9</sup>. Non-adherence can have serious consequences for the child's health status. Therefore, depending on the child's development, parents must take responsibility for administering and supervising the specific CF treatments, which has been shown to increase role strain in parents and lead to greater conflict with adolescents.<sup>3,10</sup> Studies have demonstrated that parents' symptoms of depression and anxiety, as well as general family functioning show a strong association with health outcomes in patients with CF.<sup>11,12</sup> These findings suggest that the impact of CF on parent caregivers' psychological functioning and quality of life requires further study.

1  
2  
3 From the late 1960s on, studies have examined the impact of CF on parents/caregivers  
4 (for review see <sup>13,14</sup>) with most studies finding high levels of psychological distress and  
5 increased risk of depressive symptoms.<sup>15</sup> A Turkish study on sleep quality and the  
6 psychological well-being of mothers caring for children with asthma or CF reported higher  
7 anxiety and depression scores than mothers of healthy children.<sup>16</sup> A single center study in the  
8 US examining the relations between symptoms of psychological distress and quality of life in  
9 caregivers of children with CF <sup>17</sup> found elevated rates of depressive and anxious symptoms,  
10 which were negatively correlated with parental quality of life. Rates of anxious symptoms  
11 were more pronounced (43-51%) compared to 14-31% (depending of the measure used) of  
12 the parents reporting elevated levels of depressive symptoms. In another US study, over one-  
13 third of parents scored in the elevated range on a depression measure and more symptoms of  
14 depression were associated with worse adherence to enzymes as well as either loss of weight  
15 or failure to make expected weight gains in children with CF three months later <sup>18</sup>. Similarly,  
16 a single center study from Smith and colleagues found 35% of mothers and 23% of fathers  
17 reported elevated symptoms of depression and 57% of mothers and 25% of fathers reported  
18 elevated anxiety. Further, symptoms of depression in parents of school-age children were  
19 associated with worse adherence to airway clearance.<sup>19</sup>

20  
21  
22 Research has also shown that caring for a child with a chronic condition can  
23 negatively affect parents' quality of life,<sup>20,21</sup> as they are confronted with the threat of a life-  
24 limiting illness and additionally have to face multiple social and emotional stressors  
25 associated with their child's disease, e.g., fear, less time for social activities, financial  
26 burdens, etc. Also, parents' health-related quality of life proved to be worse than that  
27 reported by parents of healthy children.<sup>22,23</sup> However, specific studies on the health-related  
28 quality of life of parents caring for a child with CF are rare. In the single-center study by  
29 Driscoll and colleagues already mentioned above, a good child lung functioning was  
30

1  
2  
3 associated with better quality of life in mothers caring for a child with CF. Depressive and  
4  
5 anxious symptoms predicted parental quality of life, even after controlling for psychosocial  
6  
7 treatment received by the caregiver. However, the relation was stronger between depressive  
8  
9 symptoms and quality of life <sup>17</sup>.

10  
11  
12 To date, no large scale epidemiological studies have systematically examined the  
13  
14 prevalence of anxiety and depression and subjectively reported quality of life of parents  
15  
16 caring for a child with CF. Therefore “The International Depression/Anxiety Epidemiological  
17  
18 Study” (TIDES, [www.tides-cf.org](http://www.tides-cf.org)) was initiated in 2007 with more than ten countries  
19  
20 worldwide participating so far. The objectives were to screen for depressive and anxious  
21  
22 symptoms in adolescent and adult patients with CF and parents caring for a minor child with  
23  
24 CF, and to link these psychological data to the patients` health outcomes. Here, parent data  
25  
26 from the German arm of the study including 32 CF Centers are presented. The patient data  
27  
28 have been published elsewhere.<sup>24</sup> Standardized screening tools were used to estimate the  
29  
30 prevalence of anxious and depressive symptoms in parents caring for a child with CF. Further,  
31  
32 rather than evaluating the broader concept of quality of life, the focus was on assessment of  
33  
34 life satisfaction, defined as subjectively perceived quality of life based on individual  
35  
36 preferences and reported satisfaction in multiple life domains.<sup>25</sup>

37  
38  
39 Thus, the purpose of the current study was to test the following hypotheses using a large,  
40  
41 nationally representative sample:  
42  
43

- 44  
45 1. Compared to the general population, symptoms of anxiety and depression were  
46  
47 expected to be more prevalent in parent caregivers of minors (under age 18 years) with  
48  
49 CF.  
50  
51
- 52  
53 2. Life satisfaction was expected to be lower in parent caregivers of minors with CF than  
54  
55 in the general population.  
56  
57  
58  
59  
60

- 1  
2  
3 3. Among parents, a significant negative association was expected between symptoms of  
4 anxiety/depression and life satisfaction.  
5  
6  
7  
8  
9

## 10 **Materials and Methods**

### 11 **Procedure**

12  
13  
14  
15 Data collection took place between February 2007 and April 2008. The study protocol  
16 was approved by the Institutional Review Board of the University of Ulm and the local IRBs  
17 at the 32 participating CF clinics (representing about one third of the German CF outpatient  
18 units). This study was part of a larger international prevalence study initiated in the United  
19 States (see [www.tides-cf.org](http://www.tides-cf.org)). During routine clinic visits, parents of children with CF ages 0  
20 to through 17 were informed of the study's purpose and objectives and were asked to  
21 participate. After completion of informed consent, a demographics questionnaire and  
22 screening instruments (see below) for symptoms of anxiety/depression and life satisfaction  
23 were administered by a member of the CF team, such as a social worker, psychologist, or  
24 nurse. Anxious and depressive symptoms in parents were measured with the Hospital Anxiety  
25 and Depression Scale (HADS). Additionally, to measure parental depressive symptoms, the  
26 CES-D was administered, as the HADS Depression scale excludes relevant somatic items  
27 (e.g., fatigue). Thus, the CES-D was considered the primary measure and more appropriate  
28 screener for depressive symptoms. The Questions on Life Satisfaction (FLZ<sup>M</sup>) were used to  
29 evaluate parental life satisfaction. Completion of the questionnaires took about 20 minutes.  
30 The measures were scored immediately upon completion and if the participant scored above  
31 the clinical cut-off score ( $\geq 8$  points) on either the anxiety or depression scale, a referral to a  
32 mental health professional was initiated.  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56

57 Parents also agreed to the collection of medical data on their child with CF, which  
58 were extracted from the German CF registry. The variables extracted were current height,  
59  
60

1  
2  
3 weight, FEV1 in liters, FEV1% predicted, colonization with germs (*Pseudomonas aeruginosa*  
4  
5 yes/no; *Burkholderia cepacia* yes/no), complications during the last year (hemoptysis yes/no,  
6  
7 pneumothorax yes/no or new diagnosis of CF-related Diabetes yes/no).  
8  
9

## 10 Measures

### 11 Hospital Anxiety and Depression Scale (HADS)

12  
13 The HADS<sup>26</sup> is a brief and easy to administer 14-item instrument which measures symptoms  
14  
15 of anxiety (7 items) and depression (7 items). It was designed specifically for use with  
16  
17 chronically ill patients and therefore, physical symptoms (such as headaches or fatigue) that  
18  
19 could be associated with a medical condition were excluded. The instrument has been  
20  
21 translated into numerous languages and has been used extensively in different countries with  
22  
23 different populations. Respondents rate each symptom using a 4-point scale (range 0-3),  
24  
25 indicating the current extent of the symptom. Results of this screening measure can be  
26  
27 analysed both categorically, discriminating normal (0-7 points), borderline (8-10 points) and  
28  
29 clinical levels of symptoms ( $\geq 11$  points) as indicated by cut-off scores provided by the  
30  
31 authors, and dimensionally by adding the raw scores of each scale.  
32  
33  
34  
35  
36  
37

38  
39 The HADS has extensive reliability and validity data<sup>27,28</sup> with strong internal  
40  
41 consistency as measured by *Cronbach's*  $\alpha$  of .82 for the Anxiety subscale (HADS-A) and .83  
42  
43 for the Depression subscale (HADS-D) in the current sample. Optimal sensitivity and  
44  
45 specificity (approximately .80 each) was achieved most frequently using a cut-off score of 8  
46  
47 for the Anxiety scale.<sup>28</sup> External validity has been demonstrated, with strong convergence  
48  
49 found between the HADS and other validated anxiety and depression measures. In this study,  
50  
51 the German version of the HADS<sup>29</sup> was administered.  
52  
53

### 54 Center of Epidemiologic Studies Depression Scale (CES-D)

55  
56 The Center for Epidemiologic Studies Depression Scale, CES-D,<sup>30</sup> is a frequently used 20-  
57  
58 item self-report instrument screening for the major components of depression, including  
59  
60

1  
2  
3 depressive mood, feelings of guilt and worthlessness, loss of appetite, and sleep disturbance.  
4  
5 It was designed to assess all major symptoms of depression in community samples and has  
6  
7 excellent psychometric properties, evidencing good internal consistency (Cronbach's  $\alpha = .89$   
8  
9 in the current sample). For each item, respondents rate the frequency of their symptoms over  
10  
11 the past week on a 4-point scale ranging from 0-3. All items scores are summed to yield a  
12  
13 total score, ranging from 0-60. Higher scores indicate more depressive symptoms, with a  
14  
15 score of 16 or higher identified as the clinical cut-off score for depressive symptoms.<sup>30</sup> In this  
16  
17 study, the German version of the CES-D<sup>31</sup> was administered. In the German manual the use of  
18  
19 an adapted cut-off score of 24 or higher is suggested, referring to a large but non  
20  
21 representative community sample. To allow for international comparability, both, the  
22  
23 international cut-off score of 16 and the German cut-off score of 24 were applied in this  
24  
25 study.  
26  
27  
28  
29  
30

### 31 Questions on Life Satisfaction (FLZ<sup>M</sup>)

32  
33 The Questions on Life Satisfaction (German: Fragen zur LebensZufriedenheit, FLZ<sup>M25</sup>) is a  
34  
35 multidimensional measure of General and Health-related Life Satisfaction in eight domains of  
36  
37 daily life (e.g., leisure time/hobbies, family life, physical condition, ability to relax, etc.). The  
38  
39 instrument includes ratings of the subjective importance for each domain, which can be used  
40  
41 to weight ratings of satisfaction. Each domain is evaluated twice, once for the importance and  
42  
43 once for satisfaction, on 5-point rating scales ranging from 1 (not important/dissatisfied) to 5  
44  
45 (extremely important/very satisfied). Weighted scores for each item are then calculated using  
46  
47 the following formula: *weighted satisfaction = (importance rating - 1) x ((2x satisfaction*  
48  
49 *rating) - 5)*.<sup>25</sup> Item-specific weighted scores range from -12 to +20, with negative scores  
50  
51 indicating dissatisfaction with the domain measured. Domains without subjective importance  
52  
53 are weighted 0, and thus do not impact the individual's life satisfaction. Total scores for  
54  
55 General and Health-related Life Satisfaction are computed by summing the eight general and  
56  
57  
58  
59  
60

1  
2  
3 eight health-related domain scores, and they range from -96 to +160. Higher scores indicate  
4  
5 better satisfaction with life. Good reliability and validity of the FLZ<sup>M</sup> has been reported in  
6  
7 previous studies using the instrument with adolescent and adult populations.<sup>25,32-34</sup> In the  
8  
9 current sample *Cronbach's alpha* was .83 for the General Life Satisfaction module and .88 for the  
10  
11 Health-related Life Satisfaction module.  
12  
13

### 14 15 **Statistical analyses**

16  
17 To allow for group comparisons, we used the most recent instrument-specific data  
18  
19 from normative reference samples. For the HADS data, we used data from a German survey  
20  
21 study.<sup>35</sup> The general population sample was selected based on 216 sample points in Germany  
22  
23 using the random-route-technique (random selection of street, house, flat and target subject in  
24  
25 the household). This sample, with a response rate of 68%, can be assumed to be representative  
26  
27 of the adult German population living in private households. Individuals from foreign  
28  
29 countries were not included in the sample because of problems with command of the German  
30  
31 language. The original sample, with complete data consisted of 2037 people aged 14-92 years,  
32  
33 with a mean age of 49.2 (SD=17.3). These respondents were matched for age and gender with  
34  
35 our parent sample, leading to a sample size of 614 (22-60 years,  $M=40.0$  years,  $SD=7.2$ ,  
36  
37 76.4% female).  
38  
39  
40  
41  
42

43  
44 To analyse the CES-D data we used comparative data from a representative population  
45  
46 sample in cooperation with the German study group mentioned above ( $N=2005$ , 14-91 years,  
47  
48  $M=48.0$ ,  $SD=18.3$ ). Matching for age and gender led to a sample size of 620 people aged 21-  
49  
50 60 years ( $M=40.0$  years,  $SD=7.3$ , 76.6% female).  
51  
52

53  
54 The life satisfaction data, measured with the Questions on Life Satisfaction (FLZ<sup>M</sup>),  
55  
56 were also compared to community samples. For the general life satisfaction module, data  
57  
58 came from a large community sample ( $N=5036$ , 14-92 years,  $M=48.4$ ,  $SD=18.0$ , 53.7%  
59  
60 female). Comparison data for the health-related life satisfaction module came from the FLZ<sup>M</sup>

1  
2  
3 standardization study<sup>36</sup> with 1338 German adults from the community (17-95 years,  $M=46.9$ ,  
4  
5  $SD=17.2$ , 54.6% female). An analogous matching procedure was completed for both samples,  
6  
7 selecting those participants with an age-gender combination paralleling the parent caregiver  
8  
9 sample. Their responses were weighted so that the age and gender distribution in the two  
10  
11 community samples paralleled the distribution in the parent caregiver sample. The matching  
12  
13 procedure resulted in a sample of 2718 subjects for the general life satisfaction module and  
14  
15 768 subjects for the health-related life satisfaction module.  
16  
17  
18

19  
20 The frequencies of elevated HADS Anxiety and Depression scores and CES-D scores  
21  
22 were calculated using the established cut-off scores. Group comparisons with the community  
23  
24 sample, matched for age and gender, were performed using  $\chi^2$ -tests. Gender differences  
25  
26 comparing the mean scores of mothers and fathers were determined using *Student's t*-tests.  
27  
28 Associations of elevated levels of anxious/depressive symptoms and the following socio-  
29  
30 demographic and disease-related variables were determined applying *Chi square* tests or *t*-  
31  
32 tests for independent samples: parent education (0= 10 years of school or less, 1= "Abitur" or  
33  
34 university degree), parent employment (0=no employment outside of the home,  
35  
36 1=employment outside of the home), parent age, child age, and FEV1% as indicator for child  
37  
38 health status. FLZ<sup>M</sup> raw scores were transformed into weighted scores and two total scores  
39  
40 were calculated for General and Health-related Life Satisfaction. *Student's t*-tests for  
41  
42 independent samples were used to examine potential differences between the parent and  
43  
44 matched community sample. *Spearman's rho* was used to test the associations between life  
45  
46 satisfaction and the same sociodemographic and disease-related variables that were used to  
47  
48 explore the associations with parental anxious and/or depressive symptoms. To test the  
49  
50 associations among symptoms of anxiety and depression and life satisfaction, univariate  
51  
52 analyses of covariance (ANCOVAs) were calculated with the level of anxious symptoms  
53  
54 (normal – borderline - abnormal) and depressive symptoms as measured with the CES-D  
55  
56  
57  
58  
59  
60

(normal-abnormal<sub>international</sub>-abnormal<sub>German</sub>) as independent variables and General and Health-related Life Satisfaction scores as dependent variables, controlling for child age and lung function (FEV<sub>1</sub>%). In those cases with double data sets (mother and father filled in a questionnaire) we randomly selected only one parent for inclusion in the ANCOVA model in order to avoid data dependency. Effect sizes were calculated using  $\eta^2$ , with  $\eta^2 > .01$  as small,  $\eta^2 > .10$  as medium and  $\eta^2 > .25$  as large effects.<sup>37</sup> All statistical analyses were conducted with the software package SPSS version 12.0 for Windows.

## Results

### Sample Characteristics

A total of 650 parent caregivers of 564 minors with CF (0-17 years,  $M=9.5$ ,  $SD=4.6$ ; 54.9% male) were consecutively recruited for the study during a routine clinic visit at their CF center. This was approximately 50% of all eligible families at the participating sites. Reasons for non-participation included no time, no interest in the study, data protection concerns, etc. In 478 cases, data were obtained from only one parent (73 fathers, 405 mothers), whereas we received two data sets (one from father, one from mother) for the remaining 86 children. Children's lung function, measured as FEV<sub>1</sub>% predicted, ranged from 15.7% to 138.7% ( $M=89.8\%$ ,  $SD=21.1$ ), with 83.2% of the children falling in the normal to mild range of disease severity (FEV<sub>1</sub>%  $\geq 70$ ) and only 2.5% falling in the severely impaired range (FEV<sub>1</sub>%  $\leq 40$ ). In 17 cases (3.1%) the patients were experiencing acute medical conditions. The parents of these patients were included in the study sample; however, comparisons were made to the rest of the parents whose children were currently not sick or experiencing pulmonary exacerbations. Table 1 shows the characteristics of the parent sample, separately for mothers and fathers.

1  
2  
3 Participating patients were compared to those not participating in this study, but whose  
4 data are included in the German CF Registry. These data included socio-demographic (e.g.,  
5 age, gender, education, living situation) and medical information (e.g., height, weight,  
6 FEV<sub>1</sub>%). Fewer parents with children under the age of 6 years ( $p<.001$ ) participated in this  
7 study than were represented in the Registry, and thus there were a few differences on age-  
8 correlated indicators (lower height and weight in the study sample, as expected for this age  
9 group). No other group differences were found, indicating that this sample was representative  
10 of the school-age and adolescent CF cohort in Germany.

### 22 Symptoms of anxiety and depression

23  
24  
25  
26  
27 Parents of children with CF reported significantly more symptoms of anxiety than the  
28 general population (see figure 1). At least borderline elevations in anxious symptoms were  
29 reported by 37.2% of parent caregivers, with 17.0% in the clinical range. In contrast, only  
30 18.9% of the general population reported borderline symptoms and 5.2% reported symptoms  
31 in the clinical range ( $\chi^2=59.208, p<.001$ ). Among parents, the most frequently reported items  
32 on the Anxiety scale were “I feel restless as I have to be on the move” ( $M=1.16, SD=1.0$ ), “I  
33 get a sort of frightened feeling as if something awful is about to happen” ( $M=1.16, SD=0.9$ ),  
34 and “I feel tense or wound up” ( $M=1.15, SD=0.8$ ). In general, mothers of children with CF  
35 reported significantly more anxious symptoms than fathers (mothers:  $M=6.7, SD=3.9$  versus  
36 fathers:  $M=5.9, SD=3.7, t=-2.29, p=.02$ ). There were no significant differences in anxious  
37 symptoms regarding any of the sociodemographic variables or FEV<sub>1</sub>%.

52

53 Symptoms of depression in parent caregivers as measured on the HADS Depression  
54 scale were comparable to those reported by the general population with 16.0% and 14.8%  
55 reporting at least borderline elevated scores, respectively. Results from the CES-D identified  
56 significantly more parent caregivers with elevated depression scores, compared to the general  
57  
58  
59  
60

1  
2  
3 population sample, using the international cut-off score of 16. Twenty-eight percent of parents  
4  
5 caring for a child with CF reported clinically elevated symptoms of depression on the CES-D  
6  
7 compared to 21% in the general population ( $\chi^2=6.339$ ,  $p=.01$ , see figure 1). Applying the  
8  
9 German cut-off score of 24, no significant group differences could be found.

Insert figure 1 about here

In the parent sample, the most frequently reported items included worries about the future ( $M=1.21$ ,  $SD=1.1$ ), feelings of being not as good as other people ( $M=1.10$ ,  $SD=1.2$ ), and problems feeling happy ( $M=1.03$ ,  $SD=1.0$ ) and enjoying life ( $M=1.03$ ,  $SD=1.0$ ). No significant gender difference was found in the level of depressive symptoms reported in the parent sample ( $t_{(598)}=-1.20$ ,  $p=.23$ ). More caregivers with elevated depressive symptoms had a low educational status ( $\chi^2=7.749$ ,  $p<.01$ ). There were no significant differences on any of the other sociodemographic variables or child lung function (FEV1%).

### Life satisfaction

Table 2 shows a comparison of the mean General and Health-related Life Satisfaction scores between the parent caregiver and community sample.

Insert Table 2 about here

Compared to the general population, parents caring for children with CF reported significantly less satisfaction on the following domains: Leisure Activities, General Health, Job Situation, Partnership/Sexuality, and General Life Satisfaction sum score ( $p=.001$ ). However, in the domain of Family Life, parents described themselves as being more satisfied than the community sample ( $p=.003$ ). In terms of health-related quality of life, parents of CF patients reported less satisfaction in the domains of Physical Condition, Ability to Relax, Energy/Zest for life, Freedom from Anxiety, Freedom from Aches/Pains and Independence of

1  
2  
3 Help/Care, compared to the general population sample. The sum score for Health-related Life  
4  
5 Satisfaction was also significantly lower in the parent than comparison sample ( $p<.001$ ).  
6  
7

8 In the parent sample no significant differences in General and/or Health-related Life  
9  
10 Satisfaction scores were found based on parental gender. Sociodemographic variables were  
11  
12 not significantly correlated with general and health-related life satisfaction. Likewise, child  
13  
14 lung function was not significantly associated with the parents' life satisfaction.  
15  
16  
17  
18  
19

### 20 Associations between symptoms of anxiety/depression and life satisfaction

21  
22 Anxious and depressive symptoms were negatively correlated with general and health-  
23  
24 related life satisfaction ( $r = -.37 - -.60, p=.001$ ). Univariate ANCOVAs, with the General and  
25  
26 Health-related Life Satisfaction scores as the dependent variables and controlling for child age  
27  
28 and lung function (which were inversely correlated,  $r = -.24$ ), indicated that life satisfaction  
29  
30 scores decreased when a concomitant increase of symptoms on the HADS Anxiety scale  
31  
32 ( $p<.001$ ) and on the CES-D ( $p<.001$ ) was observed. Results are shown in table 3. Moderate  
33  
34 effects were shown, with effect sizes ranging between  $\eta^2 = .077-.245$ .  
35  
36

42

## 43 **Discussion**

44  
45 This is the first large scale, multi-center study to assess the prevalence of symptoms of  
46  
47 anxiety, depression and life satisfaction in parents caring for children and adolescents with  
48  
49 CF. Although it was shown that the majority of parents of children with CF was doing fairly  
50  
51 well overall, the study results supported the central hypothesis, that anxious and depressive  
52  
53 symptoms are more common in German parents of minors with CF than a community sample  
54  
55 of adults matched by age and gender.  
56  
57  
58  
59

### 60 Anxious symptoms in parents

1  
2  
3 As expected we found elevated levels of anxious symptoms in the parent sample  
4 compared to the comparison group. This result is in line with the recent US single-center,  
5 where up to 50% of the caregivers reported elevated levels of anxious symptoms<sup>17</sup>. The  
6 ongoing real or anticipated threat of the progressive and fatal nature of their child's disease  
7 may explain these feelings of tension and fear parents' experience. An examination of  
8 individual items indicated that the most frequent concerns were worries directed towards the  
9 future and feelings of tension and restlessness. This result parallels findings from studies of  
10 pediatric asthma patients and their parent caregivers.<sup>38,39</sup>

11  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21  
22 Special attention should be paid to the functionality of parents' anxiety and its  
23 potential positive effects on caregiving. Disease-specific anxiety may facilitate parental  
24 alertness and monitoring of symptoms and help them stay prepared for changes in their  
25 child's disease status, including worsening symptoms, signs of an acute exacerbation, and  
26 need for treatment changes. In other chronic conditions, such as asthma, caregiver anxiety  
27 was associated with an increased use of asthma services and hospitalizations.<sup>39</sup> In a recent  
28 study of children with CF, co-morbid anxiety disorders and high levels of family cohesion  
29 were associated with better adherence to treatment.<sup>40</sup> However, parental anxiety may also  
30 induce a disproportionate level of care and overprotection,<sup>41</sup> which may lead to parent-teen  
31 conflict, e.g., adolescents desire for autonomy in managing their disease.<sup>42</sup> The association  
32 between parental anxiety and disease management is an important area that needs further  
33 study. Another important issue is the familial pattern of symptoms of anxiety, as in general  
34 psychopathological symptoms are likely to aggregate in families<sup>43,44</sup> and thus, it is possible  
35 that anxious symptoms in caregivers beget anxious symptoms in the child or vice versa. We  
36 addressed this issue in a separate paper on symptoms of psychological distress in parent-child  
37 dyads which is currently under review.

60 Depressive symptoms in parents

1  
2  
3 Concerning the prevalence of depressive symptoms somewhat inconsistent results  
4 emerged. As predicted and in line with the international literature<sup>45,46,16,17</sup>, we found a higher  
5 prevalence of depressive symptoms in our parent sample compared to the general population.  
6  
7 However, this was only true when the CES-D measure was applied using the international  
8 cut-off score of 16. Applying the adjusted national cut-off score of 24, which has been  
9 recommended for German samples,<sup>31</sup> results of the parent sample were comparable to those  
10 found in the control group and no significant group differences emerged. Thus, primarily  
11 using the broadly applied international cut-off score of 16 (which is part of the study  
12 methodology in order to allow for international comparisons) might lead to an overestimation  
13 of symptoms of depression in the German parent caregiver sample. The different thresholds  
14 for cut-points in this screening measure needs further study and should be kept in mind when  
15 conducting cross-cultural analyses of the international data set.  
16  
17

21  
22  
23  
24  
25  
26  
27  
28  
29  
30

31 Using the Depression Scale of the HADS, parent data were comparable to those of the  
32 general population sample. A similar result was found for male caregivers of children with CF  
33 in the study by Driscoll and colleagues; 31% of the sample had elevated scores on the CES-D  
34 compared to only 14% on the HADS depression scale<sup>17</sup>. Methodical differences in the two  
35 measures likely explain these differential findings. The HADS does not include any somatic  
36 items, such as fatigue, which are clearly relevant for parent caregivers who take major  
37 responsibility for managing daily CF treatments. This is the reason for considering the CES-D  
38 to be the more appropriate and valid screening measure. The fact that nearly one-third of  
39 parents reported elevated symptoms of depression on this measure points to the need for a  
40 more thorough clinical examination, given evidence which suggests that depressive moods in  
41 parents are linked to adherence to treatments and thus, health outcomes in the child (for  
42 review see<sup>15, 19</sup>). These results indicate that annual screening of parents caring for a child with  
43 CF, with referrals to mental health specialists when needed, should be initiated. In reporting  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 back the screening results and offering further support a high degree of tactfulness and  
4  
5 caution will certainly be needed in order to avoid opposition and defensiveness. Parents  
6  
7 should not get the impression that they and their reactions to their child's progressive disease  
8  
9 are characterized as psychologically abnormal, but rather as a normal reaction to the  
10  
11 tremendous burden of being a parent of a child with CF. In fact, the results underline the  
12  
13 necessity for support programs tailored to the specific needs of parents caring for a  
14  
15 chronically ill child.  
16  
17

18  
19  
20 It should also be noted that the vast majority of children were in good health, with  
21  
22 85% of children demonstrating no or only mild impairment of lung function, yet levels of  
23  
24 both anxious and depressive symptoms were clinically elevated for a large number of parents.  
25  
26 It is possible that despite the dramatic increase in life span for those diagnosed with CF,  
27  
28 recently projected as 37.4 years (CF Foundation Registry, 2008), it appears that management  
29  
30 of the disease takes a toll on parent caregivers. Future longitudinal studies should focus on the  
31  
32 course of the child's disease and its effects on parental functioning. It is possible that as the  
33  
34 child's condition worsens, symptoms of depression in parent caregivers may increase further  
35  
36 and require referral to mental health specialists. The comparison of those families with a sick  
37  
38 child (N=17) to the rest of the sample points in this direction. No significant group differences  
39  
40 were found, however, this is likely to be an effect of the small sample size, as the numerical  
41  
42 differences in the scores clearly indicate higher levels of depressive (and anxious) symptoms  
43  
44 in the group with acute medical conditions.  
45  
46  
47  
48  
49

#### 50 Life satisfaction

51  
52  
53 Results on Life Satisfaction supported our hypothesis and converged with previous  
54  
55 studies focusing on pediatric cancer patients,<sup>22,23</sup> with parents reporting less Life Satisfaction  
56  
57 compared to the community sample. In the General Life Satisfaction module, the worst life  
58  
59 satisfaction was reported in the domains of Leisure Activities, Job Situation and  
60

1  
2  
3 Partnership/Sexuality. When interpreting these results, note that most of the respondents were  
4  
5 mothers, who typically serve as the primary caregivers for their children and thus, have less  
6  
7 time for their own activities. This is in line with other studies pointing out that parents caring  
8  
9 for a child with CF have less time as a couple to engage in social and recreational activities  
10  
11 <sup>3,4748</sup>. Interestingly, parents reported better satisfaction with their family life compared to the  
12  
13 community sample. This finding also fits with prior literature on family adaptation to  
14  
15 childhood cancer, in which families commonly report higher levels of closeness and family  
16  
17 cohesion than families of healthy children. A study on the impact of a new diagnosis of a  
18  
19 chronic illness yielded similar results for parental quality of life,<sup>21</sup> concluding that coping  
20  
21 with a child's chronic illness may strengthen family cohesion and decrease conflict, as parents  
22  
23 utilize the emotional support of other family members in their adaptation process. Further,  
24  
25 Health-Related Life Satisfaction in this parent sample was impaired in most of the life  
26  
27 domains reported. This may be explained by the burden of everyday management of the  
28  
29 disease, which results in excessive demands on parents (e.g., establishing good relationships  
30  
31 with the CF healthcare team and integrating CF treatments into daily routines <sup>14</sup>) and  
32  
33 increased fatigue. As expected, anxious and depressive symptoms were negatively correlated  
34  
35 with General and Health-related Life Satisfaction and with higher levels of symptom severity,  
36  
37 a finding that converges with others on quality of life in patients with CF and their families.<sup>49</sup>  
38  
39  
40  
41  
42  
43  
44

#### 45 Study limitations

46  
47  
48 The strengths of this study include its multi-center design, large sample size and use of  
49  
50 standardized screening measures. However, the study had also several limitations. First, we  
51  
52 used data from comparison groups that were collected in previous studies. However, although  
53  
54 we did not collect these data in a parallel manner, we successfully matched the community  
55  
56 samples for age and gender. It is of course an interesting question whether or not parents  
57  
58 caring for a child with CF should be compared to general population controls, given the very  
59  
60

1  
2  
3 special circumstances and challenges of living with a chronically ill child which limit the  
4 comparability of these two groups. However, comparing parents of children with CF to a  
5 community sample seems to be a reasonable way to estimate the additional psychological  
6 distress of caring for a child with CF as opposed to “normal” levels of anxious and/or  
7 depressive symptoms. Unfortunately we have no information about the percentage of parents  
8 in the comparative populations. Thus, a biasing effect of being a parent could not be ruled out.  
9  
10 Second, two widely used screening measures were employed to assess the prevalence of  
11 anxious and depressive symptoms, but these screening results were not further validated with  
12 a structured, clinical interview. Hence, it is important to note that the elevated rates of above  
13 cut-off screening results should not be mixed up with respective diagnoses of anxiety and/or  
14 depressive disorders but rather indicate that a more rigorous clinical assessment is warranted.  
15  
16 Also, no multi-informant approach was used, but we only relied on parent self-report data.  
17  
18 Additional selection biases may also have occurred in relation to which CF Centers in  
19 Germany decided to participate and which parents were recruited for the study. For example,  
20 in a sub-study in one clinical site of the German arm of the TIDES study<sup>50</sup> the presence of a  
21 sample selection bias in terms of healthier persons being more likely to take part was shown.  
22  
23 This allows for the suggestion, that the present results are rather underestimating the presence  
24 of symptoms of anxiety and/or depression requiring further clinical evaluation. Unfortunately,  
25 for practical reasons, we could not gather information on non-participants, which limits the  
26 generalizability of our results. However, the fact that we were able to recruit a large number  
27 of parents is supposed to counteract this threat to external validity.  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51

52  
53 The cross-sectional design of our study precluded the monitoring of how parental  
54 symptoms of anxiety, depression and life satisfaction affected long-term health outcomes.  
55  
56 Future studies should investigate how changes in the child’s health (e.g., acute exacerbations,  
57 new diagnosis of CF-related diabetes) affect parents’ reports of psychological symptoms and  
58  
59  
60

1  
2  
3 quality of life. Thus, more complex, longitudinal studies are needed to examine the  
4  
5 bidirectional nature of these relationships.  
6  
7

### 8 Conclusions

9  
10 These results provided evidence for the importance of measuring psychological  
11  
12 symptoms and quality of life in parents caring for children with CF. Even though a huge part  
13  
14 of the parents was doing fairly well overall, a significant proportion of caregivers was  
15  
16 reporting borderline and clinical elevations of anxious and/or depressive symptoms.  
17  
18 Therefore, systematic screening during routine care, followed by a more thorough clinical  
19  
20 examination and the provision of psychosocial support and counselling if necessary may  
21  
22 facilitate improved family functioning, which is likely to have positive effects on children's  
23  
24 health outcomes.  
25  
26  
27  
28  
29  
30  
31

### 32 **Acknowledgments**

33  
34 The authors would like to thank all study centres and all patients and parent caregivers who  
35  
36 participated in the current study for generously giving of their time and support. We also  
37  
38 thank Paul Wenzlaff from the ZQM Hannover for his assistance with the analyses based on  
39  
40 the registry data.

Running head: Psychopathology in parents of minors with CF

**Abstract**

**Objective** To assess the prevalence of symptoms of anxiety and depression and the extent of life satisfaction in parents caring for children with cystic fibrosis (CF) in Germany.

**Methods** The study included 650 caregivers of 564 children with CF ages 0 to 17, who completed the Hospital Anxiety Depression Scale (HADS), the Center for Epidemiologic Studies Depression Scale (CES-D) and the Questions on Life Satisfaction (FLZ<sup>M</sup>).

**Results** More than one-third (37.2%) of parents showed elevated levels of anxious symptoms, compared to 18.9% of a population sample ( $p \leq .001$ ) and significantly more parents reported elevated levels of depressive symptoms compared to a community sample (28% vs. 21%,  $p = .01$ ). Higher levels of anxious and depressive symptoms were associated with lower life satisfaction ( $p < .001$ ).

**Conclusions** High levels of anxious and depressive symptoms among parents of children with CF suggested that annual symptom screening is warranted. This will facilitate identification of those at risk and provide referrals and intervention for those who are in need of it.

**Keywords:** Anxiety; cystic fibrosis; depression; life satisfaction; parent caregivers.

## Introduction

Chronic medical conditions, such as cystic fibrosis (CF), have significant implications for the psychosocial well-being of the family system.<sup>1</sup> Parents of children with chronic illnesses must cope with uncertainty about progression of the disease, as well as challenges in everyday life, including adherence to complex treatment regimens, regular clinic visits, hospitalizations, financial stress due to costs of care, and disruptions in future plans.<sup>2</sup> As a consequence of these caregiving challenges, parents are at a high risk for the development of psychological symptoms and decreased quality of life.<sup>3</sup>

Advances in medical care and treatments over the past 20 years have led to an increase in life span of patients with CF, with a majority of children in developed countries now living into adulthood.<sup>4</sup> However, management of CF requires adherence to a complex and time-consuming treatment regimen, including inhaled and oral medications, airway clearance, and

alterations in diet.<sup>5</sup> In general, poor adherence (50% or less) is reported in chronically ill pediatric populations<sup>6</sup>, and this was also shown for children with CF<sup>7</sup>. Adherence rates in children with CF vary depending on the specific treatment component, with adherence for chest physical therapy rated between 40-47%<sup>8</sup> and approximately 51% in a newer US study<sup>7</sup> and estimates being especially low for dietary recommendations<sup>9</sup>. Non-adherence can have serious consequences for the child's health status. Therefore, depending on the child's development, parents must take responsibility for administering and supervising the specific CF treatments, which has been shown to increase role strain in parents and lead to greater conflict with adolescents.<sup>3,3,10</sup> Studies have demonstrated that parents' symptoms of depression and anxiety, as well as general family functioning show a strong association with health outcomes in patients with CF.<sup>11,12</sup> These findings suggest that the impact of CF on parent caregivers' psychological functioning and quality of life requires further study.

From the late 1960s on, studies have examined the impact of CF on parents/caregivers (for review see <sup>13,14</sup>) with most studies finding high levels of psychological distress and increased risk of depressive symptoms.<sup>15</sup> A Turkish study on sleep quality and the psychological well-being of mothers caring for children with asthma or CF reported higher anxiety and depression scores than mothers of healthy children.<sup>16</sup> A single center study in the US examining the relations between symptoms of psychological distress and quality of life in caregivers of children with CF<sup>17</sup> found elevated rates of depressive and anxious symptoms, which were negatively correlated with parental quality of life. Rates of anxious symptoms were more pronounced (43-51%) compared to 14-31% (depending of the measure used) of the parents reporting elevated levels of depressive symptoms. In another US study, over one-third of parents scored in the elevated range on a depression measure and more symptoms of depression were associated with worse adherence to enzymes as well as either loss of weight or failure to make expected weight gains in children with CF three months later.<sup>18</sup> Similarly, a single center study from Smith and colleagues found 35% of mothers and 23% of fathers reported elevated symptoms of depression and 57% of mothers and 25% of fathers reported elevated anxiety. Further, symptoms of depression in parents of school-age children were associated with worse adherence to airway clearance.<sup>19</sup>

Research has also shown that caring for a child with a chronic condition can negatively affect parents' quality of life,<sup>20,21</sup> as they are confronted with the threat of a life-limiting illness and additionally have to face multiple social and emotional stressors associated with their child's disease, e.g., fear, less time for social activities, financial burdens, etc. Also, parents' health-related quality of life proved to be worse than that reported by parents of healthy children.<sup>22,23</sup> However, specific studies on the health-related quality of life of parents caring for a child with CF are rare. In the single-center study by Driscoll and colleagues already mentioned above, a good child lung functioning was

Deleted: ¶

9  
10 To date, no large scale epidemiological studies have systematically examined the  
11  
12 prevalence of anxiety and depression and subjectively reported quality of life of parents  
13  
14 caring for a child with CF. Therefore “The International Depression/Anxiety Epidemiological  
15  
16 Study” (TIDES, www.tides-cf.org) was initiated in 2007 with more than ten countries  
17  
18 worldwide participating so far. The objectives were to screen for depressive and anxious  
19  
20 symptoms in adolescent and adult patients with CF and parents caring for a minor child with  
21  
22 CF, and to link these psychological data to the patients' health outcomes. Here, parent data  
23  
24 from the German arm of the study including 32 CF Centers are presented. The patient data  
25  
26 have been published elsewhere.<sup>24</sup> Standardized screening tools were used to estimate the  
27  
28 prevalence of anxious and depressive symptoms in parents caring for a child with CF. Further,  
29  
30 rather than evaluating the broader concept of quality of life, the focus was on assessment of  
31  
32 life satisfaction, defined as subjectively perceived quality of life based on individual  
33  
34 preferences and reported satisfaction in multiple life domains.<sup>25</sup>

35  
36 Thus, the purpose of the current study was to test the following hypotheses using a large,  
37  
38 nationally representative sample:

- 39 1. Compared to the general population, symptoms of anxiety and depression were  
40  
41 expected to be more prevalent in parent caregivers of minors (under age 18 years) with  
42  
43 CF.
- 44 2. Life satisfaction was expected to be lower in parent caregivers of minors with CF than  
45  
46 in the general population.  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

3. Among parents, a significant negative association was expected between symptoms of anxiety/depression and life satisfaction.

## Materials and Methods

### Procedure

Data collection took place between February 2007 and April 2008. The study protocol was approved by the Institutional Review Board of the University of Ulm and the local IRBs at the 32 participating CF clinics (representing about one third of the German CF outpatient units). This study was part of a larger international prevalence study initiated in the United States (see [www.tides-cf.org](http://www.tides-cf.org)). During routine clinic visits, parents of children with CF ages 0 to through 17 were informed of the study's purpose and objectives and were asked to participate. After completion of informed consent, a demographics questionnaire and screening instruments (see below) for symptoms of anxiety/depression and life satisfaction were administered by a member of the CF team, such as a social worker, psychologist, or nurse. Anxious and depressive symptoms in parents were measured with the Hospital Anxiety and Depression Scale (HADS). Additionally, to measure parental depressive symptoms, the CES-D was administered, as the HADS Depression scale excludes relevant somatic items (e.g., fatigue). Thus, the CES-D was considered the primary measure and more appropriate screener for depressive symptoms. The Questions on Life Satisfaction (FLZ<sup>M</sup>) were used to evaluate parental life satisfaction. Completion of the questionnaires took about 20 minutes. The measures were scored immediately upon completion and if the participant scored above the clinical cut-off score ( $\geq 8$  points) on either the anxiety or depression scale, a referral to a mental health professional was initiated.

Parents also agreed to the collection of medical data on their child with CF, which were extracted from the German CF registry. The variables extracted were current height,

weight, FEV1 in liters, FEV1% predicted, colonization with germs (*Pseudomonas aeruginosa* yes/no; *Burkholderia cepacia* yes/no), complications during the last year (hemoptysis yes/no, pneumothorax yes/no or new diagnosis of CF-related Diabetes yes/no).

## Measures

### Hospital Anxiety and Depression Scale (HADS)

The HADS<sup>26</sup> is a brief and easy to administer 14-item instrument which measures symptoms of anxiety (7 items) and depression (7 items). It was designed specifically for use with chronically ill patients and therefore, physical symptoms (such as headaches or fatigue) that could be associated with a medical condition were excluded. The instrument has been translated into numerous languages and has been used extensively in different countries with different populations. Respondents rate each symptom using a 4-point scale (range 0-3), indicating the current extent of the symptom. Results of this screening measure can be analysed both categorically, discriminating normal (0-7 points), borderline (8-10 points) and clinical levels of symptoms ( $\geq 11$  points) as indicated by cut-off scores provided by the authors, and dimensionally by adding the raw scores of each scale.

The HADS has extensive reliability and validity data<sup>27,28</sup> with strong internal consistency as measured by *Cronbach's*  $\alpha$  of .82 for the Anxiety subscale (HADS-A) and .83 for the Depression subscale (HADS-D) in the current sample. Optimal sensitivity and specificity (approximately .80 each) was achieved most frequently using a cut-off score of 8 for the Anxiety scale.<sup>28</sup> External validity has been demonstrated, with strong convergence found between the HADS and other validated anxiety and depression measures. In this study, the German version of the HADS<sup>29</sup> was administered.

### Center of Epidemiologic Studies Depression Scale (CES-D)

The Center for Epidemiologic Studies Depression Scale, CES-D,<sup>30</sup> is a frequently used 20-item self-report instrument screening for the major components of depression, including

Formatted: Font: Italic

Deleted: Subjects¶

Parents of children and adolescents with CF¶

A total of 650 parent caregivers (75.5% mothers) of 564 minors with CF (0-17 years,  $M=9.5$ ,  $SD=4.6$ ; 54.9% male) were consecutively recruited for the study during a routine clinic visit at their CF center. Participating patients were compared to those not participating in this study, but whose data are included in the German CF Registry. These data included socio-demographic (e.g., age, gender, education, living situation) and medical information (e.g., height, weight, FEV<sub>1</sub>%). Fewer parents with children under the age of 6 years ( $p<.001$ ) participated in this study than were represented in the Registry, and thus there were a few differences on age-correlated indicators (lower height and weight in the study sample, as expected for this age group). No other group differences were found, indicating that this sample was representative of the school-age and adolescent CF cohort in Germany. ¶ In 478 cases, data were obtained from only one parent (73 fathers, 405 mothers), whereas we received two data sets (one from father, one from mother) for the remaining 86 children. Children's lung function, measured as FEV<sub>1</sub>% predicted, ranged from 15.7% to 138.7% ( $M=89.8\%$ ,  $SD=21.1$ ), with 83.2% of the children falling in the normal to mild range of disease severity (FEV<sub>1</sub>%  $\geq 70$ ) and only 2.5% falling in the severely impaired range (FEV<sub>1</sub>%  $\leq 40$ ). Table 1 shows the characteristics of the parent sample, separately for mothers and fathers. ¶

depressive mood, feelings of guilt and worthlessness, loss of appetite, and sleep disturbance.

It was designed to assess all major symptoms of depression in community samples and has excellent psychometric properties, evidencing good internal consistency (Cronbach's  $\alpha = .89$  in the current sample). For each item, respondents rate the frequency of their symptoms over the past week on a 4-point scale ranging from 0-3. All items scores are summed to yield a total score, ranging from 0-60. Higher scores indicate more depressive symptoms, with a score of 16 or higher identified as the clinical cut-off score for depressive symptoms.<sup>30</sup> In this study, the German version of the CES-D<sup>31</sup> was administered. In the German manual the use of an adapted cut-off score of 24 or higher is suggested, referring to a large but non representative community sample. To allow for international comparability, both, the international cut-off score of 16 and the German cut-off score of 24 were, applied in this study.

#### Questions on Life Satisfaction (FLZ<sup>M</sup>)

The Questions on Life Satisfaction (German: Fragen zur LebensZufriedenheit, FLZ<sup>M25</sup>) is a multidimensional measure of General and Health-related Life Satisfaction in eight domains of daily life (e.g., leisure time/hobbies, family life, physical condition, ability to relax, etc.). The instrument includes ratings of the subjective importance for each domain, which can be used to weight ratings of satisfaction. Each domain is evaluated twice, once for the importance and once for satisfaction, on 5-point rating scales ranging from 1 (not important/dissatisfied) to 5 (extremely important/very satisfied). Weighted scores for each item are then calculated using the following formula: *weighted satisfaction = (importance rating -1) x ((2x satisfaction rating)-5)*.<sup>25</sup> Item-specific weighted scores range from -12 to +20, with negative scores indicating dissatisfaction with the domain measured. Domains without subjective importance are weighted 0, and thus do not impact the individual's life satisfaction. Total scores for General and Health-related Life Satisfaction are computed by summing the eight general and

Deleted: <sup>19</sup>

Formatted: Superscript

Formatted: Superscript

Deleted: <sup>19</sup>

eight health-related domain scores, and they range from -96 to +160. Higher scores indicate better satisfaction with life. Good reliability and validity of the FLZ<sup>M</sup> has been reported in previous studies using the instrument with adolescent and adult populations.<sup>25,32-34</sup> In the current sample *Cronbach's α* was .83 for the General Life Satisfaction module and .88 for the Health-related Life Satisfaction module.

### Statistical analyses

To allow for group comparisons, we used the most recent instrument-specific data from normative reference samples. For the HADS data, we used data from a German survey study.<sup>35</sup> The general population sample was selected based on 216 sample points in Germany using the random-route-technique (random selection of street, house, flat and target subject in the household). This sample, with a response rate of 68%, can be assumed to be representative of the adult German population living in private households. Individuals from foreign countries were not included in the sample because of problems with command of the German language. The original sample, with complete data consisted of 2037 people aged 14-92 years, with a mean age of 49.2 (SD=17.3). These respondents were matched for age and gender with our parent sample, leading to a sample size of 614 (22-60 years, *M*=40.0 years, *SD*=7.2, 76.4% female).

Formatted: Indent: First line: 35.4 pt

Formatted: Superscript

To analyse the CES-D data we used comparative data from a representative population sample in cooperation with the German study group mentioned above (*N*=2005, 14-91 years, *M*=48.0, *SD*=18.3). Matching for age and gender led to a sample size of 620 people aged 21-60 years (*M*=40.0 years, *SD*=7.3, 76.6% female).

The life satisfaction data, measured with the Questions on Life Satisfaction (FLZ<sup>M</sup>), were also compared to community samples. For the general life satisfaction module, data came from a large community sample (*N*=5036, 14-92 years, *M*=48.4, *SD*=18.0, 53.7% female). Comparison data for the health-related life satisfaction module came from the FLZ<sup>M</sup>

standardization study<sup>36</sup> with 1338 German adults from the community (17-95 years,  $M=46.9$ ,  $SD=17.2$ , 54.6% female). An analogous matching procedure was completed for both samples, selecting those participants with an age-gender combination paralleling the parent caregiver sample. Their responses were weighted so that the age and gender distribution in the two community samples paralleled the distribution in the parent caregiver sample. The matching procedure resulted in a sample of 2718 subjects for the general life satisfaction module and 768 subjects for the health-related life satisfaction module.

Formatted: Superscript

The frequencies of elevated HADS Anxiety and Depression scores and CES-D scores were calculated using the established cut-off scores. Group comparisons with the community sample, matched for age and gender, were performed using  $\chi^2$ -tests. Gender differences comparing the mean scores of mothers and fathers were determined using *Student's t*-tests. Associations of elevated levels of anxious/depressive symptoms and the following socio-demographic and disease-related variables were determined applying *Chi square* tests or *t*-tests for independent samples: parent education (0= 10 years of school or less, 1= "Abitur" or university degree), parent employment (0=no employment outside of the home, 1=employment outside of the home), parent age, child age, and FEV1% as indicator for child health status. FLZ<sup>M</sup> raw scores were transformed into weighted scores and two total scores were calculated for General and Health-related Life Satisfaction. *Student's t*-tests for independent samples were used to examine potential differences between the parent and matched community sample. *Spearman's rho* was used to test the associations between life satisfaction and the same sociodemographic and disease-related variables that were used to explore the associations with parental anxious and/or depressive symptoms. To test the associations among symptoms of anxiety and depression and life satisfaction, univariate analyses of covariance (ANCOVAs) were calculated with the level of anxious symptoms (normal – borderline - abnormal) and depressive symptoms as measured with the CES-D

### Sample Characteristics

A total of 650 parent caregivers of 564 minors with CF (0-17 years,  $M=9.5$ ,  $SD=4.6$ ; 54.9% male) were consecutively recruited for the study during a routine clinic visit at their CF center. This was approximately 50% of all eligible families at the participating sites. Reasons for non-participation included no time, no interest in the study, data protection concerns, etc. In 478 cases, data were obtained from only one parent (73 fathers, 405 mothers), whereas we received two data sets (one from father, one from mother) for the remaining 86 children. Children's lung function, measured as FEV<sub>1</sub>% predicted, ranged from 15.7% to 138.7% ( $M=89.8\%$ ,  $SD=21.1$ ), with 83.2% of the children falling in the normal to mild range of disease severity (FEV<sub>1</sub>% >70) and only 2.5% falling in the severely impaired range (FEV<sub>1</sub>% <40). In 17 cases (3.1%) the patients were experiencing acute medical conditions. The parents of these patients were included in the study sample; however, comparisons were made to the rest of the parents whose children were currently not sick or experiencing pulmonary exacerbations. Table 1 shows the characteristics of the parent sample, separately for mothers and fathers.

### Symptoms of anxiety and depression

Parents of children with CF reported significantly more symptoms of anxiety than the general population (see figure 1). At least borderline elevations in anxious symptoms were reported by 37.2% of parent caregivers, with 17.0% in the clinical range. In contrast, only 18.9% of the general population reported borderline symptoms and 5.2% reported symptoms in the clinical range ( $\chi^2=59.208, p<.001$ ). Among parents, the most frequently reported items on the Anxiety scale were “I feel restless as I have to be on the move” ( $M=1.16, SD=1.0$ ), “I get a sort of frightened feeling as if something awful is about to happen” ( $M=1.16, SD=0.9$ ), and “I feel tense or wound up” ( $M=1.15, SD=0.8$ ). In general, mothers of children with CF reported significantly more anxious symptoms than fathers (mothers:  $M=6.7, SD=3.9$  versus fathers:  $M=5.9, SD=3.7, t=-2.29, p=.02$ ). There were no significant differences in anxious symptoms regarding any of the sociodemographic variables or FEV<sub>1</sub>%.

Formatted: Font: Not Bold

Deleted: Δ

Deleted: anxiety

Symptoms of depression in parent caregivers as measured on the HADS Depression scale were comparable to those reported by the general population with 16.0% and 14.8% reporting at least borderline elevated scores, respectively. Results from the CES-D identified

1  
2 significantly more parent caregivers with elevated depression scores, compared to the general  
3  
4 population sample, using the international cut-off score of 16. Twenty-eight percent of parents  
5  
6 caring for a child with CF reported clinically elevated symptoms of depression on the CES-D  
7  
8 compared to 21% in the general population ( $\chi^2=6.339, p=.01$ , see figure 1). Applying the  
9  
10 German cut-off score of 24, no significant group differences could be found.

11  
12 Insert figure 1 about here

Formatted: Centered

14 In the parent sample, the most frequently reported items included worries about the  
15 future ( $M=1.21, SD=1.1$ ), feelings of being not as good as other people ( $M=1.10, SD=1.2$ ),  
16 and problems feeling happy ( $M=1.03, SD=1.0$ ) and enjoying life ( $M=1.03, SD=1.0$ ). No  
17  
18 significant gender difference was found in the level of depressive symptoms reported in the  
19  
20 parent sample ( $t_{(598)}=-1.20, p=.23$ ). More caregivers with elevated depressive symptoms had a  
21  
22 low educational status ( $\chi^2=7.749, p<.01$ ). There were no significant differences on any of the  
23  
24 other sociodemographic variables or child lung function (FEV1%).

## Discussion

Deleted: \_\_\_\_\_

This is the first large scale, multi-center study to assess the prevalence of symptoms of anxiety, depression and life satisfaction in parents caring for children and adolescents with CF. Although it was shown that the majority of parents of children with CF was doing fairly well overall, the study results supported the central hypothesis, that anxious and depressive symptoms are more common in German parents of minors with CF than a community sample of adults matched by age and gender.

Deleted: T

Anxious symptoms in parents

Deleted: Parental anxiety

As expected we found elevated levels of anxious symptoms in the parent sample compared to the comparison group. This result is in line with the recent US single-center, where up to 50% of the caregivers reported elevated levels of anxious symptoms<sup>17</sup>. The ongoing real or anticipated threat of the progressive and fatal nature of their child's disease may explain these feelings of tension and fear parents' experience. An examination of individual items indicated that the most frequent concerns were worries directed towards the future and feelings of tension and restlessness. This result parallels findings from studies of pediatric asthma patients and their parent caregivers.<sup>38,39</sup>

Deleted: anxiety

Deleted:

Formatted: Superscript

Deleted: about the prognosis of their child

Formatted: Superscript

Deleted: <sup>32,33</sup>

Special attention should be paid to the functionality of parents' anxiety and its potential positive effects on caregiving. Disease-specific anxiety may facilitate parental alertness and monitoring of symptoms and help them stay prepared for changes in their child's disease status, including worsening symptoms, signs of an acute exacerbation, and need for treatment changes. In other chronic conditions, such as asthma, caregiver anxiety was associated with an increased use of asthma services and hospitalizations.<sup>39</sup> In a recent study of children with CF, co-morbid anxiety disorders and high levels of family cohesion were associated with better adherence to treatment.<sup>40</sup> However, parental anxiety may also induce a disproportionate level of care and overprotection,<sup>41</sup> which may lead to parent-teen conflict, e.g., adolescents desire for autonomy in managing their disease.<sup>42</sup> The association between parental anxiety and disease management is an important area that needs further study. Another important issue is the familial pattern of symptoms of anxiety, as in general psychopathological symptoms are likely to aggregate in families<sup>43,44</sup> and thus, it is possible that anxious symptoms in caregivers beget anxious symptoms in the child or vice versa. We addressed this issue in a separate paper on symptoms of psychological distress in parent-child dyads which is currently under review. Depressive symptoms in parents

Deleted: <sup>33</sup>

Formatted: Superscript

Deleted: <sup>34</sup>Deleted: <sup>35</sup>Deleted: <sup>36</sup>

Deleted:

Deleted: Parental depression

Concerning the prevalence of depressive symptoms somewhat inconsistent results emerged. As predicted and in line with the international literature<sup>16,17,45,46</sup> we found a higher prevalence of depressive symptoms in our parent sample compared to the general population. However, this was only true when the CES-D measure was applied using the international cut-off score of 16. Applying the adjusted national cut-off score of 24, which has been recommended for German samples,<sup>31</sup> results of the parent sample were comparable to those found in the control group and no significant group differences emerged. Thus, primarily using the broadly applied international cut-off score of 16 (which is part of the study methodology in order to allow for international comparisons) might lead to an overestimation of symptoms of depression in the German parent caregiver sample. The different thresholds for cut-points in this screening measure needs further study and should be kept in mind when conducting cross-cultural analyses of the international data set.

Deleted: <sup>11</sup>

Deleted: .

Formatted: Superscript

Using the Depression Scale of the HADS, parent data were comparable to those of the general population sample. A similar result was found for male caregivers of children with CF in the study by Driscoll and colleagues; 31% of the sample had elevated scores on the CES-D compared to only 14% on the HADS depression scale<sup>17</sup>. Methodical differences in the two measures likely explain these differential findings. The HADS does not include any somatic items, such as fatigue, which are clearly relevant for parent caregivers who take major responsibility for managing daily CF treatments. This is the reason for considering the CES-D to be the more appropriate and valid screening measure. The fact that nearly one-third of parents reported elevated symptoms of depression on this measure points to the need for a more thorough clinical examination, given evidence which suggests that depressive moods in parents are linked to adherence to treatments and thus, health outcomes in the child (for review see<sup>15,19</sup>). These results indicate that annual screening of parents caring for a child with CF, with referrals to mental health specialists when needed, should be initiated. In reporting

Formatted: Superscript

Formatted: Superscript

Deleted: <sup>11</sup>

Formatted: Superscript

Deleted: <sup>13</sup>

Deleted: caregiver

back the screening results and offering further support a high degree of tactfulness and caution will certainly be needed in order to avoid opposition and defensiveness. Parents should not get the impression that they and their reactions to their child's progressive disease are characterized as psychologically abnormal, but rather as a normal reaction to the tremendous burden of being a parent of a child with CF. In fact, the results underline the necessity for support programs tailored to the specific needs of parents caring for a chronically ill child.

It should also be noted that the vast majority of children were in good health, with 85% of children demonstrating no or only mild impairment of lung function, yet levels of both anxious and depressive symptoms were clinically elevated for a large number of parents.

Deleted: anxiety

Deleted: depression

It is possible that despite the dramatic increase in life span for those diagnosed with CF, recently projected as 37.4 years (CF Foundation Registry, 2008), it appears that management of the disease takes a toll on parent caregivers. Future longitudinal studies should focus on the course of the child's disease and its effects on parental functioning. It is possible that as the child's condition worsens, symptoms of depression in parent caregivers may increase further and require referral to mental health specialists. The comparison of those families with a sick child (N=17) to the rest of the sample points in this direction. No significant group differences were found, however, this is likely to be an effect of the small sample size, as the numerical differences in the scores clearly indicate higher levels of depressive (and anxious) symptoms in the group with acute medical conditions.

**Deleted:** In interpreting these results, it should be noted that we applied the international cut-off score of 16, even though an adjusted cut-off score of 23 has been recommended for German samples.<sup>27</sup> Applying this adjusted national cut-off score, results of the parent sample were comparable to those found in the control group and no significant group differences emerged. Thus, our study methodology using the broadly applied international cut-off score of 16 might have led to an overestimation of symptoms of depression in the German parent caregiver sample. The different thresholds for cut-points in this screening measure needs further study and should be kept in mind when conducting cross-cultural analyses of the international data set. ¶

#### Life satisfaction

Results on Life Satisfaction supported our hypothesis and converged with previous studies focusing on pediatric cancer patients,<sup>22,23</sup> with parents reporting less Life Satisfaction compared to the community sample. In the General Life Satisfaction module, the worst life satisfaction was reported in the domains of Leisure Activities, Job Situation and

Formatted: Superscript

Deleted: <sup>16,17</sup>

Partnership/Sexuality. When interpreting these results, note that most of the respondents were mothers, who typically serve as the primary caregivers for their children and thus, have less time for their own activities. This is in line with other studies pointing out that parents caring for a child with CF have less time as a couple to engage in social and recreational activities

<sup>3,47,48</sup>. Interestingly, parents reported better satisfaction with their family life compared to the community sample. This finding also fits with prior literature on family adaptation to

childhood cancer, in which families commonly report higher levels of closeness and family cohesion than families of healthy children. A study on the impact of a new diagnosis of a

chronic illness yielded similar results for parental quality of life,<sup>21</sup> concluding that coping with a child's chronic illness may strengthen family cohesion and decrease conflict, as parents utilize the emotional support of other family members in their adaptation process. Further,

Health-Related Life Satisfaction in this parent sample was impaired in most of the life domains reported. This may be explained by the burden of everyday management of the

disease, which results in excessive demands on parents (e.g., establishing good relationships with the CF healthcare team and integrating CF treatments into daily routines<sup>14</sup>) and

increased fatigue. As expected, anxious and depressive symptoms were negatively correlated with General and Health-related Life Satisfaction and with higher levels of symptom severity, a finding that converges with others on quality of life in patients with CF and their families.<sup>49</sup>

#### Study limitations

The strengths of this study include its multi-center design, large sample size and use of standardized screening measures. However, the study had also several limitations. First, we used data from comparison groups that were collected in previous studies. However, although we did not collect these data in a parallel manner, we successfully matched the community samples for age and gender. It is of course an interesting question whether or not parents caring for a child with CF should be compared to general population controls, given the very

**Deleted:** When interpreting these results, note that most of the respondents were mothers, who typically serve as the primary caregivers for their children and thus, have less time for their own activities (see also<sup>3</sup>).

1  
2 special circumstances and challenges of living with a chronically ill child which limit the  
3 comparability of these two groups. However, comparing parents of children with CF to a  
4 community sample seems to be a reasonable way to estimate the additional psychological  
5 distress of caring for a child with CF as opposed to “normal” levels of anxious and/or  
6 depressive symptoms. Unfortunately we have no information about the percentage of parents  
7  
8  
9  
10  
11 in the comparative populations. Thus, a biasing effect of being a parent could not be ruled out.

60

Second, two widely used screening measures were employed to assess the prevalence of  
anxious and depressive symptoms, but these screening results were not further validated with  
a structured, clinical interview. Hence, it is important to note that the elevated rates of above  
cut-off screening results should not be mixed up with respective diagnoses of anxiety and/or  
depressive disorders but rather indicate that a more rigorous clinical assessment is warranted.

Deleted: This might have biased the prevalence estimates we found.

Also, no multi-informant approach was used, but we only relied on parent self-report data.

Deleted:

Additional selection biases may also have occurred in relation to which CF Centers in  
Germany decided to participate and which parents were recruited for the study. For example,  
in a sub-study in one clinical site of the German arm of the TIDES study<sup>50</sup> the presence of a  
sample selection bias in terms of healthier persons being more likely to take part was shown.  
This allows for the suggestion, that the present results are rather underestimating the presence  
of symptoms of anxiety and/or depression requiring further clinical evaluation. Unfortunately,  
for practical reasons, we could not gather information on non-participants, which limits the  
generalizability of our results. However, the fact that we were able to recruit a large number  
of parents is supposed to counteract this threat to external validity.

Deleted: since

Deleted: ,

Deleted: seems minimal

The cross-sectional design of our study precluded the monitoring of how parental  
symptoms of anxiety, depression and life satisfaction affected long-term health outcomes.  
Future studies should investigate how changes in the child's health (e.g., acute exacerbations,  
new diagnosis of CF-related diabetes) affect parents' reports of psychological symptoms and

1  
2 quality of life. Thus, more complex, longitudinal studies are needed to examine the  
3  
4 bidirectional nature of these relationships.

### 5 6 Conclusions

7  
8 These results provided evidence for the importance of measuring psychological  
9  
10 symptoms and quality of life in parents caring for children with CF. Even though a huge part  
11 of the parents was doing fairly well overall, a significant proportion of caregivers was  
12 reporting borderline and clinical elevations of anxious and/or depressive symptoms.  
13  
14 Therefore, systematic screening during routine care, followed by a more thorough clinical  
15 examination and the provision of psychosocial support and counselling if necessary may  
16  
17 facilitate improved family functioning, which is likely to have positive effects on children's  
18  
19 health outcomes.

### 26 **Acknowledgments**

27  
28 The authors would like to thank all study centres and all patients and parent caregivers who  
29  
30 participated in the current study for generously giving of their time and support. We also  
31  
32 thank Paul Wenzlaff from the ZQM Hannover for his assistance with the analyses based on  
33  
34 the registry data.

For Peer Review

**Subjects***Parents of children and adolescents with CF*

A total of 650 parent caregivers (75.5% mothers) of 564 minors with CF (0-17 years,  $M=9.5$ ,  $SD=4.6$ ; 54.9% male) were consecutively recruited for the study during a routine clinic visit at their CF center. Participating patients were compared to those not participating in this study, but whose data are included in the German CF Registry. These data included socio-demographic (e.g., age, gender, education, living situation) and medical information (e.g., height, weight,  $FEV_1\%$ ). Fewer parents with children under the age of 6 years ( $p<.001$ ) participated in this study than were represented in the Registry, and thus there were a few differences on age-correlated indicators (lower height and weight in the study sample, as expected for this age group). No other group differences were found, indicating that this sample was representative of the school-age and adolescent CF cohort in Germany.

In 478 cases, data were obtained from only one parent (73 fathers, 405 mothers), whereas we received two data sets (one from father, one from mother) for the remaining 86 children. Children's lung function, measured as  $FEV_1\%$  predicted, ranged from 15.7% to 138.7% ( $M=89.8\%$ ,  $SD=21.1$ ), with 83.2% of the children falling in the normal to mild range of disease severity ( $FEV_1\% \geq 70$ ) and only 2.5% falling in the severely impaired range ( $FEV_1\% \leq 40$ ). Table 1 shows the characteristics of the parent sample, separately for mothers and fathers.

Insert Table 1 about here

*Normative data from the German general population*

1  
2  
3 To allow for group comparisons, we used the most recent instrument-specific data from  
4  
5  
6 normative reference samples. For the screening of anxiety, we used data from a German  
7  
8 survey study.<sup>20</sup> The general population sample was selected based on 216 sample points  
9  
10 in Germany using the random-route-technique (random selection of street, house, flat and  
11  
12 target subject in the household). This sample, with a response rate of 68%, can be  
13  
14 assumed to be representative of the adult German population living in private households.  
15  
16 Individuals from foreign countries were not included in the sample because of problems  
17  
18 with command of the German language. The original sample, with complete data  
19  
20 consisted of 2037 people aged 14-92 years, with a mean age of 49.2 ( $SD=17.3$ ). These  
21  
22 respondents were matched for age and gender with our parent sample, leading to a  
23  
24 sample size of 614 (22-60 years,  $M=40.0$  years,  $SD=7.2$ , 76.4% female).  
25  
26  
27  
28

29 To analyse the data on depression we used comparative data from a representative  
30  
31 population sample in cooperation with the German study group mentioned above  
32  
33 ( $N=2005$ , 14-91 years,  $M=48.0$ ,  $SD=18.3$ ). Matching for age and gender led to a sample  
34  
35 size of 620 people aged 21-60 years ( $M=40.0$  years,  $SD=7.3$ , 76.6% female).  
36  
37  
38

39 The life satisfaction data, measured with the Questions on Life Satisfaction  
40  
41 ( $FLZ^M$ ), were also compared to community samples. For the general life satisfaction  
42  
43 module, data came from a large community sample ( $N=5036$ , 14-92 years,  $M=48.4$ ,  
44  
45  $SD=18.0$ , 53.7% female). Comparison data for the health-related life satisfaction module  
46  
47 came from the  $FLZ^M$  standardization study<sup>21</sup> with 1338 German adults from the  
48  
49 community (17-95 years,  $M=46.9$ ,  $SD=17.2$ , 54.6% female). An analogous matching  
50  
51 procedure was completed for both samples, selecting those participants with an age-  
52  
53 gender combination paralleling the parent caregiver sample. Their responses were  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 weighted so that the age and gender distribution in the two community samples paralleled  
4  
5 the distribution in the parent caregiver sample. The matching procedure resulted in a  
6  
7 sample of 2718 subjects for the general life satisfaction module and 768 subjects for the  
8  
9 health-related life satisfaction module.

3 Response to re-reviews  
4

5 Dear Dr. Chernick,  
6  
7

8 Many thanks for forwarding the reviewers' comments on the revised version of our  
9 manuscript. We are pleased to learn that our manuscript has been provisionally accepted for  
10 publication in Pediatric Pulmonology. Again, we would like to thank the reviewers for their  
11 valuable and helpful comments during the review process.  
12

13  
14 # reviewer 1:

15 We apologize for not having updated the reference list in the marked version of the revision.  
16 However, the updated reference list including all references cited in the revised text was  
17 already attached to the "clean version" of the revision (R1clean). We have now also updated  
18 the reference list in the marked version of the revision (R2marked). No other changes have  
19 been made to the manuscript.  
20  
21

22 Best wishes,  
23

**Table 3: Results of the two ANCOVAs for weighted Life Satisfaction scores as dependent factors and level of symptom severity on the HADS Anxiety scale (normal-borderline-abnormal) and on the CES-D (normal-international cut-off 16-German cut-off 24) as independent factors, controlling for child age and lung function**

		<i>N</i>	<i>M (SD)</i>	<i>F</i>	<i>p</i>	$\eta^2$
<b>General Life Satisfaction</b>						
HADS-Anxiety	normal	211	69.5 (33.8)			
	borderline	75	54.9 (33.8)	14.133	<.001	.077
	abnormal	58	43.5 (36.7)			
CES-Depression	normal	232	70.6 (31.8)			
	cut-off 16	72	48.8 (34.7)	29.502	<.001	.147
	cut-off 24	43	32.4 (37.3)			
<b>Health-related Life Satisfaction</b>						
HADS-Anxiety	normal	239	83.9 (36.7)			
	borderline	85	56.5 (31.8)	36.957	<.001	.162
	abnormal	63	43.4 (45.0)			
CES-Depression	normal	266	85.1 (34.7)			
	cut-off 16	79	46.6 (33.4)	62.779	<.001	.245
	cut-off 24	47	35.3 (41.9)
