Abstract—Heterodyne Holography is a variant of Digital Holography, where the optical frequencies of signal and reference arms can be freely adjusted by acousto-optic modulators. Heterodyne Holography is an extremely versatile and reliable holographic technique, which is able to reach the shot noise limit in sensitivity at very low levels of signal. Frequency tuning enables Heterodyne Holography to become a Laser Doppler imaging technique that is able to analyze various kinds of motion.

I. INTRODUCTION

Heterodyne Holography (HH) [1], [2] is a variant of the Digital Holography technique (i.e. holography where the holographic film is replaced by a Digital camera) where the frequencies of the illumination beam (signal arm) and of the holographic reference beam (local oscillator arm) are freely adjusted thanks to Acousto-Optic Modulators (AOM). This technique is called Heterodyne Holography, because it can be viewed as an optical heterodyne detection, in which the detector is a multipixel detector (i.e. a camera) which acquires the heterodyne signal on all the pixels at the same time keeping trace of the pixel to pixel correlations. These correlations bring the holographic information that can be used for holographic reconstruction.

II. HETEROODYNE HOLOGRAPHY

A typical heterodyne holographic setup is presented on Fig.1. Thanks AOM1 and AOM2, the frequency $\omega_{LO}$ of the local oscillator field $E_{LO}$ and the frequency $\omega$ of the signal field $E$ are

$$\omega_{LO} = \omega_L + \omega_{AOM1}$$
$$\omega = \omega_L + \omega_{AOM2}$$

where $\omega_L$ is the main laser frequency, and $\omega_{AOM1,2} \approx 80\text{MHz}$ are the frequencies of the signals that drive AOM1 and AOM2.

This setup is extremely versatile and allows to perform either off-axis holography [3] or phase shifting holography [4]. For example, to perform a 4-phase detection, the frequency shift between the LO and signal beam must be chosen such as:

$$\omega_{LO} - \omega = \omega_{AOM1} - \omega_{AOM1} = \omega_{CCD}/4$$

where $\omega_{CCD}$ is the frame rate of the camera. In that case, the holographic signal $EE_{LO}$ is obtained by 4 phases demodulation of the camera signal. If $I_n$ where $n = 0..3$ is the camera signal, and $n$ camera frame index, the holographic signal $EE_{LO}$ is then given by:

$$EE_{LO} = (I_0 - I_2) + j(I_1 - I_3)$$

where $j^2 = -1$.
Here, by combining the frames with the 4-phase linear combination \((I_0 - I_2) + j(I_1 - I_3)\) of Eq.2, we tune the heterodyne receiver at frequency
\[
\omega_H = \omega_{LO} - \omega_{CCD}/4 \quad (4)
\]
Because of Eq.2, \(\omega_H\) is equal to \(\omega\), and the heterodyne receiver is tuned at the signal frequency \(\omega\). One of the advantages of this method, used here to shift the phase (AOMs), is the accuracy of the \(\pi/2\) phase shift that is applied to the reference beam, from one frame to the next [5]. As a consequence, the parasitic twin image [6] is minimized.

We must note that it is possible to make another choice for the frequency offset \(\omega_{LO} - \omega\). In that case, the holographic detector will be able to explore different frequency components, opening the way to Laser Doppler Holographic Imaging [7], and to Sideband Digital Holographic Imaging [8].

III. SHOT NOISE HOLOGRAPHY

Because the holographic signal results from the interference of the object complex field \(E\) with a reference complex field \(E_{LO}\), whose amplitude can be much larger (i.e. \(E_{LO} \gg E\)), it benefits of an optical heterodyne gain
\[
G_H = \frac{|EE_{LO}^*|}{|E|^2} \quad (5)
\]
and is thus potentially well-suited for the detection of signal fields \(E\) of weak amplitude [9], [10].

To better analyze this effect, one must measure the camera signal in photoelectron (e) Units. In typical experimental conditions, the LO beam intensity is adjusted to be at half saturation of the camera. With a 12 bits camera, whose gain is \(G \simeq 5\) e/DC (photoelectron per Digital Count), the LO beam signal is then
\[
I_n \simeq |E_{LO}|^2 \sim 2000\ DC \simeq 10^4\ e \quad (6)
\]
per pixel, and the LO beam shot noise standard deviation is \(\sqrt{I_n} \sim 100\).

For a weak signal of about 1 e per pixel, the heterodyne gain is \(G \sim 100\). The 1 e heterodyne signal: \(|EE_{LO}^*| \sim 100\ e\), is thus equal to the LO beam shot noise, yielding \(SNR = 1\) (Signal to Noise Ratio). We must note here that the camera reading noise (\(\simeq 20\ e\)), and the camera Analog Digital Converter quantization noise (\(\simeq 5\ e\)) can be neglected with respect to the LO beam shot noise (\(\sim 100\) e) [11].

One can generalize this result for a sequence of \(M\) images. One get that the shot noise limit, which corresponds to \(SNR = 1\), is reached for 1 e per pixel for the whole sequence of \(M\) images, i.e. for \(1/M\) e per pixel and per frame. One must notice also that the total amount of shot noise is proportional to the number of pixels (or spatial modes) that are used in the reconstruction procedure. If spatial filtering in the Fourier space is used [6], the shot noise must be multiplied by the ratio
\[
\eta = A_{filter}/A_{calc} < 1 \quad (7)
\]
where \(A_{filter}\) is the number of pixels of the spatial filter in Fourier space, and \(A_{calc}\) the number of pixels of the calculation grid. The shot noise limit corresponds thus to \(\eta/M\) e per pixel and per frame [12].

Figure 2 shows, as an example, images of an USAF target that has been reconstructed from holographic data recorded at very low signal levels (0.0127 and 0.00127 e per pixel and per frame in (a) and (b) respectively). These images illustrate the ability of heterodyne holography to reach the shot noise limit in low light with a standard array detector.

IV. LASER DOPPLER HOLOGRAPHY

A. Flows

\[
\begin{align*}
\text{(a)} \quad \text{Image of a mouse crania reconstructed by Laser Doppler Holography:} \\
\text{(b)} \quad \text{average of the intensity images reconstructed from data recorded with } \omega_{\text{LO}} = \omega \text{ varying from 36 to 48 Hz (a), and from 0.6 to 2.0 kHz (b).}
\end{align*}
\]

The ability to control the frequency of the heterodyne detection \(\omega_H\), following Eq.4, allow us to develop a Laser Doppler Holography. Thanks to the AOMs, we can adjust the frequency of the local oscillator \(\omega_{\text{LO}}\) so as we can select a velocity component, whose optical frequency is \(\omega_H\), and we can image it by holography [7]. It is also possible to reconstruct the images of the various velocity components by recording a sequence of images \((I_1, I_2, \ldots, I_n)\), and by making a time to frequency Fourier transformation [13], [14].
As the optical wavelength is much smaller than the ultrasound wavelength, this Laser Doppler Holography presents the advantage to allow the analyze flows in the \(\mu m/s\) range [15]. This Laser Doppler Holography has been applied to the analysis of blood flow in capillaries. We have for example imaged cerebral blood flow in the micro vessels, in mice, in vivo [16], [17], [14]. The imaging is made in vivo, in minimally invasive conditions (the cranial skull remains present). Figure 4 gives an example of mouse cerebral blood flow images that can be obtained by this way. Similar results have been obtained on the retina of a rat [18].

B. Vibrations

![Fig. 4. Reconstructed holographic images of a clarinet reed vibrating at frequency \(\omega_v = 2143 \text{ Hz}\) perpendicularly to the plane of the figure. Figure (a) shows carrier image obtained with \(\omega_H = \omega\); Fig. (b)-(d) show the frequency sideband images obtained with \(\omega_H = \omega + n\omega_v\), where \(n\) is the sideband harmonic order: \(n = 0\) (a), 1 (b), 10 (c) and 100 (d).](image)

If the object vibrates periodically, the light that is reflected or diffracted by the object exhibit sidebands. It is then possible to tune the holographic heterodyne receiver at a sideband frequency [19], [8], and not simply at the carrier frequency like with standard digital holography [20]. If the amplitude of vibration is large, it is even possible to explore the whole comb of sideband lines, and to get, by the way, the map of the vibration amplitudes of the object. Figure 4 shows sideband images of a vibrating clarinet reed. Images with harmonic order up to \(n \approx 1200\) have been obtained by Heterodyne Holography [21].

V. CONCLUSION

Heterodyne Holography is an extremely versatile and robust holographic technique, which is able to reach the shot noise limit of sensitivity in low light, and that is perfectly suited to the analysis of many modulation phenomena, flows or vibrations [17], [22], [23].
