Abstract — Homogeneous Charge Compression Ignition: Formulation Effect of a Diesel Fuel on the Initiation and the Combustion - Potential of Olefin Impact in a Diesel Base Fuel — In this work, attention is paid on initiation and HCCI combustion control through fuel formulation. This article shows the effect of olefin addition (and in particular 1-octene and octa-1,7-diene addition) in a Diesel base fuel. Tests are made with a jet-stirred reactor and an engine bench. The current Diesel fuel cetane numbers are not really adapted for a perfect control of HCCI combustion. In HCCI conditions, the autoignition of a Diesel fuel occurs too early in the cycle. This study shows that, with the jet-stirred reactor, 1-octene addition allows decreasing the advancement of the cool flame reaction of n-octane. Engine bench experiments show that, at 1500 rpm, 1-octene and octa-1,7-diene addition decrease the physical delay and increase the chemical auto-ignition delay of the Diesel base fuel. These results can be explained by olefin chemistry: olefin double bonds imply reactions (with radicals) that are in competition with the cool flame reactions. There is also the fact that the intermediate species are stabilised by mesomery. About pollutants, olefin addition decreases HC emissions of the Diesel base fuel. Adding light olefins in a Diesel base fuel could improving the HCCI combustion.
DEFINITIONS, ACRONYMS, ABBREVIATIONS

CA  Crank angle
CAX Crank angle degree which corresponds at X% of the burned fraction
CFR Cooperative fuel research
CO  Carbon monoxide
DICl Direct Injection Compression Ignition
fsn  Fuel smoke number
HC  Unburned hydrocarbon
HCCI Homogeneous charge compression ignition

IMEP Indicated mean effective pressure
JSR Jet-stirred reactor
LTC Low temperature combustion
LTHR Low temperature heat release
NTC Negative temperature coefficient
ppm Part per million
rpm Rotation per minute
TDC Top dead centre
τ Residence time
Φ Equivalence ratio

INTRODUCTION

Ground transportation is responsible for most of the air pollution. To better respect the exhaust emission regulations, new Low Temperature Combustion (LTC) processes such as HCCI engine (Homogeneous Charge Compression Ignition) are currently studied. HCCI process is based on the auto-ignition of a highly diluted air/fuel mixture. The ignition occurs at several locations in the whole combustion chamber. It can reduce significantly NOx and particulate exhaust emissions by a factor 10 to 100 [1]. Meanwhile some problems must be solved: the limited combustion range, the difficulty to control the combustion process, the high HC and CO emissions and the noise. Engine technology can improve HCCI combustion [2-5] and due to the fact that HCCI combustion occurs at lower temperature than conventional Diesel combustion, another solution to solve these problems is to control HCCI combustion through fuel formulation [2, 6-9].

The subject of this work is in a first step to extend chemistry knowledge for in a second step to improve the control of the initiation and the HCCI combustion through fuel formulation.

It seems to be difficult to have only an “HCCI engine” because the operation zone of the engine is too small. More likely, it will be a DICI/HCCI engine. So, it is necessary to have a fuel formulation adapted for these two combustion modes. To have an optimised combustion with the conventional direct injection compression ignition engine without engine modifications, fuel properties need to be near Diesel base fuel properties. So a Diesel base fuel is chosen for the experiments. It is difficult to have an adapted HCCI combustion with a Diesel base fuel because the combustion occurs too early in the cycle [10-12]. Components are added in the Diesel base fuel to try to better control the combustion. The components are used as a refinery blending components and no as an on-board second fuel. There are several ways to improve the HCCI combustion thanks to the fuel formulation like aromatic addition. For this study, the components chosen are olefins. Olefins are chosen for their kinetic of oxidation and their oxidation products. The particularity of olefins is to be unsaturated (presence of C-C double bond). In chemistry, the double bond of olefins implies a higher reactivity than that of paraffin. However, they have a cetane index lower than the corresponding alkanes. These two aspects, which seem to be contradictory, show the interest to test olefin addition in HCCI conditions. It allows seeing if, in HCCI conditions, the aspect “reactivity higher” or “cetane index lower” control the impact of olefin addition.

For this work, two experimental tools are used: a jet-stirred reactor and a single cylinder engine. Of course a comparison between the jet-stirred reactor and the engine experiments is not directly possible because the experimental conditions are very different and it is not the aim of this article. First, the jet stirred reactor experiments allow to see if the double bond of the olefin can have an effect on the cool flame. Then engine experiments allow studying the influence of fuel formulation with olefins in real conditions.

1 EXPERIMENTAL DETAILS AND PROCEDURE

1.1 Jet Stirred Reactor (JSR)

1.1.1 Experimental Details

The experimental setup described previously [13] is used. The JSR is a 4 cm diameter fused-silica sphere. The inside volume is 39 cm³. The reactor is equipped of 4 nozzles of 1 mm diameter admitting the gases which achieve the stirring. It is surrounded by two independent insulated heating wires and located inside a stainless steel pressure resistant jacket filled with insulating material. It can operate at pressures as high as 40 bar. A regulated nitrogen flow in the outer part of the reactor balances the pressure inside the reaction cell. Previous residence time distribution studies, using pulse injection of a tracer, have demonstrated that this type of reactor is well-stirred for residence times of 10 ms to several seconds, depending on the total pressure in the range 1-10 bar [14]. All the gases are delivered by mass flow controllers. The liquid fuel is delivered by an HPLC pump to a homemade vaporizer providing a homogeneous nitrogen-fuel mixture flowing through a capillary, up to the mixing point at the
top of the reactor, to prevent reactions before the entrance of the reactor. A nitrogen flow of 100 L/h is used to dilute the fuel. The reactants flow continually in the reactor. A high degree of dilution is used (0.1% of fuel) in order to reduce temperature gradients and heat release in the reaction cell, thus operating at steady state is possible. It should be noted that no flame occurs in the JSR due to dilution. All the gases are preheated before injection in order to reduce temperature gradients in the JSR. A 12.5 kW induction heating system is used. Two regulated heating wires of 1 kW each are used to maintain the temperature of the upper and lower part of the reaction cell to the desired temperature. The upper part of the capillary is also temperature-regulated in order to avoid condensation of the fuel. The good homogeneity of the reactor cell is checked by moving a thermocouple (Pt-PT/Rh 10% wires of 0.13 mm of diameter located inside a thin-wall fused-silica housing) and a sonic quartz probe along the whole vertical axis of the JSR. No temperature gradients, inside the reactor, higher than 10 K (typically 2-5 K) are allowed in these experiments and no concentration gradients are observed. The samples are taken at steady temperature.

In this work, gas chromatography and different detectors are used for the analyses of oxidation products. HC are measured by a FID (Flame Ionisation Detector); CO₂, CO and CH₂O after been methanised by a FID; O₂ and H₂ by a TCD (Thermal Conductivity Detector).

1.1.2 Experimental Conditions

The jet-stirred reactor experiments allow studying the influence of 1-octene addition on the oxidation of n-octane. Due to its high distillation range, the Diesel base fuel can not be tested with the jet-stirred reactor, so n-octane is preferred. Experiments are performed at 10 bar, for a mean residence time of 1 s, at equivalence ratio equal to 1, temperature varies from 580 K to 1080 K.

The wide temperature range considered allows the observation of the cool flame, the negative temperature coefficient (NTC) and the hot flame.

1.2 Engine Bench

1.2.1 Experimental Details

The engine used is a direct-injection single-cylinder engine based on a standard Audi V6 engine with a Bosch common rail injection system. A Bosch injector with 6 holes (diameter = 0.14 mm, permeability = 340 mL/30 s at 100 bar) is used. The injection rail pressure and the injection phasing are controlled electronically. The engine is based on the NADITM (Narrow Angle Direct Injection) concept developed by IFP [15]: the spray cone angle is at 60°.

The EGR rate is measured with the Pierburg AMA 2000 gas analyser.

The in-cylinder pressure is measured using an AVL (QH33D) pressure transducer and the heat release rate and the temperature by a software based on the thermodynamic laws, internal to IFP.

The main engine characteristics are given in Table 1.

### Table 1

</tbody>
</table>

The engine control is made thanks to Emtronics for the control of the injection parameters and Klepcat for the acquisition of the measures.

Air is supplied thanks to a system of sonic throat. The air flow rate is made with the section of the throat.

The temperatures are measured (in the plenum and in the engine) using K thermocouples.

The noise is calculated thanks the average of the 100 cycles of the in-cylinder pressure, with an AVL noise meter and the soot with an AVL smoke meter 415.

The equivalence ratio is calculated thanks to the analysis of the CO, CO₂, HC, NOₓ and O₂ emissions.

The equivalence ratio is calculated thanks to the equation:

\[
R = 1 + 3.764 \times \frac{A - B}{C}
\]

with \( A = \text{CO(\%)} + \text{CO}_2(\%) + \frac{\text{HC(ppmC)}}{10^4(\text{ppm})} \)

\[
B = \frac{(1-0.3) \times \text{CO(\%)} + \text{CO}_2(\%) + \text{O}_2(\%)}{2} - \\
\frac{1}{4} \times \text{H/C} \times \frac{\text{HC(ppmC)}}{10^4(\text{ppm})} + \text{EN} \times 0.5 \times \frac{\text{NO}_x(\text{ppm})}{10^4(\text{ppm})}
\]

\[
C = 100 - E - (1+0.3) \times \text{CO(\%)} - \text{CO}_2(\%) - \text{O}_2(\%)
\]

\[
\frac{1}{7} \times \frac{\text{HC(ppmC)}}{10^4(\text{ppm})} - \frac{1}{2} \times \frac{\text{NO}_x(\text{ppm})}{10^4(\text{ppm})}
\]

with \( \text{EN} = 1.2 \) (this is an approximation of the part of NO₂ in NOₓ), \( E \) is the relative humidity after the drying.
1.2.2 Fuel Formulation

The Diesel fuel as the reference fuel for the experiments is a current EN590 Diesel fuel. The main Diesel fuel properties are given in the Table 2.

<table>
<thead>

</tr>
</tbody>
</table>

Table 2 gives the boiling point and the auto-ignition temperature of 1-octene and octa-1,7-diene. Table 4 gives the cetane number of the Diesel base fuel/olefin blends. The cetane numbers of the fuels are measured with a CFR engine.

The single well known components added to improve the HCCI combustion of the Diesel base fuel are olefins: 1-octene and octa-1,7-diene (Fig. 2). A di-olefin is chosen to study the influence of two C-C double bonds on HCCI combustion.

10% (volumetric percent) of 1-octene and octa-1,7-diene are added in the Diesel base fuel.

1.2.3 Engine Experimental Methodology

The Diesel fuel combustion experiments are optimised with a respect of three criteria: noise, smoke index and NO\textsubscript{x} levels (Table 5).

<table>
<thead>
<tr>
<th>Noise, smoke index and NO\textsubscript{x} levels HCCI criteria</th>
</tr>
</thead>
<tbody>
<tr>
<td>Maximum noise allowed (dB)</td>
</tr>
<tr>
<td>Maximum smoke index allowed (fsn)</td>
</tr>
<tr>
<td>Maximum NO\textsubscript{x} allowed (g/kWh)</td>
</tr>
</tbody>
</table>
These experiments allow obtaining a reference set-up. This reference set-up is then used for the two blends Diesel fuel/olefin. The different fuels have different properties so it is not possible to keep constant all the parameters therefore the overall equivalence ratio and fuel flow are kept constant and the IMEP (Indicated Mean Effective Pressure) can vary (Table 6). To keep the overall equivalence ratio at constant for neat Diesel base fuel and blends fuels, the air flow is modified.

<table>

</tbody>
</table>

1.2.4 Experimental Conditions

Four operating conditions are tested. For each operating conditions two or three injections per cycle are applied:
- 1500 rpm × IMEP = 3 bar, equivalence ratio = 0.7, 2 injections before TDC: 1st injection at 55 CA and 2nd at 25 CA.
- 1500 rpm × IMEP = 6 bar, equivalence ratio = 0.81, 3 injections before TDC: 1st injection at 90 CA, 2nd at 60 CA and 3rd at 20 CA.
- 2500 rpm × IMEP = 3 bar, equivalence ratio = 0.61, 2 injections before TDC: 1st injection at 40 CA and 2nd injection at 17 CA.
- 2500 rpm × IMEP = 6 bar, equivalence ratio = 0.84, 3 injections before TDC: 1st injection at 100 CA, 2nd injection at 70 CA and 3rd injection at 30 CA.

1.2.5 Fuel Formulation Adapted for the HCCI Combustion

Figure 3 shows the important points for the HCCI combustion: the initiation, the CA10 (crank angle degree which corresponds at 10% of the burned fraction), the peak of the HTHR, the CA50 (crank angle degree which corresponds at 50% of the burned fraction) and the CA90 (crank angle degree which corresponds at 90% of the burned fraction). They are important because their positions in the cycle can help to improve the HCCI combustion.

Figure 8 is a schematic representation of the modifications needed to improve the HCCI combustion.

To improve the HCCI combustion of a Diesel base fuel:
- The physical delay, which corresponds to the vaporisation of the fuel, must be short to improve the homogenisation of the air/fuel mixture and to better control the initiation of the combustion. In this work the physical delay is not directly measured but it is associated to the addition of lighter fractions in the Diesel base fuel.
- The initiation must be delayed in the cycle. It allows having a better homogenisation of the air/fuel mixture and to decrease NOx and smoke emissions (Figs. 4, 5).
- The combustion propagation time between the CA10 and the CA50 must increase. It allows to decrease the pressure gradient and so to decrease the noise (Fig. 6).
- The time of the end of the combustion between the peak of the HTHR (CA_HTHR) and the CA90 must decrease. It allows to help smoke post oxidation and so to decrease smoke emissions (Fig. 7). It allows also keeping good engine efficiency.

2 RESULTS

First jet-stirred reactor experiments allow visualising double bond effect on the cool flame. Then engine experiments allow to study 1-octene and octa-1,7-diene effects on the HCCI combustion of a Diesel base fuel.

2.1 Jet-Stirred Reactor Experiments

Figure 9 shows the evolution of CO and CO₂ mole fractions versus temperature during the oxidation of
pure n-octane and n-octane/1-octene 75/25 (volumetric percent) blend in a jet-stirred reactor operating at \( P = 10 \) bar, \( \tau = 1 \) s and \( \Phi = 1 \). The advantage of a study with the jet-stirred reactor is that the conditions are well controlled. It allows studying the fuel conversion and olefin effects on n-octane oxidation.

Figure 9 shows that 1-octene addition decreases the advancement of the cool flame reaction of n-octane.

Olefin addition seems to be a good way to improve HCCI combustion by delaying the initiation of the combustion.

Figure 8
Schematic representation of the modifications needed to improve the HCCI combustion.
2.2 Engine Bench

In the next figures, the errors represent the standard deviation.

2.2.1 Olefin Impact on the Distillation Range of the Diesel Base Fuel

Olefin impact on the physical delay of the Diesel base fuel is not directly measured but it is associated to the impact of olefin addition on the distillation range of the Diesel base fuel. Olefin addition decreases in temperature the distillation range of the Diesel base fuel (Fig. 10).

2.2.2 Olefin Impact on the Initiation of the Combustion

Figure 11 and Figure 12 show olefin effects on the initiation of the combustion at 1500 rpm × IMEP = 3 and 6 bar and at 2500 rpm × IMEP = 3 and 6 bar.

At 1500 rpm, olefin addition delays the initiation of the combustion of the Diesel base fuel (Fig. 11). At 2500 rpm, there is no significant effect (Fig. 12).

2.2.3 Olefin Impact on the Combustion Propagation Time Between the CA10 and the CA50

Figure 13 and Figure 14 show olefin effects on the combustion propagation time between the CA10 and the CA50 at 1500 rpm × IMEP = 3 and 6 bar and at 2500 rpm × IMEP = 3 and 6 bar.

At 1500 rpm × IMEP = 3 bar, olefin addition increases the combustion propagation time between the CA10 and the CA50. At 1500 rpm × IMEP = 6 bar, there is no significant effect (Fig. 13). At 2500 rpm, olefin addition decreases the combustion propagation time between the CA10 and the CA50 (Fig. 14).

2.2.4 Olefin Impact on the Time of the End of the Combustion Between the Peak of the HTHR and the CA90

Figure 15 and Figure 16 show olefin effects on the time of the end of the combustion between the peak of the HTHR and the CA90 at 1500 rpm × IMEP = 3 and 6 bar and at 2500 rpm × IMEP = 3 and 6 bar.
At 1500 rpm × IMEP = 3 bar, olefin addition decreases the time of the end of the combustion between the peak of the HTHR and the CA90. At IMEP = 6 bar, olefin addition increases the time of the end of the combustion but results are in the variability of the Diesel base fuel measurements (Fig. 15). At 2500 rpm × IMEP = 3 bar, olefin addition increases the time of the end of the combustion between the peak of the HTHR and the CA90 and at 6 bar, it decreases the time of the end of the combustion (Fig. 16).

2.2.5 Olefin Impact on the Noise and the Pollutants of a Diesel Base Fuel

Figure 17 shows olefin addition impact on the noise. The significant values are for the point 1500 rpm × IMEP = 3 bar: olefin addition allows decreasing the noise. This is connected to the evolution of the combustion propagation time between the CA10 and the CA50 (Figs. 18, 19).

Figure 20 to Figure 22 show olefin addition impact on smoke emissions. The comportment of olefin addition on

---

**Figure 12**
Olefin effect on the initiation of the combustion of the Diesel base fuel at 2500 rpm.

**Figure 13**
Olefin effect on the combustion propagation time between the CA10 and the CA50 of the Diesel base fuel at 1500 rpm.

**Figure 14**
Olefin effect on the combustion propagation time between the CA10 and the CA50 of the Diesel base fuel at 2500 rpm.

**Figure 15**
Olefin effect on the time of the end of the combustion between the peak of the HTHR and the CA90 of the Diesel base fuel at 1500 rpm.
smoke emissions is different for each point and is linked to the evolution of the time of the end of the combustion between the HTHR and the CA90 (Figs. 15, 16).

Figure 23 to Figure 26 show olefin addition impact on NOx emissions. Olefin addition decreases NOx emissions in accordance with the evolution of the initiation of the combustion at 1500 rpm (Fig. 11). At 2500 rpm, NOx values are in the Diesel fuel value variability.

Figure 27 and Figure 28 show olefin addition impact on HC emissions. Except for octa-1,7-diene addition at 2500 rpm × IMEP = 3 bar, olefin addition decreases HC emissions.

Figure 29 to Figure 31 show olefin addition impact on CO emissions. It is not possible to link CO emission evolution and olefin chemistry because the evolution changes for the four operating conditions.

2.2.6 Summary of Olefin Effects

1. Olefin addition decreases the physical delay of the Diesel base fuel because the distillation range of the Diesel base fuel decreases in temperature.
2 Olefin addition increases the chemical delay (at low engine speed) of the Diesel base fuel.

3 For the combustion propagation time between the CA10 and the CA50 and the time of the end of the combustion between the peak of the HTHR and the CA90 it is difficult to explain the evolution of the results only with olefin chemistry.

4 About pollutants, olefine addition decreases HC emissions.

3 DISCUSSION

Olefin addition delays the initiation of the combustion of the Diesel base fuel at 1500 rpm. This can be explained by olefin chemistry.

The reaction which corresponds to the production of the cool flame is:

\[
\text{RH} + \text{O}_2 \rightarrow \text{R}^+ + \text{O}_2 \rightarrow \text{RO}_2^+ \rightarrow \text{QOOH}^+ + \text{O}_2^= \rightarrow \text{QOO}^+ \rightarrow 2 \text{OH}^\text{+}
\]

Reaction 1

Reaction of the cool flame production
(RH is the hydrocarbon, 1: isomerisation).

This is a ramification process: for one radical QOOH\(^+\) consumes, two radicals OH\(^+\) are formed.
In the case of olefin addition, there is a double bond. This double bond implies different oxidation pathway like radical addition on the double bond [16].

Reaction 2 implies an OH° addition on the double bond followed by an O₂ addition; it is the Waddington's mechanism [17]. The six membered transition stage ring structure is favoured [18]. Radical R2 is a secondary radical. It is more stabilised than primary radical R1. So it is preferentially formed [19].

Reaction 2 does not occur in the paraffin chemistry because this reaction implies a radical addition on a double bond. This reaction is not a ramification process: for one radical consumed, one radical is formed so olefin addition does not yield easily to cool flame.

A second reason which can explain the decrease of the advancement of the cool flame reaction when olefins are added, is that a large percent of radicals obtained are stabilised by electron delocalisation (called mesomery) between the double bond and the radical (Reaction 3).

This is the result of the easier H-atom abstraction of the allylic hydrogens [20], Table 7.
Table 7

<table>
<thead>
<tr>
<th>Hydrocarbon</th>
<th>Molecular bond dissociation energy of C-H</th>
</tr>
</thead>
<tbody>

<td>431 KJ/mol</td>
</tr>
<tr>
<td>H\textsubscript{2}C=CH\textsubscript{2}H (H allylic)</td>
<td>364 KJ/mol</td>
</tr>
</tbody>
</table>

According to the temperature and the pressure, the kinetic of the reactions varies: the reactions which control the reactivity are different.

Olefins do not work at 2500 rpm because the mesomery and the competitive reactions “radical-double bond” do not control the reactivity (due to the temperature and the pressure). The reaction involving the cool flame (Reaction 1) controls the reactivity so olefin addition does not modify the initiation of the Diesel base fuel.
At 1500 rpm, the mesomery (Reaction 3) and the competitive reactions “radical-double bond” (Reaction 2) control the reactivity so olefin addition delays the initiation of the Diesel base fuel.

Figure 32 is a schematic summary of the results obtained.

**CONCLUSION**

- These experiments show the advantage of light olefin addition in a Diesel fuel. Olefin addition allows to delay the initiation of the combustion and to reduce the physical delay: the blend is more homogeneous. Also, HC emissions decrease.

- The fact that olefin addition delays the initiation of the Diesel base fuel can be explained by olefin chemistry. The competitive reactions, involving the double bond and the radical, seem to delay the initiation of the Diesel base fuel. There is also radical stabilisation by mesomery which can explain this comportment.

- Olefin addition impacts the initiation of the combustion. For the combustion propagation time between the CA10 and the CA50 and the time of the end of the combustion between the peak of the HTHR and the CA90, it is difficult to explain the results only with olefin chemistry. Other works are needed to visualise the link between the chemistry of the fuel and the combustion between the CA10 and the CA90.

---

Reaction 2
Olefin oxidation pathway.

Reaction 3
