The secondary coordination ability of a paramagnetic nickel dithiolene complex, bearing an ether coordinating function within a nine-membered flexible ring, has been demonstrated in its [NiCl(DMF)] + complex, through coordination by both ether and thioether functions, allowing for a ferromagnetic interaction between both paramagnetic entities.

Paramagnetic metal dithiolene complexes aff ord a wide variety of structures with associated conducting and magnetic properties. The most common magnetic species are, either the d 5 (S = ½) Cu(dithiolene) 2 + copper complexes, or the oxidized, formally d 6 (S = 1) M(dithiolene) 2− (M = Ni, Pd, Pt) anionic complexes, and the gold neutral complexes Au(dithiolene) 2. The magnetic properties of these salts are essentially controlled by the overlap interactions between radical species, from weak interactions favoring localized magnetic states within dimers or spin chains, to stronger interactions allowing for metallic conductivity.

Besides, as recently reviewed, paramagnetic dithiolene complexes can also be considered as metallo-ligand toward other metallic centres for the elaboration of more complex architectures. For example, complexes such as [M(mnt)] 2+−1+ or [M(tfadt)] 2+−1+ form heterobimetallic chains through metal-nitrogen coordination, with Mn porphyrins, [Ni(cyclam)] 3+−10 or polynuclear 11 complexes such as [Mn(hmp),(CH,CN) 3]+ (hmp: 2-hydroxymethylpyridine). Other examples of nitrogen coordination can be also found in fused pyrazine or in 4-pyridyl derivatives.

On the other hand, complexes with oxygen-based coordinating functions are essentially limited to the chelating dithiooxalate (dto) and dithiosquarate (dts) ligands. Because of the strongly electron-withdrawing nature of the carbonyl groups, both ligands only stabilize the most reduced dianionic forms of the dithiolene complexes, the diamagnetic [Ni(dto)] 2− or the paramagnetic d 0 (S = 1₂) [Cu(dto)] 2−. Looking for alternative substitution patterns that would allow the use of the monoanionic, formally d 7, S = ½ [Ni(dithiolene) 2− complexes while keeping oxygen atoms for secondary coordination, we considered the unknown monoanionic nickel complex 1 where a –(CH,2)−O–(CH,2)− flexible moiety is directly linked to the outer sulfur atoms.

Such a complex can potentially coordinate extra metal cations through combined coordination of the ether and thioether functions, with the latter taking part to the spin density distribution of the dithiolene complex. Note that this coordination function has been considered on analogous tetraethylfulvalene derivatives such as 2 only for alkali cations, while coordination to paramagnetic metal cations was never investigated.

We describe here the synthesis of the paramagnetic (S = ½) nickel complex 1, isolated as a tetrabutyl ammonium salt. Further reaction with nickel salts afforded a first example of coordination of 1 to an octahedral nickel dication through the combined ether and thioether moieties to afford a bimetallic (S = 1, S = ½) complex demonstrating the potential of such dithiolene complexes to act as metallogligands.

The preparation of the nickel complex (Scheme 1) relies on the base opening of the dithiocarbonate obtained itself from the trithiocarbonate 3, 14−17 Addition of half equiv. of NiCl 2 afforded directly (air oxidation) the monoanionic complex as a DMF
solvent, (nBu4N+)I(1−)-DMF. It reduces reversibly to the dianion at −0.66 V vs. SCE, while it oxidizes reversibly to the neutral complex at +0.32 V vs. SCE. Further irreversible oxidation to the cationic state is found at 1.16 V vs. SCE.

Note that during our attempts to coordinate 1− with Fe3+ salts, a few crystals of the oxidized neutral complex 1 was obtained instead, allowing for a comparison of the intramolecular bond distances within the dithiolene core in the two redox states, 1− and 1.

Investigation of the secondary coordination of the 1− radical anions was performed with two Ni2+ different salts, Ni(ClO4)2 and NiCl2. With the former, an insoluble product was first obtained. Redissolution in DMF and EtO layering afforded a bimetallic nickel salt, which analyzes as [Ni(DMF)2]2+, that is two radical anion complexes for one Ni2+ cation solvated with six DMF molecules. On the other hand, with NiCl2, another salt was obtained, which analyzes as [NiCl(DMF)]2+ (2DMF,EtO), where direct coordination of the dithiolene complex to the outer Ni2+ species is actually observed.

The 1− dithiolene complex in the two salts with nBu4N+ and [Ni(DMF)2]2+, as well as in its neutral state, adopts a common geometry of the nine-membered ring (Fig. 1), with the oxygen atom pointing toward the centre of the molecule. Comparison of the intramolecular bond distances with those found in the oxidized 1 (Table 1) shows the anticipated evolutions, with the shortening of the Ni–S and S–C bonds, of antibonding character in the SOMO of such dithiolene radical anions, combined with the lengthening of the C=C bond, associated with its bonding character in the dithiolene SOMO.

The temperature dependence of the magnetic susceptibility of [Ni(DMF)2]2+ (1) (Fig. 2a) shows a Curie–Weiss type behavior, with a Curie constant of 2.00(1) K cm3 mol−1, (and θ = −0.33(1) K), corresponding to the contribution of two 1− radical anions (S = 1/2), without interaction with the [Ni(DMF)]2+ species in octahedral environment (S = 1). EPR determination of the g value of 1 in its tetrabutyl ammonium salt gives g⊥ = 2.069. It follows that the g value for the [Ni(DMF)]2+ species amounts here to g⊥ = 2.188, a value comparable to that usually observed for Ni(II) centres in an octahedral coordination sphere.

Fig. 1 Ortep view of the 1− radical anion in (nBu4N)(1)-DMF.

Fig. 2 Temperature dependence of the χT product for (a) [Ni(DMF)2](1), and (b) [NiCl(DMF)2](1).

When the 1− tetrabutyl ammonium salt was faced with NiCl2, rather than Ni(ClO4)2, another salt was obtained, which analyzes as [NiCl(DMF)2](1)(2DMF,EtO). As shown in Fig. 3, a cationic [NiCl(DMF)2]+ moiety is now coordinated to the 1− radical anion, with the coordination sphere of the NiCl(DMF)2+ cation completed by the two sulfur atoms and the oxygen atom of the dithiolene fragment.

This salt provides the first example of coordination of such ether/thioether substituted dithiolene complexes with paramagnetic cations. The Ni2+ cation is in an octahedral environment. Bond distances within the dithiolene metallacycles (Table 1) confirm the radical anion character, with a very weak disymmetry due to the NiCl2 coordination. Note also that the recurrent conformation adopted by the flexible –(CH2)3–O–(CH2)3– arm in the other complexes (Fig. 1) is modified here to allow for the Ni2+ coordination with both the ether oxygen atom and the two thioether functions. Temperature dependence of χT (Fig. 2b),
combined contributions of temperatures, we have introduced a mean-field correction in the interaction between a ferromagnetic interaction between the two centres. The isotropic 1.67 at 25 K before decreasing sharply, indicating the presence of S measured on a compressed polycrystalline sample, gives a room with outer sulfur atoms. Note that this Et of the referees for useful comments on magnetic properties.

![Fig. 3](image)

measured on a compressed polycrystalline sample, gives a room temperature value of 1.6 K cm⁻¹ mol⁻¹, corresponding to the combined contributions of I⁺ (S = ½) and octahedral Ni⁺ (S = 1 with gₙ = 2.19). The χT product increases up to a maximum of 1.67 at 25 K before decreasing sharply, indicating the presence of a ferromagnetic interaction between the two centres. The isotropic interaction between S = 1 and S = ½ magnetic centres gives two S = ½ and S = 3/2 states, separated by 3J/2 for an Hamiltonian that writes as H = -JS₅S₆. The g values for the corresponding doublet and quartet states write as g₁/₂ = (4g_S⁻g_0)/3 and g₃/₂ = (2g_S + g_0)/3 and an approximate expression of the magnetic susceptibility χₘ of such dimers is then given by:

\[
\chi_{\text{dim}} = \frac{N\beta^2 g_{\text{eff}}^2 + 10g_{\text{eff}}^2 \exp(3J/2kT)}{4kT} + 2\exp(3J/2kT)
\]

with here g₁/₂ = 2.23 and g₃/₂ = 2.15. In order to take also into account the decrease of susceptibility observed at lower temperatures, we have introduced a mean-field correction in the expression of the susceptibility, which writes as:

\[
\chi = \frac{\chi_{\text{dim}}}{1 - \frac{zJ}{N\beta^2 g_{\text{eff}}^2 \chi_{\text{dim}}}}
\]

Best fit gives J/k = +10 cm⁻¹ and J’ = -0.6 cm⁻¹ (z = 4) and demonstrates that the direct coordination of the paramagnetic (S = 1) NiCl moieties through the combined ether and thioether functions allows for a sizeable ferromagnetic interaction with the dithiolene radical anion complex, through the coordination to its outer sulfur atoms. Note that this S = 3/2 ground state expected from the ferromagnetic coupling of the S = 1 and S = 1/2 spin states of the Ni ion and the complex should present a ZFS that could also explain the sharp decrease in the χT plot at low temperatures.

We are currently investigating other cations and crystallization conditions on magnetic properties.
