The college-to-work transition during the 1990s: evidence from Sweden

M. Gartell

Institute for Futures studies, Box 591, 101 31 Stockholm, Sweden

*From 19 October 2009: The public Employment Service, Department of Analysis, 113
99 Stockholm, Sweden*

E-mail: marie.gartell@arbetsformedlingen.se

This paper analyses the time it takes for Swedish college graduates to start a full time job that lasts for six months or more. The focus is on the transition over time during the period 1991 to 1999. This period covers both upturns and downturns of the business cycle, providing a unique opportunity to consider the importance of the timing of graduation. The results show that the risk of unemployment and the unemployment duration have varied considerably with the business cycle, both within and between cohorts. For example, field of education is of more importance for the outcomes during recessions. Further, the relative risk of unemployment has decreased over time for individuals with the highest degree of education whereas the unemployment duration has increased, indicating that the selection into unemployment for this group may have changed over time. This is interesting, not least in the light of the sharp expansion of the higher educational system during the studied period.

I. Introduction

It is of great importance to study the transition from college to work. The time it takes to gain steady employment following graduation has effects on the returns to education, and accordingly it may have long-term effects on skill accumulation and incomes.¹ Consequently, it will affect the tax income for the government. Hence, the issue addressed in this paper is important both from an individual perspective and from an economic growth perspective. Moreover, to study the transition from college to work has become increasingly relevant during the last decades given the great expansion of the higher educational system, not least in Sweden.

There are very few previous studies on unemployment duration at graduation. Betts *et al.* (2000) estimate the time it takes for Canadian college graduates to start a full time job that lasts for six months or more. The speed of transition both within and between cohorts is investigated. A related literature examines the long-term effect on earnings of graduating in a recession.²

Previous studies on Swedish data are mainly focusing on re-employment due to different unemployment benefit systems.³ No previous study on Swedish data emphasizes only highly educated, hence, nor do they explore the transition to work for

¹ Gartell (2009) shows that Swedish college graduates who get unemployed at graduation have considerably lower future earnings as compared to college graduates who do not experience any unemployment at graduation. Holmlund *et al.* (2006) show that working experience subsequent to graduation is important for individual incomes at 35 years of age. Nordström Skans (2004), studying high school graduates, shows that unemployment during the first year after high school graduation has serious long term effects on future incomes.

10 During the 1990s the business cycle fluctuations were significant, which is likely to
11
12 have affected the transition to work during the period.⁴ Business cycle variations are
13
14 likely to be related to individual opportunities to get a job at graduation as well as to the
15
16 individual risk of exiting unemployment (if unemployed at graduation), e.g. there are
17
18 fewer job offers in recessions. Moreover, human capital may depreciate with the
19
20 unemployment duration, further reducing the possibility of employment.⁵ In contrast,
21
22 unemployment during economic upturns may send a relatively more negative signal to
23
24 employers, or individuals getting unemployed during good times are a more negatively
25
26 selected sample. These factors may increase the unemployment duration in good times
27
28 as compared to bad.

at different points in the business cycle? Second, given the same graduation year, does the transition to work differ between graduates?

Examining the college-to-work transition, outcomes across the business cycle may be correlated with individual characteristics, observed or/and unobserved. One might expect the distribution of individual observed and unobserved characteristics to be similar across cohorts of graduates, i.e. across the business cycle. However, the timing of graduation might be endogenous. Although the main purpose of this paper is to describe the college-to-work transition rather than to establish a causal relationship, parental background and grade point average from high school are used to control for unobserved ability. This is a common approach in the educational literature. Furthermore, a term for unobserved heterogeneity is included, and the risk of unemployment and the unemployment duration is estimated simultaneously.

The paper proceeds as follows. The next section provides some background. In section 3 the theoretical framework is presented and in section 4 data used is described. Empirical considerations are discussed in section 5. Section 6 presents the results of the analysis. Section 7 concludes.

II. Background

During the 1990s Sweden experienced the deepest recession since the Great Depression in the 1930s. Hence, the studied period covers extreme variations in the business cycle and a unique opportunity to study the importance of the business cycle for the transition

1
2
3 to work. Fig. 1 shows the unemployment rates during the period. The fluctuations have
4
5 been significant during the period, but not as pronounced for highly educated as
6
7 compared to other groups. Fig. 2 displays the net employment rates, i.e. the difference
8
9 between jobs created and jobs destroyed, and shows that there is also variation *within*
10
11 the group of highly educated. For example, to have a higher level of degree was more
12
13 favourable in terms of net employment rates during the second half of the 1990s,
14
15 whereas it was more favourable to have a shorter university education during the first
16
17 half.

29
30

31 Furthermore, during the 1990s the share of college students in Sweden increased
32
33 dramatically, at the same time as the number of graduates was large. The number of
34
35 new students increased with 50% during the 1990s, and the number of individuals with
36
37 a university degree increased with 25%. Moreover, the share of the population with a
38
39 long university education increased relatively more as compared to individuals with a
40
41 shorter university education.⁶ The share of a yearly cohort with a university degree has
42
43 been fairly constant for cohorts born before 1965, but has increased considerably for
44
45 cohorts born after 1965.⁷
46
47
48
49
50

51
52 In addition, the size of the cohorts has varied (see Fig. 3). The cohort one belongs to
53
54 will matter for the number of graduates, the educational level of the population and the

59
60

size of the cohort exiting the labour force. This could possibly affect both the risk of unemployment and the unemployment duration.⁸

<Fig. 3 about here>

III. Theoretical framework

Search theory considers unemployed workers who maximize their utility. They do so by choosing a set of acceptable wage offers at each point in time. This set is defined by the reservation wage; the unemployed individuals will accept all offers above or equal to their reservation wage and reject offers less than their reservation wage.⁹ The reservation wage chosen by the individual will affect the probability of accepting a job offer, given that he/she has not previously done so.

The probability of acceptance is dependent on the individual reservation wage, the probability of receiving a job offer and individual search activity. The higher the reservation wage the lower the risk that an individual accepts a job offer and, consequently, leaves unemployment. The reservation wage may be dependent on time spent in unemployment, i.e. the duration. Theoretically, it will decrease with the duration. Empirically, this means that the probability of leaving unemployment will increase. On the other hand, the estimated probability of accepting a job offer is an average of the probabilities of the surviving individuals at that time, this may be a

⁷ National Agency for Higher Education (2001).
⁸ See e.g. Nordström Skans (2005) who shows that a large youth cohort has a positive effect on the local labour market in terms of unemployment rates for young workers.
⁹ See Lancaster (1979) for a more detailed model, and Jans (2002) for a simplification of the same model.

selected sample, and the probability could, as a result, fall with the duration.

The reservation wage is, however, hard to observe. The most natural way to empirically specify a search model is by using duration data and estimate the variation in the probability of leaving unemployment (as a function of time).

According to search theory, higher educated individuals have higher reservation wage.¹⁰ This means that more highly educated individuals may have trouble finding acceptable jobs. In contrast, it is assumed that highly educated individuals will have more job opportunities. Theoretically, an individual can accept a job offer below his/her educational level, but will not receive job offers above his/her educational level. The effect of education is not clear-cut; there is a positive effect due to number of job offers but a negative due to a higher reservation wage.

For new graduates other factors such as e.g. to find a job that corresponds to one's education could be of great significance. Moreover, studying the transition to work across time, the reservation wage may vary as a result of that e.g. *i*) the supply of highly educated vary, *ii*) the demand for highly educated vary, and *iii*) the business cycle fluctuations - there is e.g. a higher risk associated with turning down a job offer in a recession due to fewer job offers. These factors could both negatively and positively relate the educational level to the risk of unemployment and the unemployment duration. Van der Klaauw *et al.* (2005) show that as graduation approaches, students increase their job search effort and lower their reservation wage. Furthermore, they

show that the unemployment rate at graduation is important; mean wage offers are significantly lower in periods when the unemployment rate is high. They also find substantial returns to work experience, which suggests that individuals are relatively less selective in choosing their first job i.e. reservation wages will be lower.

IV. Data

Data are provided by IFAU and consist of a number of administrative data sets from Statistics Sweden and the Public Employment office, covering the whole population of 16-64 years old in Sweden. In this paper all graduates from Stockholm and Uppsala University during 1991 to 1999 are used. Unemployment immediately (within a year) upon graduation is considered. The unemployment spell is studied up to the point where individuals find a full-time job, lasting for six months or more. Durations are (right) censored after two years. Hence, individuals are followed for at most three years subsequent graduation.

The individual-level records in the events database (Händel) are used to study the unemployment duration. Registration at a public employment office is compulsory for anyone receiving unemployment benefits. For a student to be entitled to benefits he/she must have been registered as unemployed for 90 days.¹¹ This should provide an incentive to register as soon as one realizes the risk of unemployment. A benefit period consists of 300 benefit days corresponding to 15 months (if on full time). This period can be prolonged at most one time with a maximum of 300 benefit days.

¹⁰ Kettunen (1994, 1997).

Studying the risk of unemployment, all registrations at the public employment office are considered. Whereas examining the unemployment duration only individuals registered as full-time unemployed and able to accept employment immediately will be included. Data further contains information regarding destination after exiting unemployment. The reason for exiting unemployment is in the great majority of cases that individuals received employment; regular, temporary or reemployment at previous employer. A rather big group is the “contact broken” category (about 20%); these individuals will be considered as having found employment. Further, some individuals return to regular education, i.e., education outside the labour market programs. More than 80% of the individuals are included in the employment categories or the contact broken category. About 10% are found in the education category, and less than 10% leave for other reasons. The reason for leaving unemployment does not vary considerably across graduation years.¹²

The duration of unemployment, starting within a year following graduation, will be considered. The unemployment spell may well start before graduation; 94% of the unemployment spells however start the same semester as registered graduation, or later. All unemployment spells ending before graduation are excluded. If the gap between two subsequent unemployment periods is less than 6 month, I will consider it as ONE period.¹³ The reason is to avoid considering very temporary jobs as employment. About

¹¹ The Swedish Unemployment Insurance Board (IAF), Fakta-PM 3:2005.

¹² However, there are some changes in the coding of data over time. There are some previous studies using models for competing risks at reemployment; these studies show that different transitions are governed by different mechanisms. See e.g. Edin (1989) and Thoursie (1998).

¹³ See e.g. Betts *et al.*, where 6 months is used to define a stable employment.

14% have a gap between two subsequent periods that are greater than zero, and about 5% have a gap that is greater than 20 days.

Individuals will be censored if their unemployment spell exceeds 2 years (about 1%). Also, they will be censored due to “other” reasons if disappearing out of the data for any other (unknown) reason. Individuals not found in any other register the year of graduation will be dropped. Hence, information about age, gender and so forth is missing (less than 2% of the population); these are likely to be exchange students or non-Swedish citizens.

The spring and fall semesters range from January 20 to August 30 and September 1 to January 19 respectively. The semester of graduation is known, but not the exact date. No time varying covariates are used because the unemployment spells, on average, are too short to explore yearly variations. The duration in the 50th percentile is less than 6 months (see Appendix Table A1 and Fig. A1).¹⁴

If an individual has several registered graduation years, the latest is used. If there are several degrees, at different levels, the same year, then the highest-level degree is used. Further, if an individual have several degrees within the same field of education, an indicator is created to specify that there were actually several degrees within the same field and only one degree is kept. Finally, if there are several degrees within different fields, one is randomly chosen and a variable is created to indicate whether the

¹⁴ This may be compared to the median duration for Canadian college students which is 15 month, see Betts *et al.* (2000).

individual have several degrees (about 0,003% of the population).

Fixed variables used, i.e. variables observed in the beginning or before the unemployment spell, are age (and age squared), sex, country of birth, educational background such as length and field of education, year and semester of graduation, children¹⁵, parental education. Moreover, an indicator for the type of unemployment benefit the individual is entitled to, year of first registration in higher education and grade point average from high school are included in some specifications (see Appendix Table A2 for details).

The total number of graduates in the period 1991 to 1999, from Uppsala and Stockholm University, were 39 376. After the data processing there are 38 013 individuals, out of which 14 644 experienced unemployment at graduation. Out of these 14 644, 7 288 are registered as unemployed and able to accept employment immediately. Only these 7 288 individuals are used in the duration analysis.¹⁶ For more detailed descriptive statistics see Appendix Table A3.

<Table 1 about here>

¹⁵ There is information about number of children in different age groups in the household but no information about whom the children belong to. Consequently, for students living at home, it is possible that they will be registered as having e.g. children older than 18, but those children are in fact themselves (or possibly siblings). Therefore, children above the age 18 will be excluded from the analysis. A variable for "had a child during the first year after graduation" will be included as a sensitivity analysis.

¹⁶ The other unemployed individuals are not considered to be able to accept a job offer immediately for a number of different reasons. In previous studies on unemployment duration only individuals able to accept a job immediately are considered; only these individuals may end their unemployment immediately upon receiving a job offer.

Table 1 shows that the number of graduates has increased during the 1990s and that the share of students experiencing unemployment at graduation has varied with the business cycle. Further, the share getting unemployed at the end of the period are smaller as compared to the beginning. This pattern corresponds to some evidence presented in Gartell *et al.* (2010). Gartell *et al.* find quite strong evidence that the increased share of highly educated individuals, at least partly, has been driven by increased demand for this group. Granqvist and Regnér (2007) present results showing that the income premium of higher education have increased during the same period.

V. Empirical considerations

The risk of unemployment at graduation is estimated using a probit model. To study the unemployment duration, a proportional piecewise linear hazard model will be estimated using aML software.¹⁷ This model allows the hazard to be different over each time interval. Moreover, it is possible to introduce a term for unobserved heterogeneity, i.e. the duration dependence can be estimated conditioning on observed covariates and unobserved heterogeneity. Assumptions made are that the heterogeneity is independent of the observed covariates, starting times and censoring times. Further, it is assumed that the heterogeneity has a known distribution and enters the hazard function multiplicatively. These assumptions can not be tested; if the assumptions are not fulfilled the unobserved heterogeneity term can introduce errors into the model. However, one may argue for the likelihood of those conditions being fulfilled or not. The unobserved heterogeneity term can though be used to test the stability of the results.

If the results are stable for the inclusion, there is less reason to worry about omitted variable bias.

To examine the importance of the timing of graduation, dummy variables for each graduation year are included and the model is estimated separately for different graduation years. As already mentioned, there may be other factors linked to the year of graduation that may influence the result. First, there has been a great expansion of the higher educational system. Second, there have been fluctuations in cohort sizes and in the net employment rates for highly educated during the studied period. To try and identify or disentangle these different effects are not within this study.¹⁸

Only registered unemployment spells are considered. Considering only registered unemployment will on one hand avoid including individuals that e.g. did not have an employment but continue to study, or work abroad. On the other hand, individuals might be unemployed without being registered at the public employment office. However, the incentives to register are rather high.¹⁹

In this paper only graduates are used. Out of all individuals with a university education corresponding to three years or more, about 80% graduate.²⁰ In general, students may be divided into two groups; *program students* and *course students*. Program students enter

¹⁷ See Bossfeld and Rohwer (2002) and Lillard and Panis (2003) for description of the model.

¹⁸ See e.g. Andersson (2000) for a discussion of how to identify age, period and cohort effects respectively.

¹⁹ More than 90% of individuals reporting unemployment were registered as unemployed at a public employment office. Moreover, the share of individuals reporting unemployment who have been in contact with a public unemployment office has been rather stable during 1992-1997. See Statistics Sweden (1993) and the Swedish National Labour Market Board (1998).

a program usually lasting for 3 years or more, whereas course students register at separate courses typically lasting for at most one semester. Separate courses may be combined to correspond to a program. However, 7 years from their first registration only 10% of the course students have a degree and another 10% have achieved three years full time study without graduating. Eleven years from their first registration, about 70% of the program students have graduated. The main reason for using only graduates is that the time of graduation is registered. However, the registered date of graduation may not necessarily correspond to the actual date of graduation. Completing their studies, individuals do not routinely graduate but are required to hand in an application to be registered as graduates.

Only graduates from Stockholm and Uppsala University are studied, the reason is to reduce potential problems of differences between universities and local labour markets. Moreover, the focus is on the importance of the timing of graduation not on regional differences. Students from Stockholm and Uppsala University basically graduated into the same labour market. For graduates in 1991, about 80% of the graduates from Stockholm University worked within the county of Stockholm or Uppsala one, five and ten years following graduation. For graduates from Uppsala University about 55% worked within the region. Individuals working outside the region are quite evenly distributed among other counties.²¹ The Stockholm region labour market differs in some aspects compared to other regions. Stockholm is the capital of Sweden and by far the largest city, and unemployment rates are generally lower as compared to other parts of

²⁰ National Agency for Higher Education (2005).

²¹ See e.g. Gartell and Regnér (2002, 2005).

the country.

The selection of individuals *into* university studies may vary with the business cycle at the time for admission. Furthermore, the increasing supply of graduates over time may suggest less selection into university studies. A single administrative authority on the national level handles the admission; number of applicants often outnumbers available slots.²² Grade point average from high school is generally used in the admission procedure.

The selection *out of* university studies may also vary with the business cycle. Individuals may e.g. postpone graduation in recessions, potentially making graduates in recessions a relatively selected sample. Consequently, cohorts of graduates can differ in their ability, affecting the probability of unemployment and the risk of exiting unemployment. The option to postpone graduation is however somewhat limited by the possibility of financing. Moreover, the graduation frequency may fluctuate with the business cycle; during good times it might be more likely to receive a job offer without an actual degree. Variables commonly used to control for ability are grades from high school and parental education. Further, the quality of education is possibly affected by the expansion of the higher educational system.

In Appendix, Table A3, descriptive statistics for the different graduation years are presented. The year of first registration at a university will be included as a control

variable. This should, in combination with information about graduation year, be a good estimate of circumstances at admission as well as the time spent in education. Moreover, the level of education and grade point average from high school are included in the analysis.

VI. Results

Both the risk of unemployment and the unemployment duration across the 1990s are estimated. The risk of unemployment at graduation is estimated using a probit model.²³ The unemployment duration is estimated using a piece-wise linear proportional hazard model. Estimating the unemployment duration, only individuals registered as unemployed and able to accept a job offer *immediately* are included.

Transition to work between cohorts

In this section, only year dummies are included to estimate the effect of graduation year on the probability of unemployment and the relative risk of leaving unemployment. Fig. 4 shows that the probability of unemployment varies considerably across graduation years; the probability of unemployment for graduates in 1993 is 2.5% higher than for graduates in 1995, the probability for graduates in 1999 is 15.5% lower as compared to the reference year (results are also presented in Table A4 in Appendix). It is interesting to note that the probability of unemployment is lower for individuals graduating towards the end of the 1990's, considering the increasing supply of highly educated during the decade.

Fig. 5 shows the relative risk of exiting unemployment, if unemployed at graduation, across graduation years (results are also presented in Table A4 in Appendix). The result corresponds to the result for the probit model; the same years that increase the risk of unemployment will shift the baseline down, i.e. reduce the risk of exiting unemployment. And years with a relative low risk of unemployment will shift it up.

<Fig. 4 about here>

<Fig. 5 about here>

Further, Fig. 6 shows that there is a nonlinear relationship between time and the risk of exiting unemployment. The time intervals used are 0-3 months, 3-6 months, 6-12 months, 12-18 months and finally 18-24 months. There is a peak at 3 months, most likely due to the fact that an individual has to be registered as unemployed for three months before receiving any unemployment benefits. Once benefits are received, the risk of exiting unemployment decreases up to 6 months and then change direction and increases until 18 months and thereafter flattens. At 18 months the benefit period expires, if no extension is accepted.²⁴

<Fig. 6 about here>

²³ Weights were applied, but did not influence the results. Hence; nonweighted estimates are presented.

²⁴ The shape of the base line is very similar across individuals graduating during the spring and fall semesters respectively. The results are not presented but may be obtained from the author upon request.

The effect of observable covariates. Different covariates are included to investigate whether any of the variation across graduation years may be explained by observable factors. For neither the risk of unemployment nor the unemployment duration, are the coefficients of graduation year much affected by the inclusion of various covariates, suggesting little selection on observables across time (see Appendix Table A4). Note that this result also holds including grade point average from high school and parental educational level; traditionally considered to be highly correlated with individual ability.

Further, the inclusion of control variables reveals that the risk of unemployment is lower if graduating during the spring as compared to the fall, the probability of unemployment increases with age and is reduced if having children between the ages 0-3 years and 11-15 years (see Appendix Table A4).²⁵ Examining the educational characteristics included show that to have a degree within sciences, technology or healthcare reduces the probability of unemployment compared to having a degree within social science, whereas a degree within the fields arts/humanities and service/tourism increases the probability. More unexpectedly, the higher the level of education the higher the relative probability of unemployment at graduation.

Moreover, the year the individual first registered at a university was included. The year of first registration had some significant effect but did not affect the coefficients of the graduation years much (78 individuals lack this information), indicating that the

²⁵ Also, to have a child during the first year after graduation has a significant and negative effect. However, it does not affect the other estimates. I chose to leave this variable out of the basic specification since the exact timing of childbirth is unknown.

1
2
3 circumstances at admission are of little importance for the estimated effects.²⁶
4
5
6
7

8 Turning to the risk of exiting unemployment, if unemployed at graduation, the inclusion
9
10 of different control variables reveal that to graduate during spring reduces the risk of
11
12 exiting unemployment, the risk of exiting unemployment is reduced with age, to be born
13
14 in Sweden increases the risk and to have children between 7-10 years reduce it.²⁷ To
15
16 include information about the parental background did not have any significant
17
18 effects.²⁸ These results are analogous to the results for the probability of unemployment
19
20 at graduation; with the exception that the probit model showed that to graduate during
21
22 spring reduced the risk of getting unemployed. Hence, to graduate during spring means
23
24 a lower risk of unemployment but once unemployed the unemployment spell is longer.
25
26 This might be explained by the fact that it is easier to find, at least a temporary job,
27
28 during the summer.²⁹ A temporary job may work as a stepping stone for a more stable
29
30 employment avoiding unemployment during the first year subsequent graduation.
31
32 However, once unemployed, the probability of exiting unemployment i.e. to receive a
33
34 job offer may be relatively low due to e.g. vacations.
35
36
37
38
39
40
41
42

43 Further, examining the educational characteristics reveals that to have a degree within
44
45 teaching, technology or health care increases the risk of exiting unemployment
46
47 relatively to social science. This corresponds to the results from the probit model, i.e.
48
49
50

51
52 ²⁶ The results are not presented but may be obtained from the author upon request. The year of first
53 registration was included both as a continuous variable and as dummy variables.

54 ²⁷ A variable for “had a child during the first year” was included; the results were robust for this inclusion.

55 ²⁸ Grades from high school were included for a sub sample of 4254 individuals. The estimated risk of
56 exiting unemployment is 1.10, i.e., higher grades mean a higher risk of exiting unemployment. The other
57 estimates are stable for the inclusion, however, the baseline between 18 and 24 months changes to positive
58 but are not significant.

the same fields of education that are associated with a relative high risk of unemployment at graduation are also associated with relatively long unemployment spells. A higher level of education increases the risk of exiting unemployment i.e. of receiving a job. This is in contrast to the results in the probit model, where the estimated risk of getting unemployed was greater the higher the level of education. One explanation may be that more highly educated individuals are possibly more selective in what jobs to accept, i.e. their reservation wage is higher. An alternative explanation may be that less employable individuals stay longer in education because they have a hard time to obtain employment. And once unemployed, their reservation wage decreases and the risk of accepting a job offer increases. For individuals with a lower educational level the relationship is reversed. The risk of unemployment is lower but once unemployed it is a more long-lasting problem.³⁰

Transition to work within cohorts

In this section, the model is estimated separately for graduates in different years (see Appendix Table A5 and A6).³¹ The reason is to examine the importance of different covariates at different times of the business cycle.

First, the results for the probit model are discussed (see Appendix Table A5). The estimated effects of the covariates do differ between years of graduation though in most

²⁹ A majority of students that graduate during spring and who experience unemployment have an unemployment period that begins before or during the summer.
³⁰ Also type of unemployment benefit was included; the results are stable for this inclusion. The results may be obtained from the author upon request.
³¹ Some estimations have been done on a sub-sample including only Swedish born individuals, and the results are robust. The results can be obtained from the author upon request.

cases the estimates have the same direction over time. One exception is the estimates for humanities that vary between a significant estimate of -10% and a significant and positive estimate of 13%. There is some evidence that the estimated effects of field of education in general are larger during periods of relatively high aggregate unemployment rates. The importance of the level of education also differs across years. The effect of having a higher degree has a relative negative trend over time, i.e. the relative risk of unemployment decreases.³²

Estimating the hazard model, the graduation years will be grouped as follows; 1991-1993, 1992-1994, 1993-1995, 1994-1996, 1995-1997, 1996-1998 and 1997-1999 to obtain more observations (see Appendix Table A6). There is some variation in the estimated effects of the covariates across graduation years, though for the most part the estimates have the same sign. The effects of field of education vary considerably across years. The effect of humanities changes sign between years, i.e. it varies between 1.19 and 0.86. Again there is some indication that field of education is more important during times considered as bad. Hence, estimated effects are relatively large during recessions. The only apparent trend found is the decreasing trend of exiting unemployment for individuals with the highest level of education. Remember, during the studied period there has been a sharp increase of the number of highly educated, and even more so the higher the level of education. However, as suggested in the probit model, the risk of unemployment did decrease across time. The decreasing risk of exiting unemployment may possibly, therefore, be explained by that the selection into

³² Moreover, average grades from high school were included for a sub sample of 21 959 individuals. The estimate is significant and negative (-0.09), i.e. higher grades means lower risk of unemployment. However, to include grades did not have much effect on the other estimates.

unemployment for this group may have changed across time. The level of the baseline for the different samples is not really comparable; though the shape is similar.

Sensitivity analyses

To test for exit selection and the robustness of the results a term for unobserved heterogeneity is included in the model. Further, potential entry selection is considered estimating the probit and hazard model simultaneously.

Exit and Entry selection. To test for exit selection, i.e. if individuals who receive a job are a selected sample compared to individuals still unemployed at time t , a term for unobserved heterogeneity is included in the hazard model. Moreover, this will indicate whether the results are robust for omitted variable bias.

The model is estimated including all control variables from the previous section and a term for unobserved heterogeneity (UHG), assuming normal distribution of the UHG component (see Appendix Table A7 and Fig. 7). As is shown in Fig. 7, the duration dependence gets more positive including the UHG component.

<Fig. 7 about here>

This result is expected; the UHG component controls for that the sample is getting more selected with the unemployment duration, i.e. less employable individuals are still unemployed after some time t . Further, this is in line with search theory discussed in

section 3. Hence, there is a positively selected sample of individuals exiting unemployment. The term for unobserved heterogeneity is significant and positive. Moreover, to include a term for unobserved heterogeneity shows that the direction and significant levels of the estimates are stable. However, most estimates get larger.

It is possible that the same factors that affect the probability of unemployment will influence the unemployment duration, i.e. the outcome in the probit model may affect the outcome in the hazard model. By estimating the two models simultaneously it is possible to examine the role of entry selection into unemployment for the estimated effects in the duration model (see Appendix Table A7).³³ In the probit model, graduation years are grouped together as 1991-1993, 1994-1996 and 1997-1999. The reason is to get the model to converge. Control variables for observable characteristics are included in the models, as well as components for unobserved heterogeneity (omitted variables). Further a new term, *Rho*, is included. *Rho* measures the correlation between the two UHG components.

The UHG component is significant also in the probit model (σ^2), but the inclusion does not change the significance or the direction of the estimates. However, the estimated effects are now much stronger, the size of the estimates about doubles for most of the estimates. Further, the result suggests that there is no significant correlation between the UHG in the two models, implying that it is not the same unobserved characteristics influencing the risk of unemployment and the unemployment duration.

³³ In this case only the individuals included in the hazard are included in the probit model. The result for the probit model using this sample is presented in Appendix Table A10.

Moreover, the results for the hazard model are stable indicating there is no obvious entry selection. These results imply that there seems to be no systematic differences in the unobserved characteristics in the selection into unemployment that will influence the unemployment duration, suggesting there is no selection due to the risk of unemployment that will bias the results in the hazard model; the estimates for graduation years are robust.

VII. Conclusions

The results in this paper show that the risk of getting unemployed at graduation and the unemployment duration vary considerably both within and across graduation years. The variation across years can not be explained by observable covariates. Consequently, there is no evidence of selection *into* or *out of* university studies across years.

Theoretically, there are many explanations for variation across time and over the business cycle. First, the demand for highly educated is likely to be of importance. Previous studies suggests that the demand for highly educated varies with the business cycle and has increased across time. An increased demand means more *job offers*. Second, the *reservation wage* may or may not adjust properly to variations over time. Third, *search activity* is also likely to affect both the risk of unemployment and the unemployment duration.

The estimated effect of different covariates varies across time. There is some variation in field of education consistent with the business cycle fluctuations; field of education

1
2
3 matters more for the risk of unemployment and the unemployment duration during
4
5 recessions. In general, there are no trends over time. The one exception is the relative
6
7 decreasing trend in the risk of unemployment and the risk of exiting unemployment
8
9 across time for individuals with the highest level degree. This indicates that the
10
11 increased supply of more highly educated individuals has not posed a problem of
12
13 finding a job, but for those who don't the unemployment is a more long lasting problem.
