Abstract

This report presents a novel approach to compute high quality and alias-free soft shadows using exact visibility computations. This work relies on a theoretical framework allowing to group lines according to the geometry they intersect. From this study, we derive a new algorithm encoding lazily the visibility from a polygon. Contrary to previous works on from-polygon visibility, our approach is very robust and straightforward to implement. We apply this algorithm to solve exactly and efficiently the visibility of an area light source from any point in a scene. As a consequence, results are not sensitive to noise, contrary to soft shadows methods based on area light source sampling. We demonstrate the reliability of our approach on different scenes and configurations.

1 Introduction

Shadows and especially soft shadows play an important role in visual perception as they unveil spatial relationships between objects. This makes soft shadows essential to realistic rendering. However, they are very expensive to compute since they require solving the visibility of an area light source from any visible point in a scene. The accuracy of any solution to this problem determines the soft shadows quality and, as a consequence, the realism of the scene.

Dedicated algorithms were developed to reduce the computational complexity inherent to soft shadows. Interactive solutions exist, but they make crude assumptions leading to approximate or plausible soft shadows. They are forced to sacrifice the correctness of the shadows in order to reach interactive frame rates. Geometry-based approaches can lead to fine results, using silhouette edges [LLA06, FBP08] for example. While the accuracy of the visibility computation is crucial for soft shadows, the wide majority of algorithms are based on sampled light sources. As a consequence, whatever their accuracy, they are still sensitive to noise according to the sampling strategy and density.

In this paper, we present a new high quality soft shadow algorithm based on exact visibility computed from the area light source. Our method relies on an equivalence relation allowing to group lines according to the geometry they intersect [Pel04]. We build on this theoretical framework to provide a novel and practical approach to lazily compute the exact visibility from a polygon. This visibility data allows to solve efficiently and exactly the visibility of an area light source for each point to be shaded, taking advantage of the visibility coherence between neighbour points. Since the direct illumination is analytically evaluated using exact visibility, the shadows are optimal and alias-free. While exact approaches suffer from implementation and robustness issues, our method is easy to implement, scalable and numerically robust. In addition, our results show that it outperforms an optimized ray tracer.

The paper is organized as follows: The first section outlines the works related to this paper. The second section presents the geometrical and mathematical framework we use. Moreover, we demonstrate an
essential theorem to our algorithm. The third section details our exact from-polygon visibility algorithm which is the basis to solve the visibility of an area light source. At last, in the section 4, we test our algorithm’s behaviour in different configurations. Before concluding, we discuss these results, we analyse some limitations and we consider several perspectives.

2 Previous works

Many contributions on soft shadows can be found in the literature. A survey has been presented by Hasenfratz et al. [HLH03]. Recently, Eisemann et al. [EASW09] provide another interesting lecture. In this section, we only focus on widely used or recent physically-based algorithms able to compute very high quality or exact soft shadows. In addition, since the core of our method relies on an exact from-polygon visibility algorithm, we also focus on this topic.

Soft shadows in ray and beam tracing

Ray tracing easily supports soft shadows using shadow rays and stochastic sampling of the light sources. As a counterpart, the results are sensitive to noise. This requires increasing the number of samples in order to avoid visual artifacts. But this drastically slows down the rendering. Packet [WBWS01] and frustrum [RSH05, WK*06] traversal techniques improve ray-tracing efficiency. They take advantage of the spatial coherence and have efficient implementations, using SIMD instructions. Moreover, they can be designed for a specific graphic architecture [BW09]. Despite these improvements, soft shadows remain a challenging task. If the sample distribution can be improved using importance or interleaved sampling, the results remain sensitive to noise.

Beam tracing [HH84] methods are suited for soft shadows computation. A single beam is cast to the light to solve exactly its visibility. As a consequence, results are not sensitive to noise. Beam tracing is usually considered as lacking robustness, which can be improved by adaptive methods [GH98]. Overbeck et al. [ORM07] propose a robust beam-triangle intersection to handle more complex models with soft shadows.

Packets, frustrum or beam techniques take advantage of the spatial coherence from each point to be shaded. Our algorithm uses the spatial coherence from the light source. This is an important difference since the shading of the points is not an independent operation anymore.

Silhouette based soft shadows

Möller and Assarson [AMA02, AAM03] propose the soft shadow volume algorithm on graphics hardware. It extends the shadow volume algorithm [Cro77] using penumbra wedges. A wedge is the place where the light source view can change because of a silhouette edge. Given a point inside a wedge, the relevant silhouette edge is projected onto the light to determine the light samples visibility. However, overlapping silhouette edges lead to overestimating the shadow and silhouette edges are underestimated since they are computed only from the center of the light source. As a consequence, soft shadows are approximated.

The soft shadow volume algorithm is extended to offline ray-tracing by Laine et al. [LAA*05]. All the silhouette edges are taken into account and the algorithm deals properly with the overlapping ones. Special rules determine the light samples affected by each silhouette edges. Then a single ray is shot to recover the samples visibility. Lehtinen et al. [LLA06] remark that this algorithm can be over-conservative and less efficient than a classical ray-tracer. They change the data structure used to store the silhouette edges, improving both the algorithm efficiency and its memory consumption.

Forest et al. [FBP08] build on the works of [AAM03] and [LLA06]. They remove the shooting ray step and provide a dedicated implementation on graphics hardware allowing several frames per second on moderate scenes using an average of 16 light samples per light sources.

Research on silhouette based algorithms has lead to very efficient solutions. However, they require triangles connectivity with consistent orientation. Since these methods are object-based, visibility computations are accurate. But they are still subject to aliasing because of the light source sampling. The sampling strategy has a significant impact as shown in [FBP08].
Other methods
Laine et al. [LA05] change the pre-processing order of ray tracing. Instead of finding a triangle hit by a shadow ray, they search all the shadow rays intersecting a given triangle. Notice that the same idea was used to provide interactive GPU algorithms based on triangles [ED07, SEA08] or extended to silhouette edges [JHH\textsuperscript{*}09]. However, approximations are made to reach such frame rates. In this work, we also focus on the sets of lines intersecting triangles. However, we use an analytical representation of those sets.

Exact from-polygon visibility
Exact solutions to visibility problems are important to better understand its underlying nature, and design new algorithms. However, exact from-polygon (and thus from-region) visibility is very complex, because it is a four-dimensional problem [DDP02]. There are few solutions in the literature. They all rely on the same theoretical framework described by Pellegrini [Pel04] in the Plücker space, a 5D space of lines. His analysis provides a worst case complexity of $O(n^4 \log n)$ in space and time, where $n$ is the number of triangles. This underlines the complexity inherent to the visibility in space. To remain practicable, a very special care must be given to the algorithm design. As an example, a first approach is proposed by Mount and Pu [MP99]. But their experiments do not exceed 14 random triangles, because, as stated by the authors, they reach the theoretical complexity upper bound.

The two first practicable algorithms are provided by Nirenstein et al. [NBG02] and Bittner [Bit02] (see [MAM05] for details about the differences between the two solutions), and further improved by Haumont et al. [HMN05] and Mora et al. [MA05] respectively. It is worth underlying a major difference between the two approaches initiated by Nirenstein and Bittner respectively:

- Nirenstein and Haumont design their algorithms to prove that two polygons are visible. Thus the algorithm output is a boolean value. Whenever possible, the computation of the whole visibility set is avoided since the process can be terminated as soon as a visibility is found.
- Mount, Bittner and Mora algorithms aim to compute and store all the visibility information. In this case, the output is a partition of the Plücker space encoded in a Binary Space Partitioning tree.

Despite this difference, they all rely on Computing Solid Geometry in the Plücker space which is computationally very expensive. As a consequence, they are only used as a pre-process step. In addition 5D CSG operations are very complex to implement and prone to numerical instability. Thus, the reliability and the scalability of these solutions is restricted.

The soft shadow algorithm presented in this paper relies on a novel approach to capture the visibility from a polygon. It also leads to the construction of a BSP tree in the Plücker space. But in contrast to the previous works, the tree is built lazily and at run time, not as a pre-process step. Visibility is computed on-demand when and where it is required, according to the image resolution. It does not rely on any expensive and complicated 5D CSG operation. This makes the algorithm very easy to implement, efficient and computationally robust, whereas previous methods are complex and suffer from numerical instability.

3 Geometrical basis

In this section we introduce the geometrical knowledge underlying the work presented in this paper. In particular, we demonstrate a result on the orientation of the lines stabbing two polygons. This result is important for our algorithm.

3.1 Plücker’s coordinates

The Plücker space is a five dimensional projective space, denoted $\mathbb{P}^5$, well known in computer graphics as an efficient solution for dealing with real 3D lines [Sho98]. We only recall here the properties used in this paper. Let’s consider an oriented 3D line $l$ going through two distinct points $P$ and $Q$ of coordinates $(p_x, p_y, p_z)$ and $(q_x, q_y, q_z)$ respectively. The line $l$ maps to the Plücker point denoted $\pi_l \in \mathbb{P}^5$. The six
coordinates of \( \pi_l \), denoted \((l_0, l_1, l_2, l_3, l_4, l_5)\) are defined by:

\[
\begin{align*}
l_0 &= q_x - p_x \\
l_1 &= q_y - p_y \\
l_2 &= q_z - p_z \\
l_3 &= q_x p_y - q_y p_x \\
l_4 &= q_y p_z - q_z p_y \\
l_5 &= q_z p_x - q_x p_z
\end{align*}
\]

Any Plücker point is in bijection with its dual hyperplane:

\[
h_l(x) = l_3 x_0 + l_4 x_1 + l_5 x_2 + l_0 x_3 + l_1 x_4 + l_2 x_5 = 0
\]

with \( x \in \mathbb{P}^5 \) with coordinates \((x_0, x_1, x_2, x_3, x_4, x_5)\). Thus, any line \( l \) in the 3D space can be mapped to the Plücker space as a point \( \pi_l \) or its dual hyperplane \( h_l \). We now recall the definition of the so-called side operator:

\[
side(l, r) = l_3 r_0 + l_4 r_1 + l_5 r_2 + l_0 r_3 + l_1 r_4 + l_2 r_5
\]

where \( l \) and \( r \) are two 3D lines, \((l_0, l_1, l_2, l_3, l_4, l_5)\) and \((r_0, r_1, r_2, r_3, r_4, r_5)\) are respectively the coordinates of their Plücker point, \( \pi_l \) and \( \pi_r \). The sign of the side operator determines the relative orientation of the two lines. In particular, two lines are incident (or parallel) if their side operator equals zero. We can notice that: \( side(l, r) = h_l(\pi_r) \). This leads to the geometrical interpretation of the side operator as depicted in Figure 1.

### 3.2 On the lines intersecting the same triangles

A direct application of the side operator is an easy and robust line-triangle intersection test. A line intersects a triangle if its orientation is consistent in respect to the lines spanning the triangle edges. This is depicted in Figure 2. Beyond this intersection test, we can notice that the 3 hyperplanes related to the triangle edges
Figure 2: Left: a triangle in 3D space. \( l^0, l^1, l^2 \) are the lines spanning the triangle’s edges. \( a \) is a line stabbing the triangle. Right: \( h_{l^0}, h_{l^1} \) and \( h_{l^2} \) are the Plücker hyperplanes mapped from \( l^0, l^1 \) and \( l^2 \). \( \pi_a \) is the Plücker point mapped from the stabbing line \( a \). \( \pi_a \) has a consistent orientation in respect to \( l^0, l^1 \) and \( l^2 \). From a geometrical point of view, \( \pi_a \) lies at the intersection of the halfspaces induced by \( h_{l^0}, h_{l^1} \) and \( h_{l^2} \). Thus, these 3 hyperplanes provide an analytical representation of all the lines stabbing the triangle.

divide the Plücker space into cells and one of them contains all the lines (i.e. their Plücker points) stabbing the triangle, while the other cells contain the lines missing the triangle.

Pellegrini [Pel04] develops a more general approach. He uses the Plücker space as a framework to

Figure 3: Left: 2 triangles and 3 lines \( a, b, c \) in various configurations. Right: The arrangement of hyperplanes (illustrated by 6 2D lines) mapped from the 6 triangles edges. They divide the Plücker space into cells. Filled cells are set of lines intersecting at least one triangle. \( \pi_a, \pi_b \) and \( \pi_c \) are the Plücker points mapped from \( a, b \) and \( c \). They are located in the cells they belong to, according to the triangle(s) they stab. For example, \( \pi_b \) has a consistent orientation in respect to the 6 hyperplanes since \( b \) intersects the two triangles. Its relevant cell holds all the lines intersecting the two triangles.

provide theoretical bounds on various problems involving lines. Let \( S \) be a set of several triangles (or convex polygons) and \( L_S \) be the lines spanning the triangles edges in \( S \). Each line in \( L_S \) can be mapped to Plücker space as a hyperplane. This builds an arrangement in Plücker space: A decomposition of the space into cells by a set of hyperplanes. All the points in a same cell satisfy the following property: They all have
the same sign in respect to its bounding hyperplanes. This is illustrated in Figure 3 with 2 triangles. Thus, in Plücker space, all the lines (i.e. their Plücker points) belonging to the same cell intersect the same subset of triangles in $S$. Notice that this subset can be empty if the lines miss all the triangles in $S$.

The decomposition of Plücker space into cells allows to group lines together according to the subset of triangles they intersect. This defines an equivalence relation on lines. As a consequence, each cell corresponds to an equivalence class (sometimes called isotopy class [Pel91] or orientation class [CEG*96]). To sum up, the Pellegrini approach allows an exact and analytical representation of all the sets of lines generated by a set of triangles $S$, using the set of lines $L_S$.

### 3.3 Orientation of lines intersecting two polygons

We focus on the set of lines intersecting two convex polygons. We demonstrate the following theorem:

**Theorem 1** Let $A$ and $B$ be two convex polygons with $n$ and $m$ vertices respectively. We define $vvset = \{v_{ij}, i \in [1,n], j \in [1,m]\}$ the set of the lines $v_{ij}$ defined by one vertex of $A$ and one vertex of $B$. Let $l$ be any line and $q$ a line intersecting $A$ and $B$:

\[
\begin{align*}
\text{side}(l, x) &\geq 0, \forall x \in vvset \Rightarrow \text{side}(l, q) \geq 0 \\
\text{side}(l, x) &\leq 0, \forall x \in vvset \Rightarrow \text{side}(l, q) \leq 0
\end{align*}
\]

In other words, if all the vertex-to-vertex lines of two polygons have a positive (resp. negative) orientation in respect to any line $l$, all the stabbing lines of the two polygons will have a positive (resp. negative) orientation in respect to $l$.

To demonstrate this theorem, we use a vector notation for Plücker’s coordinates: Given two points $P$ and $Q$, the Plücker coordinates of $(PQ)$ is the vector couple $(\vec{u}, \vec{v})$ such as:

\[
\begin{align*}
(PQ) \begin{cases}
\vec{u} = \overrightarrow{PQ} \\
\vec{v} = \overrightarrow{OP} \times \overrightarrow{OQ}
\end{cases} = (l_0, l_1, l_2)
\end{align*}
\]

Where $O$ is the origin in 3D space. For simplicity, we will omit the symbol $'$, simply denoting the vector couple $(u, v)$. Using this notation, we now formulate the side operator as the sum of two dot products. For example, given two lines $l$ and $l'$ with Plücker coordinates $(u, v)$ and $(u', v')$ respectively, then: $\text{side}(l, l') = u \cdot v' + v \cdot u'$.

**Proof:** Let $A$ and $B$ be two convex polygons with $n$ and $m$ vertices in the 3D space. Using barycentric coordinates, any point $a$ on $A$ (resp. $b$ on $B$) can be defined by a combination of its vertices $(a_1, \ldots, a_n)$ (resp. $b_1, \ldots, b_m$):

\[
a = \sum_{i=1}^{n} \alpha_i a_i \quad \text{with} \quad \sum_{i=1}^{n} \alpha_i = 1, \quad \alpha_i \geq 0
\]

\[
b = \sum_{i=1}^{m} \beta_i b_i \quad \text{with} \quad \sum_{i=1}^{m} \beta_i = 1, \quad \beta_i \geq 0
\]

$a$ and $b$ define any line $q$ stabbing $A$ and $B$, and the Plücker point of $q$ is $(ab, oa \times ob)$. Thus the relative orientation of a line $q$ and any line $l (u, v)$ is:

\[
\text{side}(q, l) = u.(oa \times ob) + v.ab
\]

Since the orientation of two lines is relative, we can assume without loss of generality that $l$ goes through the origin of the 3D space (otherwise it is always possible to translate $l$). Thus $v$ (the last 3 Plücker coordinates of $l$) becomes null and:

\[
\text{side}(q, l) = u.(oa \times ob)
\]

Since the cross product is distributive over addition:

\[
\text{side}(q, l) = u.(\sum_i^n (\alpha_i a_i \times \beta_j b_j))
\]
Next, by compatibility with scalar multiplication:

\[
side(q,l) = u.(\sum_j^n \beta_j \sum_i^m \alpha_i (oa_i \times ob_j))
\]

At last, since the dot product is distributive over addition:

\[
side(q,l) = \sum_j^n \beta_j \sum_i^m \alpha_i u.(oa_i \times ob_j) = \sum_j^n \beta_j \sum_i^m \alpha_i (side(a,b_j,l))
\]

Since \(\alpha_i \geq 0\) and \(\beta_j \geq 0\), the sign of \(side(q,l)\) depends only on the sign of \(side(a,b_j,l)\). In particular, if they are all positive (resp negative) then \(side(q,l)\) is positive (resp negative).

Using this theorem, we can determine if the set of lines stabbing two polygons has a consistent orientation in respect to a given line. The visibility algorithm presented in the next section uses this essential result.

4 Algorithm

Since equivalence classes are continuous sets of lines that hit/miss the same subset of triangles, they represent coherent paths through the scene independently of any viewpoint. As a consequence, two lines belonging to the same equivalence class are spatially coherent. We use this property to build a Plücker space partition representing the visibility of an area light source.

4.1 Overview

We consider an area light source \(L\), a triangle \(T\), and define their occluders \(O\) as the triangles intersecting their convex hull. To represent the light source visibility, we focus on the sets of lines intersecting \(L\) and which either miss all the occluders in \(O\), or hit at least one occluder in \(O\). Thus, we define:

- **A visible class**: Any equivalence class representing a set of lines that do not intersect any occluders.
- **An invisible class**: Any equivalence class representing a set of lines that intersect at least one occluder.
- **An undefined class**: An equivalence class that is not yet found as visible or invisible.

Our algorithm builds a BSP tree in Plücker space, providing a hierarchical representation of the equivalence classes generated by the occluders. Each leaf represents one of these three classes. The algorithm is lazy: The BSP tree is grown on-demand depending on when and where visibility information is needed. The construction only relies on two operations: Inserting and merging an occluder into the tree. The former allows to find the leaves affected by an occluder in the tree, while the latter grows the tree by replacing a leaf with an occluder’s equivalence classes.

**Merging an occluder:**

Let \(o\) be an occluder, we note \(bsp(o)\) the BSP representation of the equivalence classes generated by \(o\) (see Figure 4). The tree grows each time an occluder is merged: The visible/invisible classes generated by the occluder are added to the tree. Merging \(o\) into the tree consists in replacing a leaf by the root of \(bsp(o)\). As a consequence, each inner node contains a hyperplane corresponding to an occluder’s edge.

**Inserting an occluder:**

Occluders are inserted into the tree and located into the leaves (and thus the classes) they may affect. Inserting an occluder \(o\) comes down to testing the relative orientation of a hyperplane (from an inner node) and the lines occluded by \(o\). Since the occlusion created by an occluder \(o\) is the set of lines intersecting both \(L\) and \(o\), we use Theorem 1 to determine the orientation of the occluded lines with respect to the hyperplane. Figure 5 details the three cases that occur.
Figure 4: Let $l_0, l_1, l_2$ be the lines defined by the edges of an occluder $o$, and $h_0, h_1, h_2$ their dual hyperplanes in Plücker space. We can build a BSP tree whose leaves are the four equivalence classes generated by the triangle: Three visible classes (left leaves) and one invisible class (right leaf). We note $bsp(o)$ such a representation.

Figure 5: A 2D illustration of an insertion. An occluder $o$ intersects a subset of all the lines originating from the light $L$. This subset may have a negative (first case), a mixed (second case), or a positive (third case) orientation in respect to a hyperplane $h$ from an inner node. As a consequence the occluder $o$ is inserted into the right, or both, or left subtree of the node. When a leaf is reached, the occluder is stored into the leaf except if it is an invisible class.
The BSP tree construction is driven by the visibility queries in order to compute only the required equivalence classes. The following section presents this process and gives the details of our visibility algorithm. Next, we describe how it is used in our soft shadow framework.

4.2 Visibility algorithm

We consider the following visibility query: Given a point \(xyz\) on the triangle \(T\), we want to find out the visible parts of the light \(L\) from \(xyz\) through the occluders \(O\). This involves all the lines originating from \(xyz\) and intersecting \(L\). As a consequence, we have to find the subsets of those lines belonging to a visible class. At first, we explain how those sets can be represented using convex fragments of \(L\). Let us consider a line \(h\) spanning an occluder edge in \(O\). We observe that \(h\) and \(xyz\) define a plane \(p\) that sets apart the lines intersecting \(xyz\) and \(L\) in two sets: The first one with a positive orientation with respect to \(h\), the second one with a negative orientation. Figure 6 gives an illustration. Notice that the orientation of \(p\) is coherent with the orientation of \(h\). As a consequence, if \(L\) is split by \(p\), we can compute the two relevant polygons \(L \cap p^+\) and \(L \cap p^-\) so that they represent respectively the positive and negative subset of lines with respect to \(h\).

The visibility algorithm (Algorithm 1) finds the equivalence classes related to the visibility of \(L\) from \(xyz\). It subdivides \(L\) into several convex fragments so that each one of them belongs to a single equivalence class. It starts with all the occluders associated to a single undefined leaf. For each inner node, we compute the plane defined by \(xyz\) and the line stored in the node (line 18). Then, \(L\) is tested against this plane to determine the orientation of the lines stabbing \(L\) and \(xyz\) (line 19). If \(L\) lies in the positive (resp. negative) half-space of the plane, then all the lines have a positive (resp. negative) orientation, and the algorithm continues in the left (resp. right) subtree (line 20 or 22). Otherwise, \(L\) is split against the plane and the algorithm continues recursively in both subtrees with the relevant parts of \(L\) (line 25). When a fragment reaches a leaf, two alternatives occur:

- The leaf has no occluders, therefore it is either a visible or an invisible class. In the former case, the fragment is a convex part of \(L\) which is visible from \(xyz\), thus it is returned (line 29). Otherwise, the fragment is invisible from \(xyz\) and it is discarded.

![Figure 6: The point \(xyz\) and the line \(h\) define a plane that sets apart the lines having a positive or negative orientation in respect to \(h\)](image-url)
Algorithm 1 Visibility algorithm: Given a point \(xyz\) on \(T\), the algorithm answers the query "which parts of \(L\) are visible from \(xyz\)? \(L\) is used to drive the BSP tree construction and may be split into several fragments representing homogeneous sets of lines from \(xyz\). The fragments reaching visible classes are the visible parts of \(L\) from \(xyz\):

1. \textbf{insertOccluder}(Node \(n\), Occluder \(o\))
2. \textbf{if} \(n\) is a leaf \textbf{then}
3. \hspace{1em} \textbf{if} \(n\) is not an invisible class \textbf{then}
4. \hspace{2em} \(n\).occluders ← \(n\).occluders \(\cup o\)
5. \hspace{1em} \textbf{end if}
6. \textbf{else if} orientation( \(o\).vvset, \(n\).hyperplane) > 0 \textbf{then}
7. \hspace{1em} \textbf{insert}( \(n\).left, \(o\))
8. \textbf{else if} orientation( \(o\).vvset, \(n\).hyperplane) < 0 \textbf{then}

10. \textbf{else}
11. \hspace{1em} \textbf{insert}( \(n\).left, \(o\))
12. \hspace{1em} \textbf{insert}( \(n\).right, \(o\))
13. \textbf{end if}
14. \textbf{end if}
15. \textbf{BSP_query}(Node \(n\), Polygon \(L\), Point \(xyz\)) \textbf{return} Polylons
16. \textbf{loop}
17. \hspace{1em} \textbf{while} \(n\) is not a leaf \textbf{do}
18. \hspace{2em} Plane \(p\) ← \textbf{makePlane}( \(xyz\), \(n\).hyperplane)
19. \hspace{2em} \textbf{if} position( \(p\), \(L\)) > 0 \textbf{then}
20. \hspace{3em} \(n\) ← \(n\).left
21. \hspace{2em} \textbf{else if} position( \(p\), \(L\)) < 0 \textbf{then}
22. \hspace{3em} \(n\) ← \(n\).right
23. \hspace{2em} \textbf{else}
24. \hspace{3em} \textbf{// split the light and work recursively}
25. \hspace{3em} \textbf{return} \textbf{BSP_query}(\(n\).left, \(L\) \(\cap p^+\))
26. \hspace{3em} \(\cup\) \textbf{BSP_query}(\(n\).right, \(L\) \(\cap p^-\))
27. \hspace{2em} \textbf{end if}
28. \hspace{1em} \textbf{end while}
29. \hspace{1em} \textbf{return} \((n\).class is visible) ? \(L\) : \(\emptyset\)
30. \textbf{else}
31. \hspace{1em} \(ro\) ← \textbf{random occluder} in \(n\).occluders
32. \hspace{1em} \(n\) ← \textbf{root of} \textbf{bsp}(\(ro\))
33. \hspace{1em} \textbf{for} \(o\) in \(n\).occluders, \(o \neq ro\) \textbf{do}
34. \hspace{2em} \textbf{insertOccluder}(\(n\), \(o\))
35. \hspace{1em} \textbf{end for}
36. \hspace{1em} \textbf{end if}
37. \textbf{end loop}

- The leaf has some occluders, the class is undefined and we cannot answer the query without further developing the tree.

In the latter case, the algorithm chooses a random occluder (line 31) \(ro\) among the occluders associated with the current leaf. This occluder is merged into the tree by replacing the leaf by \textbf{bsp}(\(ro\)), the BSP representation of the four classes generated by \(ro\) (line 32). Next, the remaining occluders are inserted into \textbf{bsp}(\(ro\)) which is now a new part of the tree. The procedure at line 1 achieve an occluder insertion as describe in Figure 5. When all the occluders have been inserted in \textbf{bsp}(\(o\)), the algorithm continues from the root of \textbf{bsp}(\(o\)) until it finds the equivalence class for the current light fragment.
4.3 Key points

This section underlines significant points of the algorithm.

Random selection of the occluders:
The algorithm’s efficiency is related to the balance of the tree. To develop the BSP tree, the algorithm chooses an occluder randomly. Obviously, some choices may lead to a more balanced tree than others. However, this is not predictable. In fact, we have tested different heuristics, trying to make a “good choice”. Unfortunately, all of them achieved poor improvements compared to the extra computational cost. Moreover, their behaviour can be very different according to the nature of the scene. We have reached the conclusion that a random choice gives better results, and more important, it has a consistent behaviour whatever the rendered scene. This is similar to the choice of the pivot in the well-known quicksort algorithm: Although a random pivot is not the optimal choice, it leads to the best performance in practice whatever the entry is.

Conservative insertion:
If all the lines occluded by an occluder $o$ do not have the same orientation in respect to a hyperplane, $o$ is inserted in both subtrees of the relevant node. As a consequence, the insertion is conservative. This step could be computed exactly as in [HMN05, MA05]. But, as explained in section 2, this is expensive and prone to numerical errors. Our algorithm avoids these problems to remain simple and robust.

Tree growth:
Notice that not all the queries will develop the BSP tree. We can expect some queries to develop new equivalence classes, at least at the beginning since the BSP tree is empty. And we can expect queries to take advantage of the previous computations thanks to the visibility coherence. This is a key point of the algorithm’s efficiency.

4.4 Soft shadows framework

To illustrate the efficiency and the reliability of our exact visibility algorithm, we plug it into a ray-tracing rendering software for computing high-quality soft shadows. Algorithm 2 describes the process.

Algorithm 2 The following pseudocode illustrates how our visibility algorithm is plugged in a ray tracer software to analytically compute soft shadows. Algorithm 2 describes the process.

1: build $visible\_triangle$, the triangle list visible from the camera
2: foreach light $L$ in the scene do
3: triangle_list ← $visible\_triangle$
4: // the following loop parallelization is straightforward
5: while triangle_list is not empty do
6: remove a triangle $T$ from the triangle_list
7: select the occluders $O$ of $T$ and $L$.
8: initialize a BSP tree root node $n$ associated with $O$
9: foreach image point $xyz$ on $T$ do
10: $visible\_parts ← BSP\_query( n, xyz, L)$
11: compute the illumination in $xyz$ using $visible\_parts$
12: end for
13: end while
14: end for

- Using the primary rays, all the image points are grouped together with respect to the triangle they belong to. This builds a list of visible triangles (line 1).
- Multiple lights are handled successively and independently (line 2).
- For each visible triangle, an empty BSP tree is created and associated with its set of occluders (line 8).
Next, for each image point, the algorithm 1 is used to compute the visible parts of the light (line 10). In our framework, we consider area light sources with a uniform emission, therefore we compute direct illumination analytically (line 11) by integrating over the visible parts of the light [NN85].

This framework is designed to allow an efficient implementation. Since one BSP tree is built per light and per visible triangle, and since visible triangles are successively handled, BSP trees are developed successively and independently. This improves the memory coherence and avoids switching many times between BSP trees. This also limits the memory consumption since each BSP tree is deleted as soon as all its related image points are shaded. Moreover, the implementation can be easily multithreaded: A thread gets a visible triangle from the list, shades its image points and starts over until the list becomes empty. In this case, the triangle list access (line 6) has to be protected.

**Implementation details**

In Section 4, occluders are defined as the geometry intersecting the convex hull of a triangle and a light source. In practice, the occluders selection relies on a shaft culling approach as described in [Hai00]. Let’s consider the bounding box of a visible triangle and the bounding box of an area light source. The shaft is defined as the convex hull of the two bounding boxes plus the triangle’s plane support and the light’s plane support. Any triangle intersecting the shaft is considered as a possible occluder. While this definition can lead to a conservative occluder set, it can be computed efficiently. At last, compared to Algorithm 1, a stack is managed to avoid recursive system calls. Except this detail, the implementation is straightforward, it uses single floating point precision and does not use SIMD instructions.

**5 Results**

All tests were run on a 2.67 GHz Intel Core i7 920 processor with 4GB of memory. For comparison purpose, all pictures were rendered at 1280x720 pixels with one primary ray per pixel. Four sets of results are presented, three sets testing the global performance of our soft shadow framework, and a last one giving an insight on Algorithm 1 behaviour.

**5.1 Comparisons on time and quality**

The first set of results compares our method to ray-traced soft shadows both at comparable time and comparable quality. The ray tracer implementation is similar to [WBWS01]: It relies on an optimized SAH kd-tree, uses SIMD instructions to trace four rays simultaneously, and supports multithreading to render several parts of the picture in parallel. Ray-traced soft shadows are computed using groups of 4 shadow rays, and an uncorrelated stratified sampling of the area light sources. Since both our method and the ray-tracer support multithreading, all computations are run using 4 threads.

We use four scenes to test our method in different configurations. Despite its moderate geometrical complexity (26 673 triangles), the T-Rex scene is challenging for our approach because it presents difficult and complex shadows due to a long rectangular light source. This means that the light source visibility is complex and this is precisely what is computed by our algorithm. The modified Sponza Atrium with the statue of Neptune (115 737 triangles) and Conference (282 873 triangles) are significant and detailed models with different kinds of shadow complexities. At last, Soda Hall (2 147K triangles) is used to test the scalability of our approach on a massive model with heterogeneous geometry.

Figure 7 details these results, and presents the time spent in soft shadows computation for each method. At comparable time, ray traced soft shadows are always noisy. At comparable quality (i.e. the noise is not noticeable anymore in the stochastic shadows), our method is always faster. In addition, this is very noticeable on a complex case such as the T-rex scene, because the stochastic approach requires a very high number of shadow rays to remove almost all the visible noise. In contrast, the exact visibility algorithm produces high quality results in a few seconds.

Figure 8 presents the computation measurements (memory and time consumption) for our exact visibility algorithm. Since we compute a BSP tree in Plücker space for each visible triangle from the camera, the memory consumption varies during the process according to the building of the BSP tree. As a consequence, our results report the maximum memory load reached by our soft shadow framework. In any case,
the memory footprint is low. The lazy evaluation of the visibility driven by the visibility queries allows to focus on the equivalence classes related to the shadows and avoid the computation of useless visibility data. In addition, our framework is designed to avoid building too many BSP trees simultaneously (at most one per thread) which helps to keep the memory low.

The total time can be subdived in three steps: The occluder selection, the BSP tree initialization (including the computation of the hyperplanes and the $v$set for each occluder), and the visibility queries used for shading the image points. We can notice that the computation time is clearly dominated by the visibility queries i.e. calls to the BSP\_query function (see Algorithm 1) which is the core of our method.

Aside the comparison with the stochastic approach, these results demonstrate the robustness of our analytical visibility algorithm in many different configurations. As expected, the sensitivity of our algorithm to the visual complexity of the light source is confirmed. For instance, the T-Rex scene required roughly the

Figure 8: The time and memory consumption using our algorithm. The Max Size (MS) column is the maximum memory load reached during the process. The Shaft Culling (SC) gives the time percentage spent to select the occluders. The Init (I) column gives the time percentage spent to initialize each BSP tree. The Queries (Q) gives the time percentage spent to query the BSP trees for each image point. The Total (T) column gives the time in seconds for the whole process. The Modified Version (MV) presents the result obtained using a Modified Version of our framework, where all queries are prevented from taking advantage of the others. The last column gives the falling off factor (FO) between our framework (Total) and its modified version (MV Time).

same amount of time than the Sponza and Neptune scene or than the Conference scene.

**About visibility coherence**

A crucial property of our approach is its ability to take advantage of the visibility coherence between image points. To test this ability, the same pictures were rendered again using a modified version of our visibility algorithm. Between each visibility query (i.e., between each BSP_query call), the related BSP tree is reset to its root node associated with its former occluder set (this additional operation is excluded from the timings). In such a case, each query is “the first one” and we prevent all queries from taking advantage of the previous ones. Figure 8 presents (two last columns of the table) the computation times compared to the timings obtained with the true version: The loss of efficiency is considerable. This demonstrates the capacity of the visibility algorithm to benefit from the visibility coherence, which is a key point to its efficiency.

**5.2 Increasing the area of the light**

The soft shadows complexity also depends on the size of the area light source. This is intrinsic to the soft shadows problem and it will inevitably affect our algorithm since it relies on the visibility coherence of the light source. If its area increases, the visibility coherence may decrease and lead to a loss of efficiency. As a consequence, the second part of our tests investigates our framework’s behavior when the area light source increases. These tests are run on the Conference model, selected for its significant number of triangles as well as the wide range of shadows cast in the scene. The tests start using a small area light source whose size is progressively increased until it becomes 100 times larger. For each size of light, the time and maximum memory used by our method is measured. Figure 9 sums up the results. As expected, it shows a loss of efficiency, both in time and memory, as the size of light source grows (left and right graph of Figure 9). By extent, there is inevitably a critical light size where the time and the memory consumption would become a problem, in particular the memory since it is a limited resource. However, our tests show that, even with the largest area light source, we are far from such a point. In addition, our approach remains competitive with a stochastic solution: At comparable quality, 512 samples are required for the largest light and the computation takes 91 seconds against 39 seconds using our framework (2.33 times slower).

**5.3 Increasing the light number**

Generally, a scene has several light sources. As detailed by Algorithm 2, our implementation supports multiple lights which are handled successively. Thus, it is interesting to test our framework behaviour in such a case. The Conference model is used again and rendered with 2 to 36 area light sources. All the lights have the same size and cast roughly the same "amount" of shadow. Figure 10 presents the results. The left
Figure 9: Increasing the light size. Left: the time consumption (top) and the maximum memory load (down) reached during the computations. Right: 3 pictures from our tests with the smallest, the medium and the largest area light source (100 times larger than the smallest one).

The graph shows that the time consumption is linear in respect to the number of area light sources. This is the expected behaviour since our framework evaluates the contribution of each light source one after another. In addition this makes the memory load independent from the number of lights, as shown on the right graph. However we can notice a significant growth of the memory load when the number of lights is more than 12. Indeed, the 12 first lights are above the conference table while the 24 other lights are mainly above the chairs, casting more complex shadows. The memory growth is independent from the number of lights in the scene, but it is coherent with the increase in the visibility complexity.

The previous set of results shows that oversized area light sources can become a limitation for our approach, mainly because of the memory consumption. The present tests give a solution: Any huge light source, even with a critical size, could always be treated as the union of several smaller lights. And the result is always guaranteed noise free, which is specially interesting with huge light sources since they require a high number of shadow rays using a stochastic method.

5.4 Focus on the **BSP_query** behaviour

Previous results demonstrate the global efficiency and robustness of this work, but they do not highlight the visibility algorithm (Algorithm 1) behaviour, *i.e.* how the visibility data and the computational cost evolve...
in respect to the visibility queries. Figure 11 gives such an insight. It focuses on the construction of a single BSP tree from the Conference model. This tree was selected because it is representative of the `BSP_query` behaviour. It has 2,896 occluders and a significant number of queries (17,878) are performed. In particular, most of the image points are located in the umbra or penumbra, which represent the most complex cases for our visibility algorithm.

At first, the tree grows quickly because there is no visibility data and the algorithm has to develop it to answer the visibility queries. The timings show the extra computational cost required for this construction. As a second step, the tree growth slows down drastically because the previously computed equivalence classes can be re-used and only need to be completed from time to time. As a consequence the computational cost falls down. This is the global behaviour of the visibility algorithm. In addition, notice that the image points are shaded in the scanline order. This allows handling consecutive points which are likely to share the same visibility data. This is noticeable locally: An "expensive" query is always followed by "cheaper" queries, taking advantage of the previous computational effort.

5.5 Discussions and future works

In this section we discuss our algorithm and point out some limitations and some issues we would like to address in the future.
Figure 11: Lazy construction of a representative BSP tree. The abscissa corresponds to the number of queries. The left ordinate is the time in milliseconds and is related to the continuous curve, while the right one is the memory consumption in MB and is related to the dashed curve. Above the graphic, a half-tone illustration of the light visibility for each query. Black means invisible while white is fully visible.

The lazy construction of the visibility data is an important feature of our algorithm. This requires to query the visibility from some points to drive the computations. On one hand, this allows our approach to fit the image resolution and to focus the computational effort where and when it is needed. On the other hand, it may be inappropriate to solve some visibility problems. For example it is not suitable to prove that the light source is invisible from a polygon or to compute exact Potentially Visible Sets. Indeed, it is not possible to query all the points on a polygon or on the PVS boundaries. However, using an adaptive sampling of the surfaces for example, our approach can still be used to query the visibility from each samples and produce an accurate solution to these problems.

In this paper, a BSP tree is built for each triangle with image points to shade and makes the most of the visibility coherence between those points. This is an easy solution to group image points. However, if the geometric resolution is very high in respect to the image resolution, it can lead to very few image points per triangle and thus, a loss of efficiency, because the visibility data may be dropped before being re-used. To overcome this problem, image points should be grouped according to their neighborhood relationship instead of the triangle they belong to. This will avoid the problem by giving control over the group size and thus, over the number of queries per BSP tree.

As a future work, we think our implementation could be improved using a parallel computing architecture such as CUDA or OpenCL to benefit from a higher number of threads on the graphic hardware. This will require fixing some technical issues, in particular about memory management. Indeed, dynamic allocations from the graphic device are not natively supported, which is not convenient for the lazy construction of data structures.

In this work, the visibility data is dropped as soon as it is not needed anymore. Instead, we are thinking it could be saved to be used again for other renderings. In addition, we plan to study how the visibility data could be simplified and compressed. This may further improve the memory footprint and the visibility queries efficiency.

At last, we also plan to introduce depth information in the visibility data, which means grouping lines according to the first triangle they intersect. This would allow extending our approach to other problems and applications such as ambient occlusion.
6 Conclusion

In this paper, we have presented a new approach to compute exact from-polygon visibility. The core of this method is an original algorithm based on equivalence classes of lines. It encodes lazily the visibility from a polygon, and allows taking advantage of the visibility coherence between successive visibility queries. In addition, the algorithm implementation is easy, and uses only basic geometric operations. As a consequence, it is fast and robust in contrast to previous works on exact from-polygon visibility.

Using this core algorithm, we have proposed an alias-free solution to analytically compute high quality soft shadows. We have tested our approach in various configurations, including different models, different sizes and different numbers of area light sources. These results demonstrated the reliability of our method.

To conclude, we hope this work illustrates that exact visibility, especially exact from-polygon visibility, is not necessarily incompatible with robustness and performance. Moreover, since visibility is a recurrent question in computer graphics, soft shadows is not the only problem that could benefit from the core of our method. As discussed in the previous section, we are interested in several issues and we intend to continue this work.
