Power Laws and Comparative Advantage¹

Jeroen Hinloopen² and Charles van Marrewijk³

FEBRUARY, 2009, REVISED JUNE, 2010

ABSTRACT:

Using a comprehensive international trade data set we document empirical power laws for the distribution of the interaction between countries as measured by revealed comparative advantage. Using the recently developed estimator by Gabaix and Ibragimov (forthcoming) we find strong evidence in favor of power laws along the time, country, and sector dimension for three different levels of data aggregation. This finding is not predicted by any of the existing trade theories. The estimated power law exponents characterizing the distribution of revealed comparative advantage are stable over time but differ between countries and sectors. These differences are related empirically to country and sector characteristics, including population size, GDP, and factor intensities.

KEYWORDS: Revealed comparative advantage, Balassa index, power law, Zipf's Law.

JEL CODES: C13; C33; F1; L1; O5; R12.

¹ Earlier versions of the paper have circulated since 2006 under the title "Comparative advantage, the rank-size rule, and Zipf's law". “No phenomenon is a phenomenon until it is an observed phenomenon”

Niels Bohr

1. INTRODUCTION

Empirical regularities are the origin of theory. For instance, Jan Tinbergen’s observation that gravity laws empirically rule international trade patterns gave us the theory behind the “gravity equation” (Frankel, 1998), and Robert Engle’s documentation of a changing variance over time in many time series triggered the search for theoretical explanations for this observed conditional heteroskedasticity (Semmler, 1994). In this paper a new empirical regularity is documented: the power law (PL) distribution of revealed comparative advantage in international trade flows as measured by the Balassa index.¹

In the last two centuries several theories are developed that explain international trade flows. These are rooted in technological differences between countries (Ricardo, 1817), in relative factor abundance (Heckscher, 1919, Ohlin, 1933), in variety and scale economies (Krugman, 1980, Ethier, 1982, and Helpman and Krugman, 1985), or in firm heterogeneity (Melitz, 2003, Helpman *et al.*, 2004, and Bernard *et al.*, 2007). None of these theories explains however why revealed comparative advantage is PL distributed.²

The notion of revealed comparative advantage was first introduced by Liesner (1958) and operationalized by Balassa (1965) with his concomitant index. It is widely used to identify a country’s weak and strong export sectors (for recent applications see e.g. Porter, 1990, Amiti, 1999, Fertő and Hubbard, 2003, or Svaleryd and Vlachos, 2005). The Balassa index is defined as a country’s exports in some sector as a fraction of national exports, divided by world exports in that sector as a fraction of world exports. Whenever the Balassa index exceeds unity, a comparative advantage is ‘revealed’ for the particular country in the particular sector. On average about one third of all sectors displays such a revealed comparative advantage, although this percentage varies considerably across countries (Hinloopen and van Marrewijk, 2001).

¹ The PL distribution is also known as Pareto distribution, scale-free distribution, or rank-size rule. It satisfies, at least in the upper tail (and perhaps up to a cutoff point), $P(size > x) \cong k x^{-\phi}$, where ϕ is the PL exponent and k is some constant. The PL exponent is independent of the units in which the law is expressed. Zipf’s Law holds if $\phi = 1$, named after the Harvard linguist George Kingsley Zipf (1902-1950, see Zipf, 1949).

² Gabaix (2009) summarizes the well-established applications of PL distributions in economics: traditional macro economic invariants (the quantity theory of money and Kaldor’s stylized facts), the distribution of city sizes, the distribution of firm sizes (measured by the number of employees, assets, or market capitalization, see Lawrence and Marks, 2008), the distribution of income and wealth, the distribution of CEO compensation (Robert’s law), and power laws on stock market activity (yielding detailed tail behavior of asset price movements and trading volumes).

Theories based on differences in technology between countries explain inter-industry trade flows with relative productivity; a country exports the goods in which it is relatively productive (technology – based comparative advantage) and imports all other goods (see, e.g. Akinlo, 2008). These theories are agnostic regarding the distribution of trade flows, in particular the Balassa index. Theories starting from differences in relative factor abundance predict that a country exports goods for which the production process relatively intensively uses the country's relatively abundant factor of production (factor abundance – based comparative advantage). This leads to clusters of countries exporting and importing the same products (see, e.g., Cortinhas, 2007, and Veeramani, 2009). An argument can be made that the distribution of factor abundance across countries translates into a distribution of trade flows through a process of production- and demand interaction. Empirically, however, factor abundance does not follow a PL distribution (see, for example, Trefler, 1995). Combined with the clustering of countries in exporting identical products, it is unclear how this would lead to a PL distribution for the Balassa index.

Productivity differences and differences in relative factor abundance cannot explain intra-industry trade flows (Grubel and Lloyd, 1975). The 'new' trade theories explain these volumes by combining variety, in either consumer preferences or as an input in the production process, with scale economies. In the core model, with identical homogeneous firms, the size of international trade flows is proportional to the size of the trading country's GDP (see, e.g. Taegi and Oh, 2001). But this yields a Balassa index of one for all countries and sectors. Although 'new' trade models can be combined fruitfully with differences in technology and relative factor abundance, the difficulty in explaining the PL distribution of the Balassa index remains.

Recent theories emphasize firm-level productivity differences. It is only profitable to overcome the costly obstacles of international trade for the most productive firms. When trade costs fall, high-productivity exporting firms survive and expand, while low-productivity firms exit the market (see, e.g. Badinger, 2007). Whether this approach provides a rationale for the PL distribution of the Balassa index is yet to be established. For that productivity differences must be translated into export differences, and ultimately in differences in revealed comparative advantage. In these models with constant price elasticity of demand $\varepsilon > 1$, firm sales and revenue are related to productivity as ϕ^ε and $\phi^{\varepsilon-1}$, respectively. Empirically, productivity differences seem to be 'thinly' distributed (for example, approximately normal for Belgium, see Mayer and Ottaviano, 2008). But this would imply that firm sales and revenue are also 'thinly' distributed (Gabaix, 2009). Moreover, the core heterogeneous firm model (with two countries and two sectors, both with the same productivity distribution) predicts aggregate trade flows that are proportional to the exporting country's GDP, and thus a Balassa index of one for all sectors in both countries (as in the core model of the 'new' trade approach). The heterogeneous firm model can also be combined with differences in technology and

factor abundance, but also then the difficulties in explaining the PL distribution of the Balassa index are not readily solved.³

We carefully document the PL distribution of revealed comparative advantage as measured by the Balassa index, and that in a substantial, but minority, of cases Zipf's law holds. Our analysis is based on a comprehensive data set that is obtained by merging two sets obtained from the Center for International Data at the University of California, Davis (see Feenstra *et al.*, 1997, and Feenstra, 2000). It consists in particular of observations on bilateral trade flows for 747 4-digit sectors, 166 countries, covering the years 1970 through 1997, yielding a total of slightly less than 18.4 million positive observations. This allows for a thorough and systematic empirical analysis of the observed phenomenon along three different dimensions: over time, across countries, and across sectors.

Although we focus on reporting the estimates of the PL exponents of the Balassa index distribution, some further empirical explorations suggest that these exponents are systematically related to country-specific characteristics and that they differ systematically across sectors according to factor-intensities. Borrowing the words of Rose (2005, p. 11) our findings suggest "an intriguing puzzle for future theoretical work." A theory should be developed that explains why the Balassa index follows a PL distribution. It should also explain why the upper cutoff value is equal to the theoretically significant value of a Balassa index above one, and what drives the differences in PL exponents for different countries and sectors.

The remainder of the paper is organized as follows. Section 2 briefly reviews PL distributions and the Balassa index. Section 3 discusses estimation issues. We use the estimation procedure recently introduced by Gabaix and Ibragimov (forthcoming) for estimating the PL exponent, as this procedure eliminates the bias inherent in traditional estimators. Section 4 contains our empirical findings regarding the PL distribution of revealed comparative advantage while Section 5 links these estimates empirically to country and sector characteristics. Section 6 concludes.

2. PL DISTRIBUTIONS AND REVEALED COMPARATIVE ADVANTAGE

Let $X_{i,t}^j$ be the value of exports from country $i \in I$ for sector $j \in J$ in period $t \in T$. Then $X_{i,t} = \sum_j X_{i,t}^j$ is the value of exports from country i in period t , $X_t^j = \sum_i X_{i,t}^j$ is the total value of exports for sector j in period t , $X_t = \sum_i \sum_j X_{i,t}^j$ is the total value of exports for all countries and sectors in that period and the Balassa index for country i and sector j in period t equals:

$$(1) \quad B_{i,t}^j = \frac{X_{i,t}^j / X_{i,t}}{X_t^j / X_t}, \quad i \in I, j \in J, t \in T.$$

³ There does seem to be some potential in this combination. Bernard *et al.* (2007) show that firm heterogeneity magnifies country differences based on comparative advantages.

If $B_{i,t}^j > 1$, country i is said to have a revealed comparative advantage in the production of commodity j in time period t as its export share for product j is larger than the concomitant export share in the group of reference countries I .⁴

We can visualize the PL distribution of the Balassa index by using double logarithmic axes on the rank (whereby the largest Balassa index value is given rank 1) and the size (the Balassa index value). The slope of this graph is then the PL exponent (Gabaix, 2009, gives an heuristic explanation of this procedure, which explains the use of the term ‘rank-size rule’). In Figure 1 the log of the Balassa index is plotted against the log of the concomitant rank (the figure is constructed using a random sample of 1,000 observations; appendix A contains the description of the data used throughout the paper). This picture serves as a first illustration that the upper tail of the Balassa index is PL distributed: observations with a Balassa index above unity are grouped almost perfectly on a straight line. It is precisely these observations that reveal a comparative advantage, implying that the upper cutoff value is equal to the theoretically significant value of a Balassa index above unity.

Figure 1. Empirical relation between the Balassa index of revealed comparative advantage and the related rank. The Figure is based on 1000 randomly drawn Balassa index values from the entire sample of 221,430 observations.

⁴ Hillman (1980) identifies a sufficient condition for the Balassa index to measure comparative advantage proper in that an increase in exports yields an increase in the Balassa index. Throughout the paper the analysis is restricted to those observations that meet this ‘Hillman condition’, which amounts to disregarding 0.25% of all observations (see Hinloopen and Van Marrewijk, 2008, for further details).

Whether or not Zipf's law holds ($\phi = 1$) has been of interest in the related literature on city size distributions and, recently, the size distribution of firms (Luttmer, 2005, Melitz, 2003). The applicability of power laws to city-size distributions is undisputed, but to date there is no agreement regarding the validity of Zipf's law. Some argue that the PL exponent does not assume unity quite regularly (Rosen and Resnick, 1980, Brakman, Garretsen, and van Marrewijk, 2001, and Soo, 2005), others stress that in most studies the hypothesis that the estimated PL exponent equals one cannot be rejected (Krugman, 1996, Gabaix, 1999, and Gabaix and Ioannides, 2004). Given the scope of our dataset we are quite confident that our findings regarding the applicability of a power law and, in particular, Zipf's law, to revealed comparative advantage, are representative for the underlying mechanisms.

3. ESTIMATING A PL EXPONENT

The two most commonly used methods for estimating the PL exponent ϕ are OLS (often referred to as the *Zipf regression*) and employing the *Hill estimator* (Hill, 1975, see also Gabaix and Ioannides, 2004). For large sample sizes the estimated PL exponent in the Zipf regression tends with probability one to the true value of ϕ . For small samples, however, the estimate is biased and inefficient. Moreover, the reported standard errors seriously underestimate the true standard errors. Alternatively, under the null hypothesis of a perfect power law, the Hill estimator is the maximum likelihood estimator of ϕ . But the properties of the Hill estimator in finite samples are also worrisome as the bias can be high in small samples and the associated computed standard errors considerably underestimate the true standard errors as a result of this bias. As the rate of convergence can be arbitrary slow (Embrechts *et al.*, 1997) the estimator also requires very large samples sizes. In addition, the choice regarding the number of order statistics to be included is problematic in view of the bias – variance tradeoff (see Beirlant *et al.*, 2004, and the citations therein).

Various estimators have been developed to address these issues, but these have not led to a consensus solution of the problem (see e.g. Embrechts *et al.*, 1997, Beirlant *et al.*, 1999, and Feuerverger and Hall, 1999). Recently however Gabaix and Ibragimov (forthcoming) provide an elegant and effective solution for the estimation of PL exponents. An unbiased estimate is obtained when using OLS in:

$$(2) \quad \ln\left(\text{rank} - \frac{1}{2}\right) = a - b \ln(\text{size}).$$

Accordingly, all that is needed is to shift the rank by $\frac{1}{2}$. Gabaix and Ibragimov (forthcoming) show further that the standard error of the so-estimated PL exponent is asymptotically equal to $\sqrt{(2/n)b}$. Using OLS in (2) is more robust to deviations from the exact power law formulation (in the sense of Hall, 1982) than is the Hill estimator (see also Ibragimov and Phillips, 2008, and Phillips, 2007).

Given that routine data typically carry up to 10 percent contamination (Hampel *et al.*, 1986) OLS estimates in (2) are likely to be biased. This calls for including as many observations as possible as Gabaix and Ibragimov (forthcoming) show that this (possible) bias is inversely related with the sample size. Accordingly, we employ as low as possible a cut-off value for identifying sectors with a revealed comparative advantage. That is, include all observations with a Balassa index of at least one. By doing so we also split the sample at a theoretically meaningful point: include all observations that relate to a revealed comparative advantage. To sum up: we report only the Gabaix-Ibragimov estimates and their associated standard errors for all observations that reveal a comparative advantage.⁵

4. EMPIRICAL RESULTS

Since the Balassa index carries three dimensions (time, country, and sector), we can empirically investigate the size of the PL exponent for these three dimensions. *Zipf's law* is said to apply in the particular dimension if the estimated PL exponent does not differ significantly from unity; in all other cases the Balassa index is PL distributed if the estimated exponent is statistically significant. Observe that there is a sub-dimension for the Balassa index with respect to the degree of data aggregation. After eliminating erroneously classified observations, our data set effectively distinguishes 66 2-digit sectors, 225 3-digit sectors, and 419 4-digit sectors (see Appendix A).⁶ All three identified dimensions are thus considered at three different levels of data aggregation.

4.1 DIMENSION I: TIME

To examine the applicability of power laws along the time dimension of revealed comparative advantage the following equation is estimated for all Balassa index values above unity:⁷

$$(3) \quad \ln \left[\text{rank}(BI_{i,t}^j) - \frac{1}{2} \right] = \alpha_{0,t} + \alpha_{1,t} \ln[B I_{i,t}^j], \quad t = 1970, \dots, 1997.$$

Table 1 contains the summary statistics for the several per-year estimates (details of the estimates for all individual years are listed in Table B1 in Appendix B), and the pooled regression whereby all years are taken together. The estimated PL exponents vary little per year and the goodness-of-fit is very high. At the 3-digit level, for example, the estimates range from 0.896 to 0.981 and the goodness-of-fit is between 98.3 and 99.4 per cent.

⁵ In all cases we also calculated the Zipf regression and the Hill estimator. These are available from the authors upon request.

⁶ To be included an observation (i) has a related export value of at least 5,000 US \$, (ii) meets the Hillman condition, and (iii) is at least one. Further, regressions with 10 or fewer observations were dismissed. The smallest number of observations for any regression is 47.

⁷ An obvious additional test for examining the validity of the linearity of the relationship is to include a quadratic term in (2), as in Black and Henderson (2003). However, as illustrated by Gabaix and Ioannides (2004), it is very likely that the estimated coefficient of this quadratic term will turn out to be statistically significant in situations where the underlying data are obtained from a data generating process as in eq. (2).

Table 1. Pooled Gabaix-Ibragimov regression of the slope parameter in (3) and summary statistics based on the 28 concomitant per-year estimates.

	2-digit	3-digit	4-digit
Average	0.958	0.930	0.870
Median	0.949	0.922	0.860
stand. dev.	0.043	0.025	0.020
min	0.882	0.896	0.849
max	1.031	0.981	0.915
average # observations	1,911	5,080	7,908
pooled	0.955	0.928	0.869
$\bar{R}^2$	0.968	0.991	0.991
# observations	53,503	142,231	221,430

The distribution of the estimated PL exponents is illustrated in Figure 2. Note that all estimated PL exponents are highly statistically significant and that in all years the goodness-of-fit indicator is very high, especially for estimates at the 2-digit and 3-digit level of data aggregation. We thus conclude:⁸

Empirical result 1

The Balassa index is PL distributed for the years 1970 – 1997 at either the 2-digit, 3-digit, or 4-digit level of data aggregation, whereby for the respective levels of data aggregation the mean estimated PL exponent is 0.96 (0.04), 0.93 (0.03), and 0.87 (0.02).

⁸ The number in brackets is the standard deviation of the estimate.

Figure 2. Distribution of the estimated per-year PL exponents at the 2-digit, 3-digit, and 4-digit level of data aggregation.

To examine whether Zipf's law applies in particular a t -test is conducted, which leads to:

Empirical result 2

The distribution of revealed comparative advantage for the years 1970 through 1997 as measured with the Balassa index at either the 2-digit, 3-digit, or 4-digit level of data aggregation follows Zipf's law in, respectively, 69%, 24% and 0% of all sample years.

4.2 DIMENSION II: COUNTRIES

The country dimension is captured by the following equation:

$$(4) \quad \ln \left[\text{rank}(BI_{i,t}^j) - \frac{1}{2} \right] = \beta_{0,i} + \beta_{1,i} \ln[B I_{i,t}^j], \quad i = 1, \dots, 166.$$

Table 2 provides summary statistics of the related estimates for the different levels of aggregation whereas details of the individual estimates for the 166 countries are in Table A2 in Appendix B.

Table 2. Summary statistics of the 166 per-country Gabaix-Ibragimov estimates of the PL exponents in (4).

	2-digit	3-digit	4-digit
average	1.048	0.964	0.890
median	0.939	0.839	0.790
stand. dev.	0.474	0.432	0.386
min	0.498	0.366	0.444

max	3.710	3.326	2.948
average # observations	322	857	1,334

All estimated PL exponents are statistically significant, and in almost all cases the goodness-of-fit is very high (the median value of the latter is 89.5, 92.7, and 94.2 per cent at the 2-digit, 3-digit, and 4-digit level, respectively). Hence:

Empirical result 3

The Balassa index is PL distributed for the 166 sample countries at either the 2-digit, 3-digit, or 4-digit level of data aggregation, whereby for the respective levels of data aggregation the mean estimated PL exponent is 1.05 (0.47), 0.96 (0.43), and 0.89 (0.39).

Figure 3. Distribution of the estimated per-country PL exponents at the 2-digit, 3-digit, and 4-digit level of data aggregation.

As is clear from Table 2 and illustrated in Figure 3, the estimated PL exponents vary considerably between countries. At the 3-digit level, for example, the maximum estimate of 3.326 for Germany is almost ten times as high as the minimum estimate of 0.366 for Comoros. Although the goodness-of-fit also varies more than before, in all cases the explanatory power remains high.⁹ This suggests that an individual country exhibits its own characteristic distribution of revealed comparative advantage which might be related to country factors (an issue taken up further in Section 5 below). Finally, considering the *t*-tests for examining whether or not Zipf's law applies leads us to observe:

⁹ This holds *a fortiori* if the number of observations is taken into account; on average a relatively low goodness-of-fit is related to a limited number of observations. For instance, the regression for Germany is based on 2,942 observations while the estimate for Comoros uses 142 observation only (Table B2).

Empirical result 4

The distribution of revealed comparative advantage for the 166 sample countries as measured with the Balassa index at either the 2-digit, 3-digit, or 4-digit level of data aggregation follows Zipf's law in, respectively, 38%, 20% and 13% of all cases.

4.3 DIMENSION III: SECTORS

The sector dimension is examined with the following equation:

$$(5) \quad \ln \left[\text{rank}(BI_{i,t}^j) - \frac{1}{2} \right] = \gamma_0^j + \gamma_1^j \ln[B I_{i,t}^j], \quad j = 1, \dots, J,$$

whereby J refers to the number of sectors for the particular level of data aggregation. At the 2-digit level there are 66 different sectors, at the 3-digit level 225 sectors are distinguished, and 419 sectors are identified at the 4-digit level. Table 3 provides the summary statistics for the sector estimates and Table B3 in Appendix B contains the details of all sector estimates separately. Figure 4 illustrates the distribution of the estimated sector PL exponents.

Table 3. Summary statistics of the 66 2-digit, the 225 3-digit sectors, and the 419 4-digit per-sector Gabaix-Ibragimov estimates of the PL exponents in (5).

	2-digit	3-digit	4-digit
average	1.411	1.347	1.198
median	1.225	1.253	1.101
stand. dev.	0.618	0.542	0.469
min	0.646	0.394	0.415
max	3.113	3.420	3.282
average # observations	811	632	528

Figure 4. Distribution of the estimated per-sector PL exponents at the 2-digit, 3-digit, and 4-digit level of data aggregation.

We arrive at similar conclusions as for the country dimension. The estimated PL exponents vary considerably between sectors even for the same level of data aggregation. At the 3-digit level, for instance, the minimum estimate is 0.394 for sector 264 (“jute and other textile bast fibres, nes, raw/processed”) and the maximum estimate is 3.420 for sector 784 (“parts and accessories of 722, 781, 782, 783 [relating to motor vehicles]”). Further, the goodness-of-fit for the individual estimates remains high: the median is 94.3, 94.9, and 94.7 per cent at the 2-digit, 3-digit, and 4-digit level, respectively. We thus conclude:

Empirical result 5

The Balassa index is PL distributed for the 66 2-digit sectors, the 225 3-digit sectors, and the 419 4-digit sectors, whereby for the respective levels of data aggregation the mean estimated PL exponent is 1.40 (0.62), 1.34 (0.54) and 1.20 (0.47).

The considerable variation across sectors in the estimated power-law coefficients is also examined further in Section 5 below. For now we observe that for a substantial number of sectors Zipf’s law applies:

Empirical result 6

The distribution of revealed comparative advantage for the 66 2-digit sectors, the 225 3-digit sectors, and the 419 4-digit sectors as measured with the Balassa index follows Zipf’s law in, respectively, 16%, 17% and 26% of all cases.

5. DISCUSSION

We have seen that the Balassa index is PL distributed and that a modest share of the estimated PL exponents does not differ significantly from unity. In addition, the estimated PL exponents do not vary from year to year, but they do vary between countries and between sectors.

5.1 ESTIMATED PL EXPONENTS ACROSS COUNTRIES

The significant differences in estimated PL exponents across countries suggests that these estimates are related to country characteristics. To give further weight to this conjecture we relate the estimated PL exponents to country characteristics that can be expected to affect the value of the Balassa index, including country size (measured by GDP and number of inhabitants), export size, openness (exports as a fraction of GDP), and export breadth (measured as the number of sectors in which a comparative advantage is obtained). At the same time, the results in Section 4.1 imply that the estimated power coefficient are stable over time. This leads us to consider the following equation:

$$(6) \quad \gamma_{it} = \beta_i + \beta_t + \beta_1 \gamma_{it-1} + \beta_2 \ln(GDP_{it}) + \beta_3 \ln(POP_{it}) + \beta_4 \ln(EXP_{it}) + \beta_5 \frac{EXP_{it}}{GDP_{it}} + \beta_6 \ln(EXPS_{it}) + \varepsilon_{it},$$

whereby γ_{it} is the estimated value of the power-law exponent for country i in year t , β_i is a country-specific fixed effect, β_t is a time-specific fixed effect, POP is the population size (measured in 1000 persons), EXP is the value of exports (measure in 1000 US \$), $EXPS$ is the number of export sectors, and ε is assumed to be *iid* with zero mean and constant variance.¹⁰ However, in (6) the estimated PL exponent γ_{it-1} depends on β_i which leads to biased estimates. To solve this problem first differences are considered:

$$(7) \quad \begin{aligned} \gamma_{it} - \gamma_{it-1} = & \alpha_t + \beta_1 (\gamma_{it-1} - \gamma_{it-2}) + \beta_2 (\ln(GDP_{it}) - \ln(GDP_{it-1})) \\ & + \beta_3 (\ln(POP_{it}) - \ln(POP_{it-1})) + \beta_4 (\ln(EXP_{it}) - \ln(EXP_{it-1})) \\ & + \beta_5 \left(\frac{EXP_{it}}{GDP_{it}} - \frac{EXP_{it-1}}{GDP_{it-1}} \right) + \beta_6 (\ln(EXPS_{it}) - \ln(EXPS_{it-1})) + \varepsilon_{it} - \varepsilon_{it-1}, \end{aligned}$$

where $\alpha_t = \beta_t - \beta_{t-1}$. This creates another problem as γ_{it-1} is correlated with ε_{it-1} . Following Anderson and Hsiao (1982) this is solved by using γ_{it-2} as an instrument for $(\gamma_{it-1} - \gamma_{it-2})$.

Table 4. Panel estimates for explaining cross country differences in estimated PL exponents; dependent variable: first differences estimated PL exponents.*

* *t*-values are within brackets.

The results of the panel estimates are in Table 4, where the estimated power-law coefficients are from the regressions of Section 4.2.¹¹ These results prompts two observations. First, although the specification in (7) is not obtained from a formally derived first-order condition, the strong significance of most estimated coefficients does suggest that the cross-country variation of the estimated PL exponent is related to country-specific characteristics. Second, at the 3-digit and 4-digit level the estimated panel coefficients are quite comparable. At the 2-digit level the export breadth variable is still significant but with an opposite sign. This is due to the related drop in the number of distinguished sectors which alienates the export breadth variable in the 2-digit case from those in which either 3-digit or 4-digit export flows are considered. We conclude:

Empirical result 7

The estimated PL exponents for revealed comparative advantage differ significantly across countries. These differences are related to country-specific characteristics: country size, export size, export breadth, and openness.

5.2 ESTIMATED PL EXPONENTS ACROSS SECTORS

Differences across sectors regarding the estimated PL exponents can be structured effectively according to the core analysis of international trade: factor intensity.¹² To that end we use the factor

¹¹ In total the panel study is based on 13,944 annually estimated PL exponents at the country level (namely 28 years × 166 countries × 3 levels of aggregation), see Appendix B.

¹² See also Carter and Li (2004).

intensity classification of the International Trade Center, the joint UNCTAD/WTO organization. In particular we have the following five broad factor intensity categories (within brackets the number of 3-digit sectors belonging to the particular category; note that there are 5 sectors that are not classified; see Hinloopen and van Marrewijk, 2008):

- A. *Primary products* (83); including meat, dairy, cereals, fruit, coffee, sand, minerals, oil, natural gas, iron ore, and copper ore.
- B. *Natural-resource intensive products* (21); including leather, cork, wood, lime, precious stones, pig iron, copper, aluminum, and lead.
- C. *Unskilled-labor intensive products* (26); including various textiles and garments, clothing, glass, pottery, ships, furniture, footwear, and office supplies.
- D. *Human-capital intensive products* (43); including synthetic colors, pigments, perfumes, cosmetics, rubber and tires, tubes, pipes, various types of steel and iron, cutlery, televisions, radios, cars, watches, and jewellery.
- E. *Technology intensive products* (62); including various chemicals, medicaments, plastics, engines, generators, machines, tools, pumps, telecommunications and photo equipment, optical equipment, and aircraft.

Table 5 contains the average estimated power-law coefficients for these factor intensity categories. It appears that the estimated PL exponents are about equal for primary products and natural-resource intensive products. Similarly, they are about equal for technology-intensive products and human-capital intensive products. Moreover, the estimated exponents tend to be lower for primary products than for unskilled-labor intensive products, which in turn tend to be lower than that for human-capital intensive products. Indeed, according to a two-sided t -test of mean differences the following ordering applies:

$$\gamma_{\text{primary}} = \gamma_{\text{natural-resource}} < \gamma_{\text{unskilled-labor}} < \gamma_{\text{human-capital}} = \gamma_{\text{technology}}$$

Table 5. Pair wise t -tests for equality of the mean of estimated power-law coefficients across sectors (3-digit).

	A	B	C	D	Mean estimate	t -value for $H_0: \bar{\gamma} = 1$
A	*				0.94	2.05
B	0.86	*			1.01	0.12
C	5.16	3.25	*		1.37	4.73
D	8.59	5.93	2.73	*	1.67	13.71
E	13.10	8.15	4.51	1.37	1.81	8.42

In addition, we have tested whether Zipf’s law applies for the five different factor intensity categories. Although the mean value of the estimated PL exponent for natural-resource intensive products does not differ from that for primary products, it is only for the former product category that Zipf’s law applies in particular (see Table 5). We thus conclude:

Empirical result 8

The estimated PL exponents for revealed comparative advantage differ significantly across sectors ordered according to factor intensities. Only for the natural-resource intensive sectors Zipf’s law holds.

6. CONCLUSIONS

The analysis of a country’s apparent strong export sectors as indicated by a revealed comparative advantage is complicated by the lack of a theoretical characterization of the distribution of the Balassa index. Using a comprehensive international trade data set we show empirically that the Balassa index is PL distributed along the time, country, and sector dimension. Our results are obtained using the estimator recently developed by Gabaix and Ibragimov (forthcoming) which yields unbiased estimates absent data contamination. As our analysis is based in total on 1,295 estimated PL exponents we are quite confident that our findings are representative for the phenomenon documented here.

Figure 5. Estimated PL exponents for different truncation values at the 2-digit, 3-digit, and 4-digit level of data aggregation.

Eeckhout (2004) shows the estimated PL exponent for city size distributions to be sensitive to the sample composition. Using a higher truncation point for cities to be included into the sample leads to higher power law estimates. As there is no natural truncation point for city sizes Eeckhout's observation questions the applicability of the rank-size rule to city size distributions. For the Balassa index on the other hand the sub sample of entries above one naturally presents itself. Thus, in Figure 5 the (absolute value of the) estimated PL exponent is plotted for higher truncation values.¹³ The observation of Eeckhout (2004) also applies here although the estimated power coefficient is much less sensitive to the truncation value compared to the city size distribution. This supports the robustness of our findings.

Our findings present a theoretical puzzle: none of the received theories on international trade can explain why the Balassa index is PL distributed. To assist in solving this puzzle, we provide panel estimates that document the empirical links between the estimated PL exponents and country and sector characteristics, including country size, openness, export breadth and factor intensities. These

¹³ Note that the fraction of industries included drops with higher truncation values. For the 2-digit, 3-digit, and 4-digit level of data aggregation going from a truncation value of one to two comes with a drop in this fraction respectively from 24.5% to 14.4%, from 24.4% to 13.9% and from 27.2% to 16.3%. Increasing the truncation value even further yields estimates that are based on a disproportionately small part of the sample.

results suggest that a theory based on factor abundance, scale economies and variety, and firm heterogeneity is needed to address the puzzle. We leave this daunting task for future research.

APPENDIX A DATA

Two separate data sets compiled by the Center for International Data, University of California, Davis (CID/UCD), were merged, the first covering the years 1970 through 1993 (see Feenstra, Lipsey and Bowen, 1997) and the second covering the years 1980 through 1997 (see Feenstra, 2000). For the overlapping years, the data from the latter source are used. The data set contains bilateral trade flows between 183 trading partners, including n.e.s. (not elsewhere specified) regions for trade flows that could not be classified further than within a broad geographical region (such as “Middle East”, or “North Africa”), an “Areas n.e.s.” region for trade flows that cannot be attributed to any country or to any of the used broad geographical regions but that do come from a well-defined geographical region, and an “Unknown Partner” category for trade flows that could not be attributed at all due to various reasons (see Feenstra, 2000). This leaves a sample of 165 genuine countries

The bilateral trade flows are decomposed into 1,249 sectors, comprising 747 genuine 4-digit sectors, based on SITC (Standard International Trade Classification), revision 2. The remaining 502 sectors refer to aggregates at the 1-, 2-, or 3-digit level, and a “Non-identified products” category. The 4-digit subset contains 60.39 % of all trade, the 3-digit subset covers 99.46 % of all trade, and the 2-digit subset comprises 99.67 % of all trade.

The data were first compiled by Statistics Canada and made available through the CID/UCD (see Feenstra, 2000). The former makes use of various sources (according to Statistics Canada 87% of all trade flows is based on independent sources of *both* imports and exports, while 98% is based on reports of at least one side of trade), yielding a rather complete coverage of world trade flows. The CID/UCD transforms the data such that trade flows for all years, all countries, and all industry groups are consistent and presented in a unified manner. Each observation in the raw data consists of four entries: importing country, exporting country, sector, and size of the trade flow (in 1,000 US \$). The data are thus classified according to the importing country. This is *not* to say that the data are based on import sources only, as explained above. After merging the two separate datasets a second dataset is created by “inverting” the data, in that all trade is classified according to the exporting country.

The income and population data are taken from the World Bank Development Indicators 2005 except for Taiwan. Those data are based on own calculations using the Maddison (2003) data set and complementary material taken from the website of the National Statistics Office of Taiwan (<http://eng.stat.gov.tw/mp.asp?mp=5>).
