Abstract: We investigate the principle and performance of fractionally-spaced adaptive single-carrier frequency-domain equalization for 16-QAM 100G coherent optical communications. The proposed solution is shown to be robust against linear impairments.

1. Introduction

The use of multilevel modulation formats combined with digital signal processing enables spectrally-efficient long-haul coherent optical transmission. Linear time-domain equalization (TDE) has received much attention as a means for compensating chromatic dispersion (CD) as well as Polarization Mode Dispersion (PMD). In particular, adaptive algorithms based on the Least Mean Squares (LMS) or the Constant Modulus (CM) criteria have been extensively studied. However, TDE often requires filters with a large number of taps as the equalizer length increases linearly with the amount of CD to compensate [1]. In order to keep a low-complexity receiver, a frequency-domain implementation of the fixed CD compensating filter has been proposed [2].

Another frequency-domain approach is Single-Carrier Frequency-Domain Equalization (SC-FDE), which allows to jointly cope with CD and PMD at reduced complexity. SC-FDE for coherent optical communications has been studied in [3,4]. In [3,4], a symbol-spaced FDE is used. Known pilot symbols are periodically transmitted in order to estimate the channel and compute the FDE coefficients.

In this paper we propose an adaptive implementation of a fractionally-spaced SC-FDE. Fractionally-spaced equalizers (FSE) are more robust to a sampling phase error than symbol-spaced equalizers. After an initial training period, our algorithm tracks the channel variations in a decision-directed manner. Section 2 presents the structure and principle of the adaptive SC-FDE. Section 3 discusses performance of the system.

2. The adaptive SC-FDE system

SC-FDE is a frame-based single-carrier transmission technique that relies on a particular frame format in order to allow for efficient block equalization in the frequency domain at the receiver [5]. Specifically, data is segmented into blocks of N symbols. As for OFDM, a cyclic prefix (CP) is added to the beginning of each block by reproducing the last N_{cp} symbols of the block before transmission. The aim of the CP is twofold: removing interblock interference and turning the channel linear convolution into a circular one.

The single-input single-output (SISO) equalizer architecture is shown on Fig. 1b. For a $T/2$ -spaced equalizer, the received signal is sampled at twice the symbol rate. After CP removal and serial-to-parallel conversion, the samples are processed blockwise. A $2N$ -point FFT converts the received block into the frequency domain. The $2N$ frequency-domain samples Y_l are then weighted by the $2N$ FDE coefficients W_l . In principle, a $2N$ -point IFFT should then be applied to return to the time domain, and the equalized signal should be downsampled at the symbol rate before entering the decision circuitry. It can be shown that downsampling can be advantageously realized directly in the frequency domain by adding the frequency components l and $l + N$ for $0 \leq l \leq N - 1$. By doing so, the IFFT length is reduced to N -point only. Then, the decided symbols $\hat{d}_l$ are subtracted to the equalized signal z_l to form the error signal $e_l = z_l - \hat{d}_l$ whose discrete Fourier transform E_l will be used to update the FDE coefficients.

For Polarization Division Multiplexed (PDM) transmission, four SISO FDEs are required to jointly cope with CD and polarization dependent effects, as illustrated in Fig. 1a.

Adaptation of the FDE weights is based on a block LMS criterion in order to converge towards the equalizer that minimizes the mean square error over the block. As for LMS-based TDE, a preamble of known data blocks is required at the beginning of the transmission to train the FDE in a data-aided manner. After the initial training period, the FDE weights are continuously adjusted in a decision-directed manner.

3. Simulation results

In order to evaluate the performance of the proposed system, we simulate 112Gbit/s PDM-16QAM transmission (14Gbaud per polarization) over uncompensated ITU-T G.652 fiber with dispersion parameter 17ps/nm/km. Transmit and receive electrical filters are square-root raised-cosine filters with roll-off factor 0.3, and sampling at twice the symbol rate is performed after the receive filters. The structure of Fig. 1a is used for jointly equalizing CD and PMD. Perfect carrier synchronization is assumed, and no phase noise is considered.

Fig. 2a shows tolerance of our algorithm to CD for $N_{cp} = 110$ symbols and $N = 1024$ symbols (10.7% overhead), in a transmission with a fixed DGD of 90ps. The symbol rate has been increased to 15.5Gbaud to take the overhead into account. With these parameters, the equalizer is able to compensate up to 47000ps/nm of CD, but is severely affected by interblock interference for higher values of CD (insufficient CP length). Finally, the dynamical behavior of the adaptive SC-FDE is evaluated using an endless polarization rotation, as suggested in [1]. Fig. 2b shows that the transmission suffers from an OSNR penalty of 1dB for an angular frequency of 2×10^4 rad/s.

4. Conclusion

We investigated a single-carrier transmission system using an adaptive frequency-domain equalizer for compensation of linear optical impairments.
