We have performed a simulation study of 3D cohesionless granular flows down an inclined chute. We find that the oscillations observed in [L. E. Silbert, Phys. Rev. Lett., 94 098002 (2005)] near the angle of repose are harmonic vibrations of the lowest normal mode. Their frequencies depend on the contact stiffness as well as on the depth of the flow. Could these oscillations account for the phenomena of “booming sand”? We estimate an effective contact stiffness from the Hertz law, but this leads to frequencies several times higher than observed. However, the Hertz law also predicts interpenetrations of a few nanometers, indicating that the oscillations frequencies are governed by the surface stiffness, which can be much lower than the bulk one. This is in agreement with previous studies ascribing the ability to sing to the presence of a soft coating on the grain surface.

PACS numbers: 45.70.Ht, 46.40.-f, 91.60.Lj

A “booming” or “singing” dune is a sand dune that emits a loud sound when an avalanche occurs on its slip face. The sound can be very loud – audible up to 10 km away – and has a well defined frequency of order one hundred Hertz. The physical origins of this phenomenon are still matter of debate in spite of much experimental and theoretical work [1–6]. A successful theory of booming sand must explain why the sound is not a mix of a wide range of frequencies, and therefore several frequency selection mechanisms have been proposed. We now summarize them non-exhaustively. According to Andreotti [5], for a given grain size, the frequency is set by the shear rate of the shear band separating the avalanche to the static part of the dune. This first explanation is not compatible with the one proposed by Donady et al. [6], in which the frequency is set by a resonance of the flowing layer. A third explanation has been proposed by Vriend et al. [4]: The frequency is not selected by the properties of the avalanche but by the acoustical resonance induced by the stratification of the dune, explaining why the frequency may vary with time. More recently [2], Andreotti and Bonneau show that the shear band separating an avalanche from the static part of the dune induces an amplification of guided elastic waves, leading to a linear instability. The frequency is then set by the maximum value of the instability growth rate. Finally Mills and Chevoir [6] made the interesting remark that something like booming sand had already been observed in numerical simulations [7] that exhibited spontaneous oscillations in granular flows near the angle of repose. These oscillations were interpreted as signs of intermittency near the jamming transition.

Here, we examine Mills and Chevoir’s re-interpretation of these oscillations as an acoustical phenomena – possibly “booming sand”. We extend the simulations performed in [7] by carrying out an extensive study of the influence of the contact normal stiffness and of the height of the flow. After a description of the method, we will show that the observed oscillations are multi-body harmonic oscillations. Their frequency is thus governed by the stiffness of the springs that model the repulsive inter-granular forces. We estimate a reasonable value for this quantity and discuss the relevance of the simulations.

Method. We use our own implementation [8] of the classical “Discrete Element Method” method where Newton’s equations of motion for a system of N “soft” grains are integrated. This requires giving an explicit expression for the forces that act between grains. Such a technique is able to reproduce successfully experimental results for gravity driven flows [9–13], sheared systems [14], granular materials close to jamming [15], silos [16] or rotating drums [17–20]. The Discrete Element Method is well known and can be found in many papers [9–21]. Therefore, we just present here the forces used in this work (and also in [2]). For the normal force between two overlapping spheres we use a standard linear spring-dashpot interaction model [22]: \( f^n = k^n \delta^n - \gamma^n \mathbf{v}^n \), where \( \delta^n \) is the normal overlap, \( k^n \) is the spring constant, \( \gamma^n \) the damping coefficient and \( \mathbf{v}^n \) the normal relative velocity. The damping models the dissipation characteristic of granular materials. Likewise we model the tangential force as a linear elastic and linear dissipative force in the tangential direction: \( f^t = -k^t \delta^t - \gamma^t \mathbf{v}^t \), where \( k^t \) is the tangential spring constant, \( \delta^t \) the tangential overlap, \( \gamma^t \) the damping coefficient and \( \mathbf{v}^t \) the tangential velocity at the contact point. The magnitude of \( \delta^t \) is truncated as necessary to satisfy Coulomb law: \( |f^t| \leq \mu |f^n| \), where \( \mu \) is the grain-grain friction coefficient.

Numerical set-up. As in [8], we simulate gravity-driven chute flow. In every way the parameters are the same as in [7] except we vary the normal stiffness between grains and the height of the flow. The grains are monosized (diameter \( d \), mass \( m \)). Unless otherwise specified the number of grains is \( N = 8000 \). The chute consists in a 3D cell whose base is flat and rectangular with size \( 20d \times 10d \). It can be inclined relative to the horizontal by an angle \( \theta \) (angle between the horizontal and the long axis of the base) and is periodic in the directions tangent to the base. The bottom of the cell is obtained by pouring under gravity \( \mathbf{g} \) a large number of grains in the cell (\( \theta = 0^\circ \)) and by fixing those that are in contact with the base. This disordered layer of fixed grains is
sufficient to prevent crystallization throughout the system. Before any measurements are taken, the inclination is increased to $\theta \approx 30^\circ$, causing a rapid flow that erases any influence of the initial state. The angle $\theta$ is then set to a final value that is cited in the captions or text below. The following values of the parameters are used: $2 \times 10^4 \leq k^n d/mg \leq 2 \times 10^6$, $k^t = 2k^n/\pi$, $\gamma^t = 0$ and $\mu = 0.5$. The value of $\gamma^n$ is adjusted to obtain a normal restitution coefficient $e_n = 0.88$ [9]. We use dimensionless quantities by measuring distances, times, and elastic constants respectively, in units of $d$, $\sqrt{d}/g$ and $mg/d$.

**Numerical Results.** In accord with previous results [7], we observe an oscillation near the angle of repose which is defined, for a given flow height, by the angle below which the flow stops. This motion can be identified through measurements of the total kinetic energy. Note that in all our simulations the rotational kinetic energy is much lower than the translational one. As reported in Fig. 1, the kinetic energy displays regular oscillations (characteristic frequency $\approx \sqrt{g/d}$) and irregular fluctuations with lower frequency ($\approx 0.1$ to $0.2\sqrt{g/d}$). We next turn our attention to the spring stiffness $k^n$ by studying its effect on the amplitude and on the frequency of the oscillations. As reported in Fig. 1, the oscillations indeed depend on the spring stiffness. As $k^n$ increases, their frequency increases while their amplitude decreases. Fig. 2 shows the frequency and amplitude of these oscillations versus spring stiffness. Frequency scales with $\sqrt{k^n}$, whereas amplitude scales with $1/k^n$. In the limit $k^n \rightarrow \infty$, the oscillations disappear. However, the avalanche does not disappear in this limit, indicating that the avalanche and the oscillations are two separate processes. For this reason, we do not think that the oscillations should be interpreted as arising from the jamming transition, or as avalanche precursors. Now let us consider the oscillation frequency. It scales as $1/t_c$ where $t_c$ is the two-body collision time. Assuming that a two particle collision is a semi-cycle of a damped harmonic oscillator leads to $t_c = \pi/[2k^n/m - (\gamma^n)^2/m^2]^{1/2} \approx \pi/(2k^n/m)^{1/2} \propto 1/\sqrt{k^n}$. This scaling of the frequency suggests that the oscillations are harmonic vibrations of a normal mode. Let us estimate the frequency of the vertical normal modes. In the simulations, there are a certain number $n_L$ of layers of grains resting on the bottom of the chute. We model the granular bed as a one dimensional chain of $n_L$ masses connected by linear springs. This model is the linear harmonic chain, used in solid state physics as a very elementary model of phonons [23]. The damping added to the particle interactions affects short wavelength vibrations most strongly, but long wavelength ones only weakly [24]. Thus the motion is dominated by the longest possible wavelength. If the bottom of the chute is considered to be fixed, and the top surface is free, the longest wavelength is four times the depth of the layer. This leads to a frequency $f_{n_L}/\sqrt{g/d} \approx (1/4n_L)\sqrt{k^n d/mg}$. With $n_L = 40$ and $k^n d/mg = 2 \times 10^6$, one obtains $f_{40} \approx 9\sqrt{g/d}$. This value is twice as large as the one shown in Fig. 2. The difference between the prediction and the simulation is probably caused by the proximity of the stability threshold. The macroscopic stiffness of a granular packing decreases as a yield condition is approached. Here, the yield condition (i.e the avalanche) is reached when $\theta$ equals the angle of repose. To support this idea, simulations were carried out using exactly the same protocol but with a final angle of $\theta = 0^\circ$. The system comes rapidly to rest, with the longest-lived motions being persistent oscillations at frequencies closer to the predicted values. But the central point is that the model reproduces the correct scaling with stiffness $f_{n_L} \propto \sqrt{k^n}$. Our results also predict that frequency should diminish as the granular layer is made deeper: $f_{n_L} \propto 1/n_L$. To check our analysis we carried out numerical simulations with $k^n d/mg = 2 \times 10^6$, $\theta = 20^\circ$ and for several numbers of grains ($8000 < N < 32000$). The results shown in Fig. 3 confirm the predicted scaling. We conclude, therefore, that the oscillations observed in the simulations are simply harmonic oscillations of the lowest normal mode.

**Relevance of the numerical results.** Up to this point,
we have discussed our results solely within the framework of the very idealized model where a relatively small number of perfect spheres flow down a fixed inclined plane, interacting via linear spring forces. The linear force law allowed us to reproduce the oscillations under exactly the same conditions as Silbert [7], and also facilitated the analysis of the observed frequencies. The idealized context of our work is emphasized by the exclusive use of dimensionless units. We did not try to give physical values to any parameter such as the particle diameter \( d \) that at \( k \) straddle the difference between the model and physical reality.

Putting in values of appropriate for glass: \( E = 50 \text{ GPa}, \) one typical contact force. We suppose that this force is of the order of the weight of a column of \( n_L \) grains:

\[
F^n = n_L mg = \pi n_L \rho g d^3 / 6,
\]

where \( \rho \) is the density of the material making up the grains. Eqs. (1), (2), and (3) involve the unknowns \( k^n \), \( \rho \), and \( \delta \). Combining these yields to

\[
k^n d / mg = \frac{3}{2} \left[ \frac{2 \sqrt{2} n_L L E}{\pi (1 - \nu^2) \rho g} \right]^{2/3}.
\]

We will consider modifying \( n_L \) and \( d \), while sweeping all the other constants into a single parameter that depends on the material:

\[
k^n d / mg = K n^{1/3} d^{2/3}, \quad K = \frac{3}{2} \left[ \frac{2 \sqrt{2} E}{\pi (1 - \nu^2) \rho g} \right]^{2/3}.
\]

Putting in values of appropriate for glass: \( g = 10 \text{m/s}^2, \rho = 2.4 \times 10^3 \text{kg/m}^3, \nu = 0.2, \) and \( E = 50 \text{GPa}, \) one obtains \( K = 2.3 \times 10^4 \text{m}^{2/3} \). Various values of the dimensionless stiffness \( k^n d / mg, \) are shown in Fig. 4.

Note that at \( d \approx 1 \text{mm}, \) even the softest contact (those that support the weight of only one grain) have a stiffness \( k^n d / mg \approx 10^6, \) i.e., equal to the half of the highest value in Fig. 4. Diameters typical of “booming dunes” – around \( 200 \mu \text{m} \) lead to even stiffer contacts. Now let us see whether the oscillation frequencies in the simulation correspond to those of “singing sand.” The unit of frequency used here is \( \sqrt{g / d} \approx 220 \text{Hz} \) for \( d = 200 \mu \text{m} \) (which is, as mentioned before, the typical diameter for grains of booming dunes). The observed frequencies in the field and in laboratory are around \( 90 \text{Hz}, \) i.e., \( 0.4 \sqrt{g / d} \) (see Fig. 3 of [3] or table I of [3]). According to laboratory experiments [3], flow heights are of order of several centimeters. For \( d = 200 \mu \text{m}, \) this corresponds to \( H / d \approx 500. \) Extrapolating the data in Fig. 3 to \( H / d = 500 \) leads to frequencies tantalizingly close to those observed. But Fig. 3 was obtained for a fixed stiffness \( k^n d / mg = 2 \times 10^5, \) much lower than the value \( k^n d / mg = 5.3 \times 10^5 \) predicted by
Eq. (5) for $n_L = 500$ and $d = 200 \mu m$. If the oscillations are indeed the origin of booming sand, the effective stiffness of the grains must be much lower than predicted by Eq. (5). To explain this disagreement, let us determine the overlap $\delta$ between two contacting grains from Hertz theory which assumes those grains as perfect spheres, without any surface asperities. Eqs. (1) and (3) yield to

$$\delta = \frac{3d^{5/3}n_L^{1/3}}{2K}.$$  \hspace{1cm} (6)

For $d = 200 \mu m$ and $n_L = 500$, we obtain $\delta \approx 3 \text{ nm}$. This is a maximum value of $\delta$, concerning contacts that support the weight of 500 grains. Contacts near the free surface of the flow ($n_L < 5$) have $\delta < 2 \AA$. For such overlaps, the contact between two real grains will be dominated by surface properties that might be quite different from the bulk properties considered in the Hertz model. In particular asperities or a layer of silica gel (as proposed in [25]) could significantly reduce the stiffness seen by acoustical waves. These speculations, however, can only be confirmed by examining the sand grains themselves. These surface effects could also account for the rapid increase in sound speed with depth [4]. The contact stiffness near the dune surface would be anomalously soft and fixed by their frequency obeys the expected dependency on particle stiffness and bed depth. They are not part of the avalanche motion but may be connected to “booming dunes”, if the effective contact stiffness is about 20 times smaller than expected from the Hertz contact law. Such a reduction of stiffness is possible because the Hertz law predicts extremely small grain overlaps, indicating that the stiffness is dominated by surface properties instead of bulk ones. If the oscillations are indeed related to “booming sand”, it would mean that the sound originates from a resonance inside a flowing layer, similar to the explanation presented in [2]. However, several issues remain open. For example, what excites the oscillations? One clue is given by the effect of polydispersity: we performed simulations with uniform size distribution of width $2\sigma$, with $\sigma = 0.05, 0.1$ or $0.2$, and observe that the oscillations disappear for $\sigma = 0.2$, consistent with the observation [26] that booming sand has a narrow grain size distribution. This suggests that the resonance is excited by quasi-periodic collisions in the shearing layer, consistent with most explanations that have been presented.

Conclusion. We have examined the oscillations observed [7] in numerical simulations of granular beds near the angle of repose. These oscillations are harmonic vibrations of the lowest vertical mode of the bed, and their frequency obeys the expected dependency on particle stiffness and bed depth. They are not part of the avalanche motion but may be connected to “booming dunes”, if the effective contact stiffness is about 20 times smaller than expected from the Hertz contact law. Such a reduction of stiffness is possible because the Hertz law predicts extremely small grain overlaps, indicating that the stiffness is dominated by surface properties instead of bulk ones. If the oscillations are indeed related to “booming sand”, it would mean that the sound originates from a resonance inside a flowing layer, similar to the explanation presented in [2]. However, several issues remain open. For example, what excites the oscillations? One clue is given by the effect of polydispersity: we performed simulations with uniform size distribution of width $2\sigma$, with $\sigma = 0.05, 0.1$ or $0.2$, and observe that the oscillations disappear for $\sigma = 0.2$, consistent with the observation [26] that booming sand has a narrow grain size distribution. This suggests that the resonance is excited by quasi-periodic collisions in the shearing layer, consistent with most explanations that have been presented.
