Abstract

We re-evaluate the Greenland mass balance for the recent period using low-pass Independent Component Analysis (ICA) post-processing of the Level-2 GRACE data (2002-2010) from different official providers (UTCSR, JPL, GFZ) and confirm the present important ice mass loss in the range of -70 and -90 Gt/y of this ice sheet, due to negative contributions of the glaciers on the east coast. We highlight the high interannual variability of mass variations of the Greenland Ice Sheet (GrIS), especially the recent deceleration of ice loss in 2009-2010, once seasonal cycles are robustly removed by Seasonal Trend Loess (STL) decomposition. Interannual variability leads to varying trend estimates depending on the considered time span. Correction of post-glacial rebound effects on ice mass trend estimates represents no more than 8 Gt/y over the whole ice sheet. We also investigate possible climatic causes that can explain these ice mass interannual variations, as strong correlations between GRACE-based mass balance and atmosphere/ocean parallels are established: (1) changes in snow accumulation, and (2) the influence of inputs of warm ocean water that periodically accelerate the calving of glaciers in coastal regions and, feed-back effects of coastal water cooling by fresh currents from glaciers melting. These results suggest that the Greenland mass balance is driven by coastal sea surface temperature at time scales shorter than accumulation.

Keywords: ice sheets, mass balance estimates, Greenland, GRACE

1. Introduction

The mass balance of the Greenland Ice Sheet (GrIS), and its contribution to sea level rise, are of high interest in the context of global warming. According to the latest IPCC report (2007), melting of the whole GrIS would contribute nearly 7m to sea level rise. Even a less substantial mass loss would have a strong impact on sea level rise. Over the last twenty years, observations of the GrIS show an acceleration of ice mass loss caused by rapid glacier flow on the southeast and northwest coasts (see Allison et al. (2009) and Zwally et al. (2011) for reviews), in response to the recent warming affecting both the atmosphere (Box and Cohen, 2006) and sea water (Hanna et al., 2009). Nevertheless, analysis of changes in the glaciers reveals a succession of periods of mass loss acceleration and deceleration.

Since its launch in March 2002, the GRACE mission has demonstrated great potential for studying the ice sheet mass changes. The GRACE data have been increasingly used for assessing mass balance of Greenland and Antarctica. First studies revealed a significant mass loss of Greenland with an acceleration of melting starting in 2004 (Velicogna and Wahr, 2005, 2006; Chen et al., 2006; Luthcke et al., 2006; Ramillien et al., 2006). Mass loss occurred mainly on the east coast of Greenland whereas the interior of the continent exhibited a small mass increase (Luthcke et al., 2006; Wouters et al., 2008). Recent studies showed acceleration of the mass loss during 2006-2008 (Velicogna, 2009) and a deceleration during 2008-2009 (Chen et al., 2011). Nevertheless, the results obtained so far are highly dependent on the length of the GRACE time series, the chosen data set, the nature of the post-processing, and the method for computing linear trends (i.e., with or without adjusting the seasonal components). Results can vary by a factor ~ 3 depending on the data set (e.g. CSR, GFZ or JPL; Baur et al., 2009). From these previous GrIS mass balance estimates, linear trends were simply computed over the complete (or parts of the) period of availability of the GRACE data, assuming the ice melting to be constant in time. Only Velicogna (2009) and Rignot et al. (2011) estimated accelerations for 2004 and 2008-2009.

In this study, we re-evaluate the Greenland mass balance over a longer time span (October 2002 - July 2010), using Level-2 GRACE data from the Science Data Centre

31 (UTCSR, GFZ and JPL) and different post-processing techniques (Gaussian and Inde-
 32 pendent Component Analysis-based approaches) at continental and ice field scales. We
 33 also analyze the interannual variability of the mass balance using the robust Seasonal
 34 Trend Decomposition by Loess (LOcally wEighted Scatterplot Smoothing) (STL) ap-
 35 proach. The non-stationarity of the mass balance is then related to climate forcings
 36 from the atmosphere and the ocean through comparisons with snow depths (SD) and
 37 sea surface temperatures (SST).

38 **2. Data sets**

39 *2.1. GRACE-based water mass variations*

40 Since its launch in March 2002, the Gravity Recovery And Climate Experiment
 41 (GRACE) mission, consisting of a pair of co-orbiting satellites at an altitude of 400-
 42 450 km, provides a systematic mapping of the spatio-temporal variations of the Earth's
 43 gravity field. These are estimated with an unprecedented precision of ~ 1 cm in terms of
 44 geoid height (Tapley et al., 2004), or equivalently ~ 15 -20 cm in equivalent-water thick-
 45 ness when averaged in regions of 300×300 of square kilometers (Ramillien et al., 2008;
 46 Schmidt et al., 2008). The Level-2 GRACE solutions consist of monthly Stokes coeffi-
 47 cients (i.e., normalized spherical harmonics of the geo-potential) estimated by a least-
 48 squares adjustment of GRACE orbit measurements -especially very accurate inter-
 49 satellite K-Band Range (KBR) variations- made by different official providers [Ge-
 50 oForschungsZentrum (GFZ) in Potsdam Germany, Center of Space Research at Uni-
 51 versity of Texas (UTCSR) in Austin, TX, Jet Propulsion Laboratory (JPL) in Pasadena,
 52 CA]. In this process, the Stokes coefficients are corrected for known atmospheric and
 53 oceanic gravitational contributions (Bettadpur, 2007), so that the residuals represent
 54 non-modeled phenomena, mainly variations in land water storage, glaciers, and ice
 55 sheet mass. These Level-2 GRACE solutions are available at: <ftp://podaac.jpl.nasa.gov/grace/>
 56 up to harmonic degree of 50-60 (i.e., spatial resolution of ~ 333 -400 km), and the corre-
 57 sponding global $1^\circ \times 1^\circ$ grids of equivalent-water heights are also downloadable. In our
 58 study, we use monthly GFZ, UTCSR and JPL solutions from 04/2002 to 07/2010.
 59 The GRACE solutions suffer from the presence of an unrealistic high-frequency noise

60 appearing as north-south striping, caused by orbit resonance during the Stokes coeffi-
 61 cient determination and aliasing with short-term oceanic and atmospheric phenomena
 62 that are not well modeled. Several post-processing methods, such as low-pass Gaussian
 63 filtering, have been proposed to solve this problem (Jekeli, 1981; Swenson and Wahr,
 64 2002). However most of them suffer from the risk of losing signal energy in the spec-
 65 trum truncation (i.e., drastic loss of spatial resolution). This also needs arbitrary tuning
 66 of required parameters (e.g., a priori level of noise, cutting spatial frequencies,...) in
 67 absence of criteria. To get rid of the noise in the L-2 GRACE solutions, we preferred to
 68 use the global ICA estimates obtained by combination of GFZ/UTCSR/JPL solutions,
 69 to isolate statistically independent components of the observed gravity field, in particu-
 70 lar the continental water storage contribution that we compared with continental water
 71 storage estimated from classical Gaussian-filtered solutions.

72 2.2. ICA solutions

73 A post-processing method based on ICA (Comon , 1994; De Lathauwer et al. ,
 74 2000) was applied to the Level-2 GRACE solutions prefiltered with Gaussian filters of
 75 400 km and 500 km of radius. This so-called blind source separation (BSS) approach
 76 does not require a priori information, except the assumption of statistical independence
 77 of the elementary sources that compose the total measured signals. Taking into account
 78 the consideration that the GRACE Level-2 products from CSR, GFZ and JPL are dif-
 79 ferent observations of the same monthly gravity anomaly, and that the land hydrology
 80 and the north-south stripes are the independent sources.

81 Assuming that the observations y collected from N sensors are the combination of P
 82 ($N \geq P$) independent sources represented by the source vector x , they can be written
 83 as a linear statistical model:

$$y = Mx, \quad (1)$$

84 where M is the mixing matrix whose elements m_{ij} ($1 \leq i \leq N$, $1 \leq j \leq P$) in-
 85 dicate to what extent the j th source contributes to the i th observation. The columns
 86 $\{m_j\}$ are the mixing vectors. ICA aims at estimating the mixing matrix M and/or the
 87 corresponding realizations of the source vector x , only knowing the realizations of the

88 observation vector y , under the following assumptions: i) the mixing vectors are lin-
89 early independent, and ii) the sources are statistically independent. The contributors to
90 the observed gravity field are forced to be uncorrelated, numerically only considering
91 completely objective constraints. The efficiency of ICA to separate gravity signals and
92 noise from combined GRACE solutions has previously been demonstrated on Level-2
93 solutions over land (Frappart et al., 2010, 2011). Series of ICA-estimated global maps
94 of continental and ice caps mass changes, computed over 08/2002-07/2010, are used
95 in this study to estimate the mass balance of Greenland.

96 2.3. *ECMWF Snow depth data*

97 We used the daily snow depth grids from the European Centre for Medium-Range
98 Weather Forecasts (ECMWF) ERA-interim reanalysis with a horizontal resolution of
99 $1.5^\circ \times 1.5^\circ$ (http://data-portal.ecmwf.int/data/d/interim_daily/; Dee et al., 2011). These
100 grids were estimated from the improved snow scheme of the Hydrology Tiled ECMWF
101 Scheme of Surface Exchanges over Land (HTESSEL) land surface model. It includes a
102 new parametrization of snow density, incorporating a liquid water reservoir, and revised
103 formulations for the sub grid snow cover fraction and snow albedo (Dutra et al., 2010).
104 The daily grids of snow depth were averaged monthly over the period April 2002 to
105 July 2010, for comparisons with the total water storage derived from GRACE.

106 2.4. *NOAA Sea Surface Temperature*

107 In this study, we used the National Oceanic and Atmospheric Administration (NOAA)
108 Optimum Interpolation Sea Surface Temperature Analysis Version 2, available at
109 <http://www.esrl.noaa.gov/psd/>. They consist of weekly grids produced by optimal in-
110 terpolation (Reynolds and Smith, 1994). Monthly solutions are then estimated by lin-
111 ear interpolation of weekly fields to daily fields, and averaging the daily values over
112 a month. The monthly fields have a resolution of $1^\circ \times 1^\circ$ on a global half degree grid.
113 Data from April 2002 to July 2010 are used in this study.

114 3. Methodology

115 3.1. Mass anomalies from GRACE data

116 The monthly Stokes coefficients of the GRACE solutions are used to estimate mass
117 anomalies by spherical harmonic expansion (Wahr et al., 1998). After removing a tem-
118 poral average, monthly maps of surface mass density anomalies ($\Delta\sigma$) can be computed
119 as:

$$\Delta\sigma(\phi, \lambda, t) = \frac{a_e \rho_e}{3\rho_w} \sum_{l=2}^{\infty} \sum_{m=0}^l \frac{2l+1}{1+k_l} P_{lm}(\sin \phi) (\Delta C_{lm} \cos m\lambda + \Delta S_{lm} \sin m\lambda) \quad (2)$$

120 where a_e is the semi major axis, ρ_e the average density of the earth (5517 kg/m³),
121 ρ_w the density of water (1000 kg/m³), k_l are the elastic Love numbers of degree l ,
122 P_{lm} are the normalized associated Legendre Polynomials of degree l and order m , ϕ is
123 the geographical latitude, λ the geographical longitude, t the time and (ΔC_{lm} , ΔS_{lm})
124 are the fully normalized dimensionless spherical harmonic (Stokes) coefficients given
125 by GRACE. The $\Delta\sigma$ are given in meters of equivalent water height. The spherical
126 harmonic expansion has been performed up to degree and order 60 which leads to a
127 spatial grid resolution of ~ 333 km.

128 To remove the noise due to aliasing of short-term phenomena (inducing north-south
129 stripes) the solutions have to be filtered. In this work a Gaussian filter with a half width
130 radius of 400km and 500km was used. As mentioned in section 2.2, the Gaussian
131 filtered solutions are further destriped by applying of the ICA method.

132 Mass variations $\Delta\sigma$ are computed at each time step and grid point, and have been
133 further averaged in the boundaries of the GrIS and subregions.

134 3.2. Correction of the Post-Glacial Rebound

135 Over Canada and northwestern Europe, the last deglaciations (~ 20 k-years ago)
136 of thick ice sheets caused rapid deloadings of ice mass. Because of its viscoelastic
137 behavior, i.e. Post Glacial Rebound (PGR), the Earth's mantle is still continuing a
138 non negligible isostatic re-adjustment (Peltier, 2004). As a consequence of this long-
139 term deformation, the Earth's surface and gravity field are still affected by PGR at

linear rates. For example, in the South of Hudson Bay in Canada, the uplift of the surface measured at GPS sites reaches 1.1 cm/yr (Sella et al., 2007). Knowledge of the deglaciation history and the Earth’s mantle viscosity remains limited to uncertainties in PGR modeling. However, according to independent models, PGR geographically-averaged over Greenland shows negative trends weaker than 10 Gt/yr, and is considered by some authors to be weak compared to ice mass loss. Using different PGR models, comparable PGR estimates, from 7 or 8 Gt/yr were found (Velicogna and Wahr, 2006; Velicogna, 2009) considering the ICE-5G model of Peltier (2004), and up to 9 Gt/y (Ramillien et al., 2006) using the IJ-2005 model developed by Ivins and James (2005). As it is available at the GRACE Tellus website (<http://grace.jpl.nasa.gov/data/pgr>), we consider the Paulson et al. (2007) model based on the ICE-5G ice model and a tuning of mantle viscosity contrasts and crust thickness. The $1^\circ \times 1^\circ$ grid of PGR trend has been downloaded from this website, and the Stokes coefficients of the PGR have been converted into rates of surface mass change and expressed in mm of water height per year. Degree-one terms were omitted as they are not included in the GRACE solutions. The results were smoothed using a Gaussian averaging function of 400 and 500 km radius. Over the whole of Greenland, we found a PGR trend close to -8 Gt/yr, representing -4 mm/yr of equivalent-water height. For each time step the modeled PGR contribution has been removed from the filtered GRACE mass anomalies. When interpreting the PGR-corrected Greenland mass balance, we keep in mind that the PGR model uncertainty can represent an important source of error.

3.3. Seasonal-Trend Decomposition by Loess (STL) Method

The STL method, based on locally weighted regression (Cleveland et al., 1990), is a robust and computationally efficient approach commonly used to decompose time series into trend (T_v), seasonal (S_v), and residual (R_v) components:

$$Y_v = T_v + S_v + R_v \quad (3)$$

STL is an iterative method consisting of two recursive procedures, one nested within the other, called the inner and the outer loops. The trend and seasonal estimates are

167 progressively refined in the inner loop in each iteration. After one complete run of the
 168 inner loop, robustness weights are computed in the outer loop. These weights are used
 169 in the next run of the inner loop to reduce the influence of outliers in the trend and
 170 seasonal signal. The local weights ϑ_v of the values depend on the time steps to the
 171 observed time in a chosen window with size q . A polynomial with power d is fitted to
 172 the weighted data.

173 The inner loop contains six steps. In the first step of the k th run of the inner loop, the
 174 time series Y_v is detrended with T_v^k :

$$Y_v^{detrend} = Y_v - T_v^k. \quad (4)$$

175 Then, every sub-cycle time series is smoothed by locally weighted regression and the
 176 results are stored in C_v^{k+1} (step 2). In the third step the smoothed sub-cycle time
 177 series are processed using a low pass filter. The low pass filter is composed of three
 178 consecutive averaging means, followed by a locally weighted regression. The low
 179 pass filtered values are stored in L_v^{k+1} . The estimated low pass filtered values of the
 180 seasonal sub-cycles are then removed from the smoothed sub-cycle time series of step
 181 2 to receive the seasonal signal S_v^{k+1} (step 4):

$$S_v^{k+1} = C_v^{k+1} - L_v^{k+1}. \quad (5)$$

182 In the next step (step 5), the original time series is reduced by the seasonal signal:

$$Y_v^{deseason} = Y_v - S_v^{k+1}. \quad (6)$$

183 In the last step (step 6) the reduced time serie from step 5 is smoothed by locally
 184 weighted regression with $d = 1$ to receive the updated trend signal T_v^{k+1} .

185 In the outer loop the trend and seasonal signal are used for computing the remaining
 186 signal R_v :

$$R_v = Y_v - T_v^{k+1} - S_v^{k+1}. \quad (7)$$

For each time step a robustness weight ρ_v is determined. Outliers will have a very small or zero weight. In the next run of the inner loop the robust weight will be multiplied to the weights ϑ_v in the locally weighted regression in step 2 and 6.

The Fortran-Code for the STL-Method has been provided at the following webpage: <http://www.stat.purdue.edu/wsc/localfitsoft.html>. For an easy start into the method the function `stleze.f` has been used. In this function just the main necessary parameters have to be entered by the user:

- 1) The number of observations n_p which are included in each period. We have time series with monthly resolution and an annual signal, choosing $n_p = 12$.
- 2) The number of iterations of the inner (n_i) and outer (n_o) loop. Because, that the convergence of estimating the different components of the signal is very fast, n_i can be set to 1. If a robust estimation of the signals is preferred, the determination of the robust weight in the outer loop is done until the convergence criteria is reached, or with a maximum of $n_o = 15$.
- 3) In step 2 the estimated seasonal signal is smoothed by Loess with the parameters $d = 1$ and $q = n_s$. The seasonal signal becomes smoother with increasing n_s . At minimum, n_s has to be odd and greater than 6. Due to this fact $n_s = 7$ has been chosen.
- 4) In step 3 the smoothing with Loess, with parameter $d = 1$ and $q = n_l$, is applied. The weight factor n_l has to be chosen as the least odd number equal to n_p . In this case with $n_p = 12$, then $n_l = 13$.
- 5) In the last step (step 6), the trend signal is smoothed with Loess with $d = 1$ and $q = n_t$. The parameter n_t should be the least odd integer value greater or equal to

$$n_t \geq \frac{1.5 * n_p}{1 - \frac{1.5}{n_s}} \quad (8)$$

With the above given values for the parameters n_p and n_s , then $n_t = 21$.

4. Results and Discussion

4.1. Re-evaluation of the recent Greenland mass change

Gaussian-filtered and smoothed ICA solutions were averaged over Greenland by simply using a geographical mask over the period 2002-2010. Figure 1 presents the six

214 mean ice fields composing the Greenland ice sheet (acc. to Luthcke et al., 2006). The
 215 corresponding ICA-based time series were corrected for the seasonal signal by apply-
 216 ing the STL decomposition (explained in paragraph 3.3). Velicogna (2009) proposed
 217 an additional filtering to cancel the long term and periodic contributions in the GRACE
 218 data, based on the least-square adjustment of annual, semi-annual, trend and constant
 219 terms using 13-month running windows. Instead of fitting empirical periodic varia-
 220 tions, we preferred to apply the more robust STL method for extracting the long-term
 221 signals. To illustrate the benefit of using the STL decomposition, Fig. 2 compares the
 222 Greenland mass balance based on the method developed here (STL, ICA), to classical
 223 Gaussian filtering. The decreasing behavior of these curves confirms the mass deple-
 224 tion of this ice sheet due to important melting during the GRACE period. Moreover,
 225 these GRACE-derived time series also contain annual and sub-annual signals that need
 226 to be isolated in order to extract the interannual ice mass variations. Differences be-
 227 tween ICA and Gaussian filtered estimates are not always correlated for wavelengths
 228 less than 1 year, and they can reach 100 mm of equivalent-water height. These short-
 229 term differences can be accounted for a reduction of the residual noise by ICA after the
 230 Gaussian low-pass filtering. Fig. 2b presents the STL-smoothed time series containing
 231 the interannual variations of GrIS ice mass, which are not a simple straight line, sug-
 232 gesting that GrIS ice mass loss cannot be represented by a constant slope. In the next
 233 sections, we attempt to explain the presence of such interannual variations by estab-
 234 lishing correlations in time with climate forcings.

235 Depending on the chosen period and time length, the linear trends computed along
 236 the time series are not constant. For example, there are obvious accelerations of ice
 237 melting (Velicogna and Wahr, 2006; Velicogna, 2009), and a relative deceleration in
 238 2009-2010, in agreement with the results found by Rignot et al. (2011) for Greenland
 239 during the last years. The change of the GrIS mass balance for the complete GRACE
 240 period (i.e., between 2003 and 2010) still exhibits a huge mass loss, even before the
 241 constant negative rate of ~ -8 Gt/yr for PGR is removed from the linear trend estimates.
 242 The amplitude of these trend estimates clearly varies with the GRACE solution provider
 243 (i.e., CSR, GFZ, JPL) and the post-processing (i.e., ICA or only Gaussian low-pass fil-
 244 tering). In terms of sensitivity relative to the GRACE solution source, the lowest values

245 are systematically obtained with the JPL solutions. This is probably due to some spe-
 246 cific pre-processings of the GRACE measurements made by this provider. Low linear
 247 trends were already found by Baur et al. (2009) using JPL solutions over Greenland
 248 while CSR solutions give values twice as large (see Table 1).
 249 Use of ICA instead of Gaussian filtering makes the GrIS ice mass time series smoother.
 250 As a consequence ICA-based linear trends are smaller. In the case of Gaussian low-pass
 251 filtering, the larger the cutting wavelength the lower the trend estimate. By using the
 252 400-km Gaussian-filtered solutions, the 2003-2010 rate ranges from -35 ± 2 Gt/yr for
 253 JPL to -89 ± 2 Gt/yr for CSR. With the 500-km ICA solutions, this rate varies from -56
 254 ± 2 Gt/yr for JPL to -74 ± 3 Gt/yr for CSR. Whatever type of post-processing is used,
 255 using the JPL solutions yields to the lowest linear trend estimates, with magnitudes
 256 <60 Gt/yr for ICA processing, and <40 Gt/yr for the Gaussian filter, once correcting
 257 from the PGR effects.
 258 Comparison with PGR-corrected GrIS ice mass loss estimates from previous studies
 259 leads to important differences (see Table 1 and Figure 3). These differences can be
 260 explained by the different time spans considered in this study and the high interan-
 261 nual variability of the GrIS ice mass change, as previously shown on the Fig.2a-b. We
 262 checked this by computing trends over different time spans. As shown in Figure 3,
 263 trend estimates are highly dependent on both the considered time span and the method-
 264 ology used. For instance, we obtained STL-base (and linear) trends of respectively
 265 -96.5 (-100.3), -78.3 (-74.7), -106.8 (-115.2) Gt/yr for the periods 04/2002-11/2009,
 266 04/2002-03/2005, 04/2005-11/2009, using CSR solutions Gaussian filtered with a ra-
 267 dius of 400 km, whereas Chen et al. (2011) found linear trends of respectively -219 ,
 268 -144 , -248 Gt/yr over the same time periods using CSR solutions, after low-pass Gaus-
 269 sian filtering using a radius of 300 km and correcting of leakage and biases of GRACE.
 270 Our trend estimates using Gaussian-filtered solutions are slightly lower (i.e., around
 271 -80 Gt/yr), but remain consistent in amplitude with the results of previous works (e.g.,
 272 Ramillien et al. (2006) obtained -109 Gt/yr considering the period 07/2003 - 03/2005).
 273 The Gaussian filter-based estimates often differ by more than a factor 2, since Wouters
 274 et al. (2008) found -171 Gt/yr for the period 03/2003 -01/2008, Baur et al. (2009) ob-
 275 tained -222 ± 13 , -178 ± 22 , -88 ± 21 Gt/yr for the period 08/2002-07/2008 considering

276 the CSR, GFZ, and JPL solutions, and Chen et al. (2011) proposed a value of -219
 277 Gt/yr for 04/2002-11/2009. Velicogna and Wahr (2006) found an extreme value of -
 278 240 Gt/yr considering a shorter period. In fact, these latter authors proposed to multiply
 279 artificially their GrIS ice mass estimate by a scaling factor of ~ 2 , to compensate the
 280 leakage effects over Greenland (i.e., loss of signal energy due to the spherical harmon-
 281 ics truncation at degree 50-60). The large value of this scaling factor over Greenland
 282 was empirically estimated from global hydrology model simulations (see Velicogna
 283 and Wahr (2006), p.331). It explains mostly the difference of previous studies and
 284 our Gaussian filter-based estimates. The lowest estimates are found by using the ICA-
 285 based time series (< 70 Gt/y). ICA reduces the magnitude of the North-South stripes
 286 that are not correlated with continental hydrology signals (Frappart et al., 2010, 2011).
 287 The choice of the cutting wavelength before ICA separation has strong consequences
 288 on the level of noise in the pre-filtered solutions, and thus on the amplitude of the lin-
 289 ear trend estimates. When the noise in the pre-filtered solutions increases, the standard
 290 deviations of the linear trend estimates do the same. In other words, a large amount
 291 of error in the trend estimate may come from the dispersion of the starting points on
 292 which a straight line is fitted.

293 Consequently, the noise-free ICA-based solution corresponds to a sea level contribu-
 294 tion of 0.19 mm/yr. This is less than the one proposed by previous studies, in particular
 295 by Velicogna and Wahr (2006) (0.5 ± 0.1 mm/yr) for the same period 2002 - 2006. The
 296 most important point is that this GrIS contribution varies from year to year and thus
 297 cannot be simply represented by a constant trend. One may wonder if adjusting a trend
 298 on time series of mass variation makes physical sense for such short time spans (i.e., a
 299 few years). Instead of considering a constant rate of ice mass loss, we propose integrat-
 300 ing numerically the total ice mass variations versus time, to establish a more realistic
 301 mass balance of the melting GrIS, which remains completely time-dependent at the
 302 multi-year time scale.

303 Figure 4 shows trend maps of the GrIS estimated from the Gaussian and STL filtered
 304 solutions for two different time spans. It can be shown that the linearly adjusted trends
 305 also depend geographically upon the chosen time span. Considering a short period
 306 (2003-2007) makes small positive trends appear in the north east of Greenland, whereas

307 considering the complete time span (2003-2010) does not reveal any positive anomalies.
308 For the period 2003-2007, the northern patterns of the STL-decomposed mass
309 trend remain consistent with the ones described by Zwally et al. (2011) using ICESat
310 data.

311 4.2. Regional mass balances

312 Time series of the mass balance for different Greenland ice-field basins were computed using the geographical boundaries from Luthcke et al. (2006). They are presented on Fig. 5. If the whole GrIS exhibits a clear mass depletion over 2003-2010,
314 the situation is more contrasted at regional scale. The highest mass loss occurs in the
315 southeastern part of the continent with an average rate of -107 Gt/yr and -120 Gt/yr for
316 ICA and Gaussian solutions respectively (Fig. 3c, d, e). In general, mass depletion is
317 larger in coastal regions than inside the continent due to a huge amount of ice lost by
318 coastal glaciers along the south coast.

320 Our regional estimates remain numerically comparable to the per-basin mascons values
321 found by Luthcke et al. (2006) for the period 2003-2005, where the most significant
322 mass loss occurs in the southeastern regions of Greenland (i.e., -71 Gt/yr). Once again,
323 the difference with our estimates comes from the facts that: (i) the period of time we
324 consider is longer (e.g., non-stationarity of the signals at inter-annual time-scales), and
325 (ii) mascons solutions probably provides a smoother solution as it is based on spatial a
326 priori constraints of a few hundreds of km (Rowlands et al., 2005).

327 4.3. Comparison with simulated snow depth

328 To explain the interannual variations of the GrIS, comparisons between GRACE-
329 derived mass changes and simulated snow depth (SD) were achieved. Assuming that
330 the horizontal displacements are low at the top of the ice fields (and then accelerate
331 progressively down to the coast), and assuming that the mass balance depends only
332 upon vertical mass fluxes (i.e. snow fall), we first computed correlation maps between
333 the monthly mass anomalies from the different GRACE products and the monthly SD
334 from ERA-interim over the period 2003-2010 (Fig. 6). The results for CSR (ICA 400
335 km), CSR (GAUSS 400 km), GFZ (GAUSS 400 km), and JPL (GAUSS 400 km) are

presented on Fig. 6a, b, c, and d respectively. We chose to only present the correlation map for that ICA CSR solution as the results obtained using GFZ and JPL solutions are very similar by construction (Frappart et al., 2010). High correlation coefficients (>0.7) are obtained over northern Greenland for the ICA, and CSR and GFZ Gaussian solutions, except in the northeastern part where ICA products exhibit negative correlation with snow depth. On the contrary, for the JPL Gaussian-filtered solutions high correlations are present only on the northwestern part of Greenland. For the southern part, CSR and JPL Gaussian solutions present medium to high correlation coefficients in the west, and negative correlations in the east, whereas GFZ Gaussian solutions exhibit negative correlations except over a small region in the center where correlations are low (0.3 to 0.4).

The spatial pattern of the correlation between SD and for GRACE solutions is more consistent with other independent data sets for the ICA solutions. For these solutions, the greater correlations are found on the higher altitudes (>2000 or 2500 m) where the GrIS is nearly in balance due to small annual cycles and seasonal variations (Luthcke et al., 2006), and negative correlations are found at lower elevations where precipitation is increasingly rainfall rather than snowfall due to a rise of air temperatures (Krabill et al., 2000; Chylek et al., 2004; van den Broeke et al., 2009). In contrast, negative correlations are present mainly on the southwest coast, in the southeast, and in a small region in the northeast of Greenland. The time variations of the GrIS mass anomalies in these regions show that the mass decreases (2003-2008) or is balanced (2008-2010), even when snow depth increases (see basin 3 to 5 in Fig. 7). These regions are covered with large glaciers, such as the Jacobshavn, Kangerlugssuaq and Helheim glaciers. The latter two have experienced an acceleration of their depletion rate in the recent years: acceleration in 2002-2003, deceleration in 2006, and acceleration in 2007 (Howat et al., 2007; Rignot et al., 2008). This spatial pattern is also in good accordance with modeled mass changes and discharge of the GrIS over 2003-2008 (van den Broeke et al., 2009), the anomalies of mean annual runoff (Hanna et al., 2005), air temperatures (Hanna et al., 2008), and melting days (Mote, 2007; Tedesco et al., 2011) during recent years: high correlations between SD and ICA solutions can be related to increasing mass, negative anomalies of temperatures and melting days,

367 and vice versa. This result confirms that the mass balance of the GrIS is dominated
368 by snowfall in regions of high elevation and by glacier discharge in regions of lower
369 elevations.

370 *4.4. Comparison with Sea Surface Temperature*

371 The recently observed reduction of both extent and duration of winter sea-ice should
372 cause an increase of snowmelt and glacier discharge due to an advection of warmer
373 water from the ocean (Hanna et al., 2008). These observations coincide with a rapid
374 succession of retreats and advances of the largest outlet glaciers (Luckman et al., 2006;
375 Howat et al., 2007; Joughin et al., 2008; Moon and Joughin, 2008; Rignot et al., 2008)
376 and suggest that Sea Surface Temperature (SST) and deeper ocean temperatures may
377 have a strong impact on glacier dynamics (Hanna et al., 2009), especially when no
378 strong correlation between air temperature and glacier dynamics was observed (Mur-
379 ray et al., 2010).

380 We focus here on the largest glaciers, present in the south east of Greenland, in the
381 region where snow depth change is not correlated with the mass change observations
382 from GRACE (see Fig. 6 and basin 4 in Fig. 7). The mass variations derived from
383 GRACE in this region were compared with SST along the south east coast of Green-
384 land. Interannual trends of mass anomalies from GRACE and SST from NOAA are
385 presented on Fig. 8 for several glaciers (further abbreviated with G1-G4, see Fig. 1)
386 and locations in the Arctic Ocean (abbreviated with S1-S3). The interannual trends for
387 south east Greenland present a decrease of the mass loss starting in 2006, consistent
388 with the slow down and advance post-2005 of the glaciers' outlets, observed using mul-
389 tispectral and Synthetic Aperture Radar (SAR) images (Howat et al., 2008; Moon and
390 Joughin, 2008; Murray et al., 2010). The mass loss over the 2003-2010 time period
391 is larger for southern glaciers (-72 ± 1 mm/yr and -73 ± 2 mm/yr on average for ICA
392 and Gaussian solutions respectively at point G4) than for northern ones (-41 ± 1 mm/yr
393 and -44 ± 1 mm/yr in average for ICA and Gaussian solutions respectively at point G1).
394 These results are in good agreement with estimates of surface mass balance models,
395 which show that the largest variations of winter accumulation and runoff are located in
396 the southeastern parts of Greenland (Murray et al., 2010).

397 Comparisons of interannual mass changes and SST in the north show that an increase
 398 (respectively a decrease) of SST is followed by an acceleration (respectively a decel-
 399 eration) of the mass change, whereas a decrease (respectively an increase) of SST in
 400 the south is followed by a deceleration (respectively an acceleration) of mass change.
 401 Larger correlations are found for northern ocean points. It seems that glacier mass vari-
 402 ations are strongly influenced by seasonal northern SST changes (succession of posi-
 403 tive and negative temperature events) with a time lag of 120 to 240 days and impact
 404 the SST in the south of Greenland, close to Fram Strait. This suggests that warm-
 405 ing/cooling phases of coastal oceanic currents can cause dynamic glacier change, as a
 406 negative feedback between glaciers and the East Greenland Coastal Current (EGCC)
 407 evoked by Murray et al. (2010).

408 **5. Conclusion**

409 Our study presents a re-evaluation of the mass balance of the Greenland ice sheet
 410 using the Level-2 GRACE solutions over the period October 2002-July 2010 and using
 411 two post-processing methods to reduce noise and estimate trends. If our results corrob-
 412 orate what was found previously for shorter time spans, the most recent observations
 413 show, for the very first time since the launch of the GRACE mission, a decrease in mass
 414 loss of the GrIS for all the considered sources (UTCSR, GFZ, and JPL) and several fil-
 415 tering methods (Gaussian and Gaussian + ICA for averaging radii of 300, 400, and
 416 500 km). The methodology, based on the combination of a Gaussian filter and an ICA
 417 approaches, reduces contamination by the spurious north-south stripes, and provides
 418 mass change rates more consistent with each other than classical filtering techniques.
 419 The decrease of GrIS ice mass is clearly not constant in time, but contains interannual
 420 variability suggesting that the ice mass melting is a transitional complex phenomenon.
 421 In terms of methodology, we therefore remain very critical about simply fitting a sim-
 422 ple straight line to a set of points that contains different levels of noise. There are
 423 important implications in understanding the causes of an observed continuous sea level
 424 change. If the mass contribution of the ice sheets melting to sea level is not constant
 425 at interannual time scales, and less than previously expected, this means a larger steric

(i.e., thermal) contribution in response of global warming. We also attempted to investigate these long-term variations by studying correlations with climate variables. The GrIS mass balance is governed inside the continent by the snow accumulation and by the dynamics of glaciers in the coastal regions. The increase in snowfall since winter 2008-2009 in the south and since 2009-2010 in the north, and also a deceleration of the glacier discharge since 2008 reported in several studies using independent data, are responsible for the decrease in mass loss of Greenland. The mass changes of the glaciers present in the southwest of Greenland were found to be anticorrelated with the SST of the Denmark strait. This confirms the assumption of Murray et al. (2010) that glacier dynamics of southeast Greenland are controlled by the oceanic currents. Unfortunately, the spatial resolution of the GRACE data (~ 333 km for harmonic coefficients expanded up to degree 60) is insufficient to resolve fjord scales.

570 on-sea (S) points used in this study for signals comparison (b).

571

572 Figure 2: Time series of water-equivalent mass of GrIS derived from GRACE solutions of dif-
573 ferent providers (CSR - blue; GFZ - red; JPL - green), and using different types of filtering
574 (Gaussian with a radius of 400 km + ICA - plain lines; Gaussian with a radius of 400 km - dot-
575 ted lines) (top), and the corresponding interannual time series after STL decomposition (bottom).

576

577 Figure 3: Histograms of trend estimates using different providers (CSR, GFZ, JPL) and vari-
578 ous time spans, considering a simple linear adjustment after no STL decomposition (a), and after
579 STL decomposition (b). Error bars are from analysis of normal equation for a posterior standard
580 deviation on the adjusted linear slope from observation uncertainties. These latter uncertainties
581 were obtained from formal errors on the monthly Stokes coefficients.

582

583 Figure 4: Geographical maps of mass trends over the GrIS using GFZ solutions post-processed
584 using Gaussian filtering with a radius of 400 km + ICA, and corrected from PGR using the Paul-
585 son's tuning of the model ICE-5G, over the period 02/2003-12/2007 with no STL decomposition
586 (a), and with STL decomposition (b), and over the period 02/2003-07/2010 with no STL decom-
587 position (c) and with STL decomposition (d).

588

589 Figure 5: Interannual mass change time series obtained after STL decomposition from CSR,
590 GFZ, and JPL GRACE solutions for the six mean ice fields (see Fig. 1), and considering differ-
591 ent types of post-processing (low-pass Gaussian filtering with a radius of 400 km + ICA - plain
592 lines; Gaussian filtering with a radius of 400 km - dotted lines).

593

594 Figure 6: Correlation GrIS maps between interannual STL-decomposed time series of GRACE-
595 based mass variations and snow depth changes from ECMWF reanalysis: a) CSR (ICA 400 km),
596 b) CSR (Gaussian 400 km), c) GFZ (Gaussian 400 km), d) JPL (Gaussian 400 km).

597

598 Figure 7: Interannual trends after STL decomposition of the GRACE-based mass time series
599 (CSR, GFZ, JPL) and snow depth from ECMWF reanalysis and considering different types of

600 post-processing (low-pass Gaussian filtering with a radius of 400 km + ICA - plain lines; Gaus-
601 sian filtering with a radius of 400 km - dotted lines) for the six ice fields.

602

603 Figure 8: Local comparisons between time series of GRACE-based GrIS mass change and Sea
604 Surface Temperature (SST) from NOAA for different couple of points (see Fig. 1 for the loca-
605 tions of these points).
