Abstract—An attractive way to make biclustering of genes and conditions is to adopt a Block Mixture Model (BMM). Approaches based on a BMM operate thanks to a Block Expectation Maximization (BEM) algorithm and/or a Block Classification Expectation Maximization (BCEM) one. The drawback of these approaches is their difficulty to choose a good strategy of initialization of the BEM and BCEM algorithms. This paper introduces existing biclustering approaches adopting a BMM and suggests a new fuzzy biclustering one. Our approach enables to choose a good strategy of initialization of the BEM and BCEM algorithms.

Keywords – biclustering; block expectation maximization algorithm; block classification expectation maximization algorithm, block mixture model; fuzzy strategy; microarray data

I. INTRODUCTION

Analysis of gene expression data obtained from microarray experiments can be made through biclustering. Indeed, gene expression data are usually represented by a data matrix $M$ (see Table.1), where the $i$th row represents the $i$th gene, the $j$th column represents the $j$th condition and the cell $x_{ij}$ represents the expression level of the $i$th gene under the $j$th condition. In general, subsets of genes are coexpressed only under certain conditions but behave almost independently under others. Discovering such coexpressions can be helpful to discover genetic knowledge such as genes annotation or genes interaction. Hence, it is very interesting to make a simultaneous clustering of rows (genes) and of columns (conditions) of the data matrix to identify groups of rows (genes) coherent with groups of columns (conditions), i.e., to identify clusters of genes that are coexpressed under clusters of conditions, or clusters of conditions that make clusters of genes coexpress. This type of clustering is called biclustering [6]. A cluster made thanks to a biclustering is called bicluster. Hence, a bicluster of genes (resp. conditions) is defined with respect to only a subset of conditions (resp. genes). Thus, a bicluster is a subset of genes showing similar behavior under a subset of conditions. Let us note that a gene/condition can belong to more than one bicluster or to no bicluster.

In other words, a bicluster can be defined as follows: Let $I=\{1, 2, \ldots, n\}$ be a set of indices of $n$ genes, $J=\{1, 2, \ldots, m\}$ be a set of indices of $m$ conditions and $X(I,J)$ be a data matrix associated with $I$ and $J$. A bicluster associated with the data matrix $X(I,J)$ is a couple $(I',J')$ such that $I' \subseteq I$ and $J' \subseteq J$.

Actually, biclustering is a special case of clustering. Indeed, in biclustering, genes are clustered according to their expression levels under a number of conditions, not necessarily all the conditions. While in clustering, genes are clustered according to their expression levels under all the conditions. Similarly, in biclustering, conditions are clustered according to the expression levels of a number of genes, not necessarily all the genes.

The biclustering problem can be formulated as follows: Given a data matrix $X$, construct a bicluster $B_{opt}$ associated with $X$ such that:

$$f(B_{opt}) = \max_{B \in BC(X)} f(B)$$ (1)

where $f$ is an objective function measuring the quality, i.e., coherence degree, of a group of biclusters and $BC(X)$ is the set of all the possible groups of biclusters associated with $X$.

| TABLE 1 | Gene Expression Data Matrix |
|---|---|---|---|---|
| Gene | Condition | Condition | Condition |
| $G_{1}$ | $x_{11}$ | $\ldots$ | $x_{1j}$ | $\ldots$ | $x_{1m}$ | $\ldots$ | $\ldots$ | $\ldots$ |
| $G_{2}$ | $x_{21}$ | $\ldots$ | $x_{2j}$ | $\ldots$ | $x_{2m}$ | $\ldots$ | $\ldots$ | $\ldots$ |
| $\ldots$ | $\ldots$ | $\ldots$ | $\ldots$ | $\ldots$ | $\ldots$ | $\ldots$ | $\ldots$ | $\ldots$ |
| $G_{n}$ | $x_{n1}$ | $\ldots$ | $x_{nj}$ | $\ldots$ | $x_{nm}$ | $\ldots$ | $\ldots$ | $\ldots$ |

Clearly, biclustering is a highly combinatorial problem with a search space size $O(2^{n+m})$. In its general case, biclustering is NP-hard [6].

In this paper, we introduce existing biclustering approaches...
II. TYPES OF BICLUSTERS

A bicluster can be in one of the following cases:

1. Bicluster with constant values: It is a bicluster where all the values are equal to a constant $c$:

   $$x_{ij} = c$$  \hspace{1cm} (2)

2. Bicluster with constant values on rows or columns:
   - Bicluster with constant values on rows: It is a bicluster where all the values can be obtained by using one of the following equations:
     $$x_{ij} = c + a_i$$  \hspace{1cm} (3)
     $$x_{ij} = c \times a_i$$  \hspace{1cm} (4)

   Where $c$ is a constant and $a_i$ is the adjustment for the row $i$, $1 \leq i \leq n$.

   - Bicluster with constant values on columns: It is a bicluster where all the values can be obtained by using one of these equations:
     $$x_{ij} = c + b_j$$  \hspace{1cm} (5)
     $$x_{ij} = c \times b_j$$  \hspace{1cm} (6)

   Where $c$ is a constant and $b_j$ is the adjustment for the column $j$, $1 \leq j \leq m$.

3. Bicluster with coherent values: It is a bicluster that can be obtained by using one of the following equations:

   $$x_{ij} = c + a_i + b_j$$  \hspace{1cm} (7)
   $$x_{ij} = c \times a_i \times b_j$$  \hspace{1cm} (8)

4. Bicluster with linear coherent values: It is a bicluster where all the values can be obtained by using the following equation:

   $$x_{ij} = c \times a_i + b_j$$  \hspace{1cm} (9)

5. Or, bicluster with coherent evolution: It is a bicluster where all the rows (resp. columns) induce a linear order across a subset of columns (resp. rows).

III. GROUPS OF BICLUSTERS

A group of biclusters can be in one of the following cases [13]:

1. Single bicluster ((Figure 1 (a))
2. Exclusive row and column group of biclusters (Figure 1 (b))
3. Non-overlapping group of biclusters with checkerboard structure (Figure 1 (c))
4. Exclusive rows group of biclusters (Figure 1 (d))
5. Exclusive columns group of biclusters (Figure 1 (e))
6. Non-overlapping group of biclusters with tree structure (Figure 1 (f))
7. Non-overlapping non-exclusive group of biclusters (Figure 1 (g))
8. Overlapping group of biclusters with hierarchical structure (Figure 1 (h))
9. Or, arbitrarily positioned overlapping group of biclusters (Figure 1 (i)).
(cluster), where \( K \), assumed to be known, is the number of the components (clusters) in the mixture. The parameter of this model is the couple \( \theta = (p, \alpha) \), where \( p = (p_1, \ldots, p_K) \) represents the mixing proportions and \( \alpha = (\alpha_1, \ldots, \alpha_K) \) represents the parameters of each component (cluster). The mixture density of the observation \( x \) is expressed as follows:

\[
f(x; \theta) = \prod_{z \in Z} \sum_{k=1}^{K} p_k \varphi_k(x; \alpha_k).
\]

Let \( z = (z_{ik}) \) be the \((n \times K)\) binary classification matrix indicating the labels of rows into \( K \) clusters (\( z_{ik} = 1 \) if the row \( i \) belongs to the \( k \)th cluster and 0 otherwise). Govaert and Nadif [9] have shown that equation (10) can be written in the following way:

\[
f(x; \theta) = \sum_{z \in Z} p(z; \theta) f(x; z, \theta)
\]

where \( Z \) is the set of all possible assignments \( z \) of \( I \) and,

\[
p(z; \theta) = \prod_{l=1}^{L} p_{lk}^{z_{lk}} \text{ and } f(x; z, \theta) = \prod_{l=1}^{L} \varphi (x_l; \alpha_l)^{z_{lk}}.
\]

In the context of the biclustering problem, equation (13) takes the following expression:

\[
f(x; \theta) = \sum_{(z,w) \in Z \times Z} p(z; \theta) p(w; \theta) f(x; z, w, \theta)
\]

where \( w = (w_{lj}) \) corresponds to the \((m \times L)\) binary classification matrix indicating the labels of columns into \( L \) clusters (\( w_{lj} = 1 \) if the column \( j \) belongs to the \( l \)th cluster and 0 otherwise) while \( W \) denotes the set of all possible assignments \( w \) of \( J \). A MM associated with equation (14) is called Block Mixture Model (BMM) [8, 10].

B. Soft and hard approaches

Approaches based on a BMM operate thanks to a Block Expectation Maximization (BEM) algorithm and/or a Block Classification Expectation Maximization (BCEM) one [2].

Let’s note that BCEM algorithm differs from BEM one by the fact that we have inserted a classification step between estimation and maximization ones.

1) Block EM algorithm

A Block EM algorithm (BEM) has the same convergence properties as Generalized EM one [11]. And, like an EM one, a BEM algorithm converges slowly in some situations. The second important drawback of this kind of algorithms is that their solutions can highly depend on their starting position and, consequently, produce sub-optimal maximum likelihood estimates. To cope with this high dependency, Govaert and Nadif [11] have proposed to use the em-EM algorithm to initialize parameters estimations of a BEM algorithm.

This strategy consists in several short runs of BEM from random positions followed by a long run of BEM from the solution maximizing the likelihood. A BEM algorithm can be defined as follows:

Step 1: Set \( r = 0 \), choose \( s \) from \([2..n] \) and \( t \) from \([2..m] \);

Choose \( z^{(0)}, w^{(0)} \) and \( \theta^{(0)} \) as initial values of \( z, w \) and \( \theta \)

Step 2: Compute \( z^{(r+1)}, w^{(r+1)} \) and \( \theta^{(r+1)} \) thanks to the alternated application of EM on intermediate data matrices; for details see for instance [11].

Step 3: Iterate Step 2 until convergence.

2) Block CEM algorithm

As we said earlier, a BCEM algorithm differs from a BEM one by the fact that we have inserted a classification step between estimation and maximization ones. That is why, we need to adopt classification log-likelihood function \( L_c(z, w, \theta) \) instead of log-likelihood one \( L(z, \theta) \). A BCEM algorithm [11] differs from a BEM one by the fact that in Step 2 we call a CEM algorithm instead of an EM one.

C. Fuzzy approaches

Hard approaches adopting a BMM present the following drawbacks:

(i) All initializations strategies, including em-EM, of parameters estimation adopted by hard approaches are still inefficient and therefore do not contribute to generate pertinent groups of biclusters, i.e., groups of biclusters with optimal values of ML/CML function.

(ii) These approaches converge slowly and therefore are time consuming.

(iii) Concerning hard approaches that operate separately on the sets of genes \( I \) and the sets of conditions \( J \) (denoted by 2EM and 2CEM), the correlations that exist between subsets of genes and subsets of conditions are ignored.

That is why researchers opted for fuzzy approaches adopting a BMM to deal with the biclustering problem. In this context, Govaert and Nadif [12] proposed Block Fuzzy C-Methods (BFCM) based on Neal and Hinton interpretation of EM [4]. The obtained approach enables to maximize a fuzzy clustering criterion. Miin-Shen Yang and Chih-Ying Lin [5], on their side, proposed a Block Fuzzy K-Modes (BFKM) clustering approach based on Huang and Ng Fuzzy K-Modes (FKM) approach [5].

1) Neal and Hinton interpretation of EM

As pointed out by Hathaway [3], in a classical MM context, an EM algorithm can be viewed as an alternated maximization of the following fuzzy clustering criterion:

\[
F_C(P, \theta) = L_c(s, \theta) - \sum_{l,k} s_{lk} \log s_{lk}
\]

where \( s \) is a \( n \times g \) data matrix, with \( n \) is the number of genes and \( g \) is the maximum number of gene clusters to generate. The \( l \)th row of \( s \) represents the \( l \)th gene, the \( k \)th column represents the \( k \)th cluster and the cell \( s_{lk} \) expresses the probability that the \( l \)th gene belongs to the \( k \)th cluster. The function

\[
L_c(s, \theta) = \sum_{l,k} s_{lk} \log(p_k f(x_l, \alpha_k))
\]

is the fuzzy complete data log-likelihood. Indeed, maximizing \( L_c \) with respect to \( s \), and consequently \( F_C \) with respect to \( s \), yields the expectation step and maximizing \( L_c \) with respect to \( \theta \), and consequently \( F_C \) with respect to \( \theta \), yields the maximization one.

To extend this interpretation to all models in which an EM algorithm may be employed, Neal and Hinton [4] proposed to use the following function:
where $z$ represents the missing data, $P$ is a distribution over the space of $z$ and $H$ is an entropy function. One can also relate $F_{c}$ to the Kullback–Leibler divergence between $P(z)$ and $P_{y}(z) = P(z; x, \theta)$, as follows:

$$F_{c}(P, \theta) = L_{M}(\theta) - KL(P, P_{y})$$

(17)

The alternated maximization of the $F_{c}$ function is then simple to set up:

(i) Maximization of $F_{c}(P, \theta)$ with respect to $P$ for fixed $\theta$ : Equation (17) leads to the minimization of $KL(P, P_{y})$ and then to $P=P_{y}$.

(ii) Maximization of $F_{c}(P, \theta)$ with respect to $\theta$ for fixed $P$: Equation (16) shows that $\theta$ maximizes the expectation $E_{p}(L_{c}(z, \theta))$.

These two steps are precisely those of an EM algorithm. Moreover, after the first step, we have $F_{c}(P, \theta) = F_{c}(P_{y}, \theta) = L_{M}(\theta)$, which shows that each iteration increases the log-likelihood $L_{M}(\theta)$.

One can easily see that the Neal and Hinton interpretation extends Hathaway’s relation (14). Indeed, for a classical MM, the missing data $z$ represents the assignments of the genes of the set $Z$, and the assignments of each $x_{i}$ obtained in the expectation step are independent. Then, the conditional distribution $P(z)$ is given by the vector that is the concatenation of the rows of the $n \times g$ data matrix $X$. Moreover, thanks to the Neal and Hinton interpretation [4, 5] of equations (15) and (16), $E_{p}(L_{c}(z, \theta))$ can be transformed to $L_{c}(s, \theta)$, and $H(P)$ can be transformed to $-\sum_{i,k} s_{ik} \log s_{ik}$.

For latent block model, Govaert and Nadif [13] adopted Neal and Hinton fuzzy criterion (15) defined by:

$$F_{c}(P, \theta) = E_{p}(L_{c}(z, \theta)) + H(P)$$

(18)

where

$$L_{c}(z, w; \theta) = \sum_{i,k} z_{ik} \ln p_{k} + \sum_{j} \theta_{ij} \ln q_{i} + \sum_{k} \phi_{ik} \ln \theta_{ik} (x_{i}; \alpha_{kl})$$

2) Block Fuzzy C-Methods

In [12] the authors proposed Block Fuzzy C-Method (BFCM) as a new biclustering method based on a BMM and fuzzy c-partitions [1]. The new optimized objective function is defined as follows:

$$F_{c}(c, d, \theta) = L_{c}(c, d, \theta) + H(c, d)$$

(19)

where

$$L_{c}(c, d, \theta) = \sum_{i,k} c_{ik} \log(p_{k}) + \sum_{j,l} d_{jl} \log(q_{l}) + \sum_{i,j,k,l} c_{ik} d_{jl} \log q_{kl} (x_{ij}, \alpha_{kl})$$

and

$$H(d, c) = \sum_{i,k} c_{ik} \log(c_{ik}) + \sum_{j,l} d_{jl} \log(d_{jl})$$

where $c_{ik}$ and $d_{jl}$ represent the fuzzy partitions of genes and conditions, respectively.

To maximize $F_{c}(c, d, \theta)$, in [12] the authors shown that this aim can be performed by maximizing alternatively two conditional fuzzy criteria $F_{c}(c, \theta|d)$ and $F_{c}(d, \theta|c)$. Their maximization can be viewed as an EM algorithm with a ML function associated with a classical MM on intermediate matrices. Thus, we can summarize BFCM algorithm as follows:

Step 1: Choose $c^{(0)}, d^{(0)}$ and $\theta^{(0)}$ as initial values of $c, d$ and $\theta$.

Set $r = 0$, choose $s$ from $[2..n]$ and $t$ from $[2..m]$.

Step 2: Compute $c^{(r+1)}, d^{(r+1)}$ and $\theta^{(r+1)}$ thanks to the alternated application of EM on intermediate data matrices.

Step 3: Iterate Step 2 until convergence.

We present now the Block Fuzzy K-Modes (BFKM) clustering algorithm [5].

3) Block Fuzzy K-Modes algorithm

For clustering categorical data, i.e., types of data which may be divided into groups, Huang and Ng [5] proposed the Fuzzy K-Modes (FKM) algorithm using simple matching dissimilarity measures. Huang and Ng [5] added the concept of biclustering with FKM, and then proposed the Block FKM (BFKM) method.

Let $Y = \{y_{1},..,y_{n}\}$ be a set of data. Let each data be defined by a set of attributes $A_{1},..,A_{m}$ such that $y_{i} = \{y_{i1},..,y_{im}\}$, $i = 1,..,n$. Each attribute $A_{j}$, $j = 1,...,J$ describes a domain of values denoted by $DOM(A_{j}) = \{a_{j1},..,a_{j|DOM(A_{j})|}\}$ where $L_{j}$ denotes the cardinality of $DOM(A_{j})$. Suppose that $\partial_{k} = (\partial_{1k},..,\partial_{jk})$ is the centroid of the $k$th cluster where each component $\partial_{kj} = (\partial_{kj1},..,\partial_{kjL_{j}})$ for $k = 1,...,K$, $j = 1,...,J$. The fuzzy k-modes algorithm is to minimize the following objective function:

$$L_{M}(\mu, \partial) = \sum_{i=1}^{n} \sum_{k=1}^{K} \mu_{ik}^{m} d(y_{ij}, \partial_{kj})$$

subject to $\sum_{k=1}^{K} \mu_{ik} = 1$.

For $i = 1,...,n$. The update equations for fuzzy k-modes are as follows: $\mu_{ik} \in [0,1]$ and $\mu_{ik} = \frac{\sum_{k=1}^{K} (\partial_{kj} - \partial_{kj})^{L_{j}}}{\sum_{k=1}^{K} (\partial_{kj} - \partial_{kj})^{L_{j}}}$.

We note $\partial_{kj}$ is the cluster center, it is defined by:

$$\partial_{kj} = \left\{egin{array}{ll}
1 & \text{if } \sum_{i=1}^{n} \mu_{ik} y_{ij} \leq f^{*} \\
\max_{ik} P_{ik} X_{ij} & \text{otherwise}
\end{array}ight.$$
\[ F_{BK}(\mu, \sigma, \beta, X, Y) = \sum_{lk} (\mu_{lk})^{m_1} d(\partial_k, x_l) + \sum_{j\ell} (\sigma_{j\ell})^{m_2} d(\beta_{j\ell}, y_{\ell}) \] (22)

Subject to \( \sum_{k=1}^{K} \mu_{lk} = 1, \) for \( k = 1, \ldots, K \) and \( \sum_{\ell=1}^{L} \sigma_{j\ell} = 1, \) for \( j = 1, \ldots, L. \) \( \partial_k \) and \( \beta_{j\ell} \) are respectively the clusters centers, \( X \) is a data matrix with \( n \) genes and \( m \) conditions, and \( Y \) is the transpose of \( X. \) The update equations for BFKM are as follows:

\[ m_1 > 1, \] \( \mu_{lk} \) \( \in \{0, 1\} \), and \( \sigma_{j\ell} \in \{0, 1\} \)

\[ \mu_{lk} = (\sum_{k=1}^{K} \left( \frac{d(\partial_k, x_l)}{d(\partial_k, x_l)^{m_1}} \right)^{\frac{1}{m_1-1}})^{-1} \]

\[ \sigma_{j\ell} = (\sum_{\ell=1}^{L} \left( \frac{d(\beta_{j\ell}, y_{\ell})}{d(\beta_{j\ell}, y_{\ell})^{m_2}} \right)^{\frac{1}{m_2-1}})^{-1} \]

We note \( \partial_{k ef} \) and \( \beta_{j fgh} \) are the clusters centers, there are defined by:

\[ \partial_{k ef} = \begin{cases} 1, & \text{if } \sum_{l=1}^{n} \mu_{lk}^{m_1} x_{l ef'} = \max_{1 \leq f', \ell \leq L} \sum_{l=1}^{n} \mu_{lk}^{m_1} x_{l ef'} \\ 0, & \text{otherwise} \end{cases} \]

\[ \beta_{j fgh} = \begin{cases} 1, & \text{if } \sum_{l=1}^{m} \sigma_{j\ell}^{m_2} y_{j fgh'} = \max_{1 \leq h', \ell \leq H} \sum_{l=1}^{m} \sigma_{j\ell}^{m_2} y_{j fgh'} \\ 0, & \text{otherwise} \end{cases} \]

Where \( f' \) and \( h' \) are the numbers of the attribute \( A_j. \)

Besides, we propose *Fuzzy Logic Block Lazy EM* algorithm (FLBLEM) to be adopted by our biclustering approach instead of BEM one. FLBLEM is based on a Lazy EM (LEM) [13] which is faster than EM. We can summarize our biclustering approach as follows:

During the first step, we fix a maximum number of biclusters, via the FMF, to initialize the parameters of our BMM.

During the second step, we cluster genes and/or conditions simultaneously, or consecutively, by applying a Block Lazy EM (BLEM) algorithm, if we are in an estimation phase.

During the last step, we tune the obtained group of biclusters either by merging biclusters or by creating others. If the algorithm does not converge, we repeat the second step.

V. CONCLUSION AND PERSPECTIVES

In this paper, we have reviewed existing biclustering approaches adopting a Block Mixture Model (BMM) and suggested a new fuzzy biclustering one.

Our approach enables to choose a good strategy of initialization of Block Expectation Maximization (BEM) and Block Classification Expectation Maximization (BCEM) algorithms.

This an ongoing work, as perspectives, we have to:

(i) Handle missing values in microarray data,

(ii) Speed-up our approach by defining a good strategy of choice of the initial number of biclusters.

(iii) Make an experimental study of our approach and compare the obtained results with those obtained by *Block Fuzzy C-Methods* (BFCM) [12] and *Block Fuzzy K-Modes* (BFKM) [5] ones.
